Mr. E. Bury of the Skinningrove Iron & Steel Works, Middlesbrough, has made trials of a process for the abstraction of ethylene from coke-oven gas and its recovery as alcohol, by which an average yield of 1·6 gallons per ton of coal carbonised is obtained. The application of this process to the whole of the 14,635,000 tons of coal reduced to coke in this country in 1918 would yield 23 million gallons of alcohol. It is calculated that the recovery of alcohol from the gas-works of the country on similar lines would yield 27 million gallons per annum.

Alcohol has a great affinity for water, and ordinary commercial qualities contain water in various proportions up to about 15 per cent.; in the following table estimated calorific values per lb. are given for alcohol-water mixtures containing from 0 to 50 per cent. of the latter ingredient.

* By permission of the British Engineering Standards Association.

Alcohol engines require larger carburettors and piping and valves than are necessary when petrol is used. As the latent heat of alcohol much exceeds that of petrol, especially when water is present in any considerable proportion, it is also necessary to well jacket the carburettor with hot water or exhaust gas, and to heat the in-going air to about 350°F. in order to ensure complete vaporisation. The cylinder-jacket water should also be kept nearly at 212°F.; too cool a cylinder results in imperfect combustion of the mixture, acetic acid, aldehyde, etc., being formed instead of CO_2 and H_2O only, with loss of efficiency and corrosion of internal parts. Starting up from cold is a special difficulty with alcohol, and engines are usually started with petrol, the alcohol being turned on when everything is well warmed up. Some engines are arranged so as to start and *stop* on petrol; in this way any traces of water or acid from the alcohol are cleared out of the cylinders and passages during the last few revolutions of the engine, and risk of corrosion of parts is thus avoided. Tests on a 14 horse-power 'Locomobile' alcohol engine of 8·28 ins. bore and 11·8 ins. stroke made by Prof. E. Meyer in 1901 showed a brake thermal efficiency of 24 per cent., using alcohol containing about 13 per cent. of water. The volume ratio of compression was 5·9. The cylinder-jacket water temperature was maintained at 208°F. The engine ran at 280 revs. per minute and developed 13·9 b.h.p. at full load.

In some German trials of alcohol engines in 1902 a horizontal Deutz engine of 8·3 ins. bore and 11·8 ins. stroke, with the high volume ratio of compression of 8·9, and using as fuel alcohol containing 13·9 per cent. of water (about 9,980 B.Th.U. per lb., lower value), consumed at the full output of 16·55 b.h.p. only 0·813 lb. of this fuel per b.h.p. hour, corresponding to the high brake thermal efficiency of 31·4 per cent.

Coal Tars and Coal Tar Distillates.

When bituminous coal is subjected to destructive distillation, gas, coke, tar and ammonia are obtained. The physical and chemical properties of the tars are dependent upon the type of coal from which they originate, and the conditions which exist in the carbonising chamber. The appliances in use for the carbonisation of coal are mainly gas manufacturing plants and coke manufacturing plants. A few special plants exist which do not belong to either of these categories.

Gas manufacturing plants may be divided into three classes—horizontal retort, inclined retort, and vertical retort plants. Retorts of the first type yield tars of high specific gravity, 1·15 to 1·25, rich in free carbon, and viscous. Vertical retorts yield thin brown tars of low gravity (about 1·05), which are comparatively low in free carbon content and rich in aliphatic hydrocarbons. The tars from inclined retorts are intermediate between the products of horizontal and vertical plants in their chemical and physical properties.

Coke-oven tars are very variable, but usually approximate to horizontal retort tars in composition.

Tars from gas producers are generally too high in water-content to be of use as fuels.

Blast furnaces yield tars containing large quantities of ash which render them useless in the raw state.

Several processes for the low temperature carbonisation of coal have been advocated, but no large quantity of the tar, which is exceptionally suitable for fuel purposes, is available.

The majority of coal tars may be employed for boiler firing purposes. Tars from vertical retorts have been found suitable for use on both two and four cycle Diesel engines, providing that certain special adjustments or fittings are employed, large quantities of such tars being

The volatile products obtained by the distillation of coal tar (mainly benzol and toluol) have been extensively used in automobile engines prior to the war. Creosote and anthracene oils are high boiling distillates of coal tars and are extensively employed for fuel purposes, both for external and internal combustion. The 'tar oil' sold for fuel is usually a mixture of both these above-mentioned fractions. Analyses of some tar oils, together with a petroleum residuum, and alcohol, are shown in the following table :—

Lignite Tars and Lignite Tar Distillates.

Lignite yields valuable liquid products by destructive distillation. The tar is of a butter-like consistency and possesses a specific gravity of ·860 to ·920. Its sole use in the raw state is as fuel for Diesel engines, for which purpose its richness in aliphatic hydrocarbons makes it behave similarly to petroleum. It therefore does not require either raised cylinder compressions or the use of an ignition oil.

Fuels for petrol engines and heavy oil engines can be obtained from lignite tar by distillation. Their properties are very similar to those of the corresponding fractions obtained from petroleum.

Tar oils have been used in considerable quantities on Diesel engines in this country recently, on account of the scarcity of petroleum. The difficulties encountered in burning tar oils are mainly due to their comparatively high spontaneous ignition temperature. The ignition of the fuel charge in a Diesel engine is dependent upon the temperature of compression, no special

ignition device being provided. With the fuel oils derived from petroleum or shale it has been found that a compression pressure of 450 to 500 lbs. is sufficient to ensure regular ignition under starting conditions and at all loads. Whereas the spontaneous ignition temperature (in atmosphere of oxygen) of petroleum and shale oils is in the neighbourhood of 270° C., this value for tar oils is generally over 400° C.* As a result of the high ignition point engines will not start, or run at low loads, on tar oil unless special means are taken for raising the temperature of the air in the combustion space at the time of fuel injection. The more important methods adopted for this purpose are—(1) to heat the cycle air, blast air and fuel, (2) to increase the

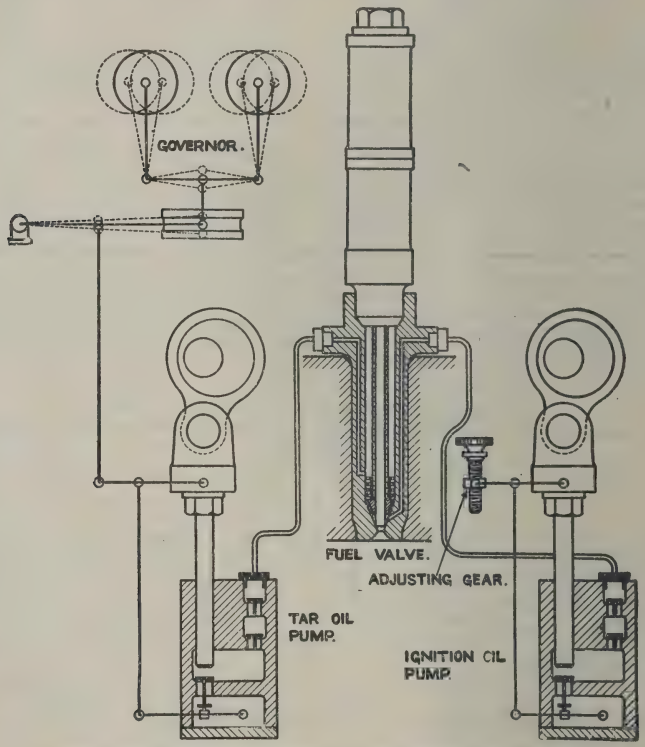

FIG. 25.—Diagrammatic Arrangement of Fuel Pumps for Tar Oil Engine.

compression ratio, (3) to employ an ignition oil, and (4) to inject a small charge of tar oil prior to the main tar oil charge.

Heating of cycle air, blast air and fuel is difficult to effect under starting conditions and has a deleterious action on the fuel valve when running. The increase of compression necessitates a specially heavy design of engine to withstand the higher stresses on liners, cylinder cover, and bearings. To ensure certain starting on tar oils the compression would require to exceed 600 lbs. The starting difficulty may be overcome by running the engine on a petroleum oil before closing down and when starting. If the engines can be always maintained at half load or over, a compression pressure of about 550 lbs. per square inch will give good running.

* Moore, *Jour. Soc. Chem. Ind.*, February 15, 1917, p. 109.

The introduction of a small charge of a petroleum oil into the working cylinder prior to the main charge of tar oil has been found the most satisfactory method of burning tar oils. The ignition oil charge is pumped to the atomiser nearer the cylinder than the place where the main tar oil charge enters. Thus when the fuel valve opens the ignition oil is first injected into the cylinder and is immediately followed by the tar oil charge. The combustion of the ignition oil heats the air in the cylinder so that the temperature exceeds the spontaneous ignition temperature of the tar oil. The proportion of ignition oil is 6 to 8 per cent. of the total fuel at full load; at other loads the quantity of ignition oil remains practically constant, the proportion increasing to about 50 per cent. at no load. This method has been found to yield satisfactory results at all loads, and under starting conditions, with cylinder compression pressures of 480 to 500 lbs. per square inch. An arrangement of ignition oil gear as given in a paper by Mr. C. Day,* is shown in fig. 25. Devices have been designed to give a small charge of tar oil prior to the main charge of tar oil. The device is so arranged that the initial tar oil charge is not accompanied by any appreciable blast air, the expansion of which would reduce the temperature of the combustion space. Such devices are said to have given good results on the Continent, but are little used in this country.

In addition to the ignition question tar oils are particularly liable to form deposits in the atomisers of Diesel engines. A résumé of some experiences of burning tar oils on Diesel engines was given by Mr. G. Porter in a paper read before the Diesel Engine Users' Association, May 24, 1917. In this paper several specifications for tar oils for use in Diesel engines are given. An abstract of these specifications is appended below :—

Specifications of Tar Oil Fuel for Diesel Engines.

(1) Specification of the M.A.N. Company :—

The tar oil must be a distillate of coal tar.

The oil must flow freely at 61° F., and on being cooled down to 46·5° F. and resting in a place undisturbed by vibration no separation shall take place at this temperature within the space of half an hour.

The following constituents shall not be present in quantities greater than the stated percentages—

Ash	·05 per cent.
Sulphur	1·0 „

Proportions of water and coke residue not stated.

Per cent. insoluble in xylol ·2.

(2) Continental specification for tar oil quoted by Mr. C. Day in his paper on 'Tars and Tar Oils as Fuel for Diesel Engines' (January 19, 1916) :—

Tar oils must not contain more than a trace of constituents insoluble in xylol.

The water content should not exceed 1 per cent.

The coke residue should not exceed 3 per cent.

At least 60 per cent. of the oil should be distilled on heating up to 300° C. (572° F.).

The net calorific value should not be less than 15,840 B.Th.U.'s per pound.

The open flash point must not be below 65° C. (143·6° F.).

The oil must be quite fluid at 61° F.

(3) Specification of tar oil proposed by Mr. C. Day (January 19, 1916) :—

The tar oil must be a product of the distillation of coal tar. No product that has not undergone distillation must be present.

Per cent. insoluble in xylol	Not more than	2·0
„ ash	„ „	0·08
„ water	„ „	2·5
„ coking residue	„ „	3·0

The oil must be liquid at 60° F. when maintained at that temperature for half an hour.

* C. Day. Paper read before the Diesel Engine Users' Association January 19, 1916.

(4) Specification of tar oil by Mr. Batho (the Diesel Engine Users' Association, February 23, 1916) :—

Specific gravity—Between 1·0 and 1·1.
Viscosity—Generally 2° Engler.
Flash point—100° F. to 130° F.
Colour—One drop on white paper should show no black residue, as is the case with tar.
Lower calorific value—Between 15,800 and 16,500 B.Th.U.'s per 1 lb.
Ash—Should not exceed 1 per cent. (unburnt residue of tar oil is mostly harmless).
Water—Should not exceed 1 per cent.
Sulphur—·5 to 1 per cent.

The burning of raw tars on Diesel engines has been accompanied by the same difficulties as the burning of tar oils, but an additional trouble is encountered on account of the free carbon which is always present in raw coal tars.

Furnace Firing with Liquid Fuel.

Liquid fuel possesses many advantages over coal or other solid fuels for furnace firing. The advantages when using heavy petroleum oils may be briefly enumerated as follows :—

(1) Petroleum fuel oil possesses a gross heat value of approximately 19,200 B.Th.U., whilst the gross heat value of coal averages about 14,000 B.Th.U. This fact alone shows two pounds of oil to be about equivalent to three pounds of coal.

(2) In spite of its lower specific gravity, oil can be stored in less space than a corresponding weight of coal.

One ton of coal occupies about 43 cubic feet.
„ oil „ 40 „

For marine purposes oil is conveniently stored in ballast tanks and inaccessible places, which could not be utilised for coal bunkerage.

(3) Oil rarely contains more than 0·1 per cent. of ash, a negligible quantity, while coal may contain as much as 15 per cent. ash. This ash necessitates the removal of clinker from the fires, and besides involving expense it causes a serious loss of heat.

(4) Oil can be conveyed by pipe line, a cheaper, cleaner and more rapid method than any method of coal conveying.

This is of great importance in naval work.

(5) Oil firing does not involve so much manual labour and attendance charges which accompany furnace firing with solid fuel.

(6) A boiler fired with oil will raise about 30 per cent. more steam than the same boiler coal fired.

(7) The furnace doors can be kept closed when oil firing, thereby increasing the efficiency of the boiler and lessening the wear and tear on the boiler plates caused by frequently being chilled with cold air, as is the case when burning solid fuel.

(8) Boilers can raise steam much more quickly when oil fired, thus lessening stand-by charges.

(9) Boilers fitted for burning both solid and liquid fuel may be run on coal under normal conditions, while oil can be burned for peak loads, thus minimising the number of boilers in use.

1 lb. coal under favourable conditions raises 9 lbs. steam.
1 lb. oil under similar conditions raises 14½ lbs. steam.

It is essential that firing devices for liquid fuel should break the oil into an exceedingly fine state of division, so that the air can reach the oil readily and ensure speedy combustion.

The methods of breaking up the oil are :—

(1) By means of steam.
(2) By means of compressed air.
(3) By a high pressure on the oil, which is pulverised on passing through a fine jet.
(4) By means of mechanical breaking up in a pulverising chamber.

Steam Jets.

The majority of oil-burning installations used on land are operated by steam. Steam is always available at the face of the boiler, and at the same time steam burners, though not giving quite so high an efficiency as air burners, give a soft flame, which is less liable to injure the plates or tubes with which it comes into contact. For marine purposes there is a distinct disadvantage in the use of steam on the oil burners, as it causes the loss of a considerable quantity of water, which has to be carried in storage tanks or else has to be specially prepared by a distillation plant whilst at sea. This drawback does not apply to land installations, where plenty of water is usually available. Steam burners operate on a variety of principles, the majority of constructions being somewhat in the form of an injector.

The Kermode steam jet burners, which have met with much success on land service, are designed to impart a rotary motion to the gases by passing the oil through a helical groove. The steam is passed through an annular space surrounding the oil duct, and in addition to causing atomisation, it is used to induce an air current which assists in the combustion of the fuel.

With the Holden steam jet burner, fuel steam and air are passed through annular spaces, the centre of the burner being left open to facilitate cleaning.

Another principle used for pulverising oil by a steam jet is to allow the oil to trickle from a weir over a thin slit through which the steam is passing. This system is used in the common type of burner known as the 'Mexican trough.' A modification of this principle is also used in the Ajax burner, made by Bamford & Co.

Compressed Air Burners.

The use of compressed air for pulverising purposes allows a higher efficiency on boiler-firing installations. At the same time the saving is not so great as might be anticipated, as the steam or power used for driving the compressors is almost as great as the amount lost through steam burners. The flame has a higher temperature than that of the steam jet, and greater care must be taken to prevent it impinging on the plates. Some of the most recent types of compressed air burners will operate on air at low pressure (about 10 lbs. per square inch), and therefore do not necessitate costly air compressors, as they can be operated with complete satisfaction by low-pressure air from a rotary blower. Such burners are the 'White' burner, the 'J. Samuel White,' and one of the burners by Alldays Onions.

The Oil Pressure System.

This is mainly used for marine purposes, and complete oil-burning installations on this principle are comparatively expensive, on account of the necessity for well-constructed and effective preheaters, fitters, and the specially constructed fuel pumps.

In this type of burner the oil is forced through fine jets under a comparatively high pressure. Many burners are so constructed as to impart a rotary motion to the pulverised fuel (e.g. Korting burner). The pressure system, although expensive, is probably the most efficient of oil-burning appliances. The power consumed in driving the fuel pumps is almost negligible, and the combustion is excellent. The pressure system is meeting with much success in marine work at the present time. Good examples of this type of apparatus are made by the Wallsend Slipway Co., Kermode, and Korting.

Mechanical Pulverisers.

It is possible also to pulverise oil by mechanical means, such as breaking the oil up in a squirrel cage. The rich oil-fog thus produced can then be treated as a gas and burned together with secondary air in the furnace. Installations of this type, however, have not met with much success, probably on account of their high initial cost.

Atomisers.

Holden's steam atomiser is shown by fig. 26; fig. **27** shows the Guyot atomiser used in the French Navy.*

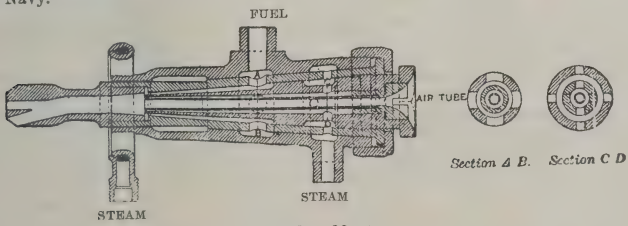

Fig. **26.**

Where boilers have the mixed coal and oil system, the oil is best atomised into the front of the furnace, parallel with the grate and about 10 ins. above it.

Where liquid fuel is used alone, the draught required is very small, because the greater part of the draught is always spent in overcoming the resistance of the fuel bed on the grate.

* From 'Liquid Fuel and its Combustion,' by W. H. Booth.

Whereas the calorific capacity of liquid fuel is roundly 20,000 B.Th.U. per pound, as compared with 15,000 for best coal, the commercial value is more nearly as 2 : 1, because liquid fuel can be burned perfectly with very little excess of air, and the temperature in the furnace is higher, the boiler efficiency is better, the boiler being also cleaner, and there are no expenses for removal of ashes and for flue cleaning. About 15½ pounds of air are required chemically to burn one pound of liquid fuel, or say 200 cubic feet of air. In the mixed system of coal and oil firing, a large excess of air may be admitted through the coal fire, and will be used by the oil, which is atomised above the fire.

In locomotives the blast-pipe may be much enlarged for liquid fuel so as to soften the draught. The Macallan variable blast-cap is used on the Great Eastern Railway for this purpose. The flow of oil requires special regulation. Exactness is secured by such devices as a stop-cock, in which the hole through the plug is square and placed diagonally, thus admitting of fine regulation.

To be successful, the burning of oil fuel must follow the lines of successful bituminous coal combustion, viz., air mixture, space, and temperature; hence the need for refractory brick linings to keep off the too early chilling effect of cold plates. In steam raising, liquid fuel has a higher percentage efficiency than solid fuel, because less excess of air need be employed; furnace temperature is higher, causing higher efficiency of heating surface, which is also cleaner. There is a large

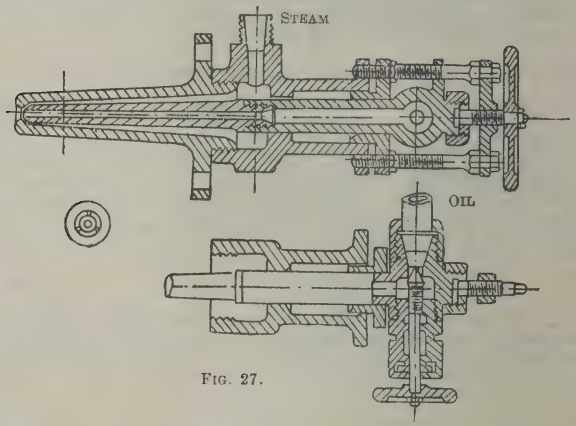

FIG. 27.

saving in labour of stoking, cleaning, ash removal, etc., but perhaps greater expense in firebrick renewals.

Liquid fuels can be burned by means of mechanical burners, without steam or air spraying, if heated to not much more than 140° F., and forced through a whirling jet nozzle at a pressure of not less than 40 lbs. per sq. in. and, with benefit, up to 150 lbs.

For general purposes ashore, high-pressure steam is a more satisfactory spraying agent than air.

At sea, for forced draught conditions, the United States Navy Liquid Fuel Board consider air to be the best medium, especially as it avoids the otherwise inevitable loss of fresh water.

In the ss. 'Nebraskan,' oil heated to 175° F. was atomised by air of 1¼ lb. pressure. The oil had a pressure itself of 15 lbs., and a very fine spray resulted; the air was heated. Retarders were necessary in the 3-in. tubes of the Scotch boilers to enable the heat of the gases to be utilised by retarding the flow, or probably by mixing up the gas.

WALLSEND-HOWDEN PATENT LIQUID FUEL BURNING SYSTEM.

In this system the liquid fuel is injected into the furnaces under pressure by means of special oil-fuel pumps, these pumps being fitted in duplicate so that one can act as a stand-by in cases of breakdown to the working pump. On its way to the burners the liquid fuel is passed through strainers and heaters in which it is thoroughly filtered and then heated to the correct temperature.

The oil is forced into the furnace in the shape of a conical spray of exceeding fine particles,

which burst into flame at a distance of six to eight inches from the nozzle. The flame being conical, and there being no fire-bars fitted in the furnace, the whole circumference of the furnace is available for heating surface. This is a great advantage in the ordinary multitubular boiler, as the lower portion of the boiler becomes heated sooner than would be the case with coal, and consequently the circulation of the water in the boiler is improved. Moreover, as the lower portion of the boiler is heated up uniformly with the upper portions, and as there is no inrush of cold air, since there are no furnace doors to be opened, there is practically none of that straining action which results from unequal expansion and contraction, due to rapid changes consequent on the opening of the door in coal stoking.

In the improved construction of the furnace front arrangement (fig. 28), which constitutes the principal feature of the arrangement, each of the oil fuel spraying nozzles projects through a

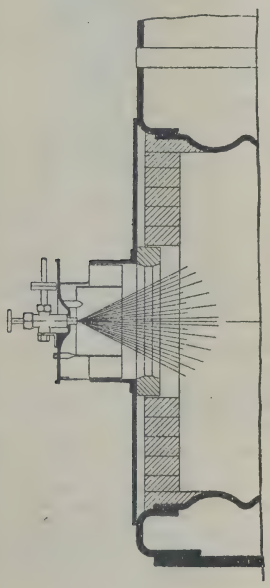

FIG. 28.

Arrangement for Working under Natural Draught or Closed Stokehold Draught.

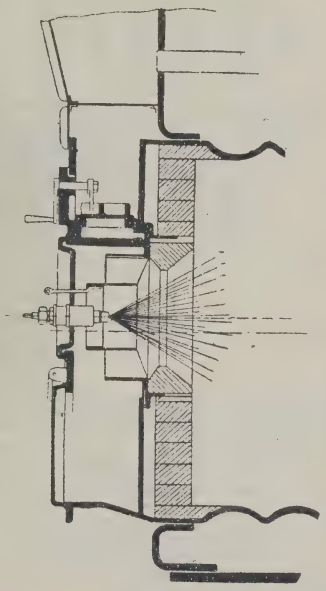

FIG. 29.

Arrangement for Working under Howden's Forced Draught.

baffle plate or the front plate of the casing into an air trunk having lateral openings at its outer end. This air trunk projects concentrically with a second air trunk carried by the furnace front, and the annular space between the inner and outer air trunks is fitted with deflectors constructed in such a manner as to give the air passing through the annulus a spiral motion. One result of this arrangement is, that the openings for the supply of air are so disposed that direct radiation of heat from the furnace is prevented. The admission of air through the second or outer air trunk keeps the outer casing cool, and hence radiation from this part is reduced to a minimum. A feature of the arrangement is the small amount of brickwork required.

With this system steam can be raised on any boiler from the start by means of oil fuel. This advantage is obtained by means of a special design of auxiliary heater and pump.

The Wallsend System is specially adapted for burning oil in conjunction with coal.

When burning liquid fuel on this system with Howden's Forced Draught, fig. 29, 16·22 pounds of water were evaporated (from and at 212° F.) per pound of oil burnt. The calorific value of the liquid fuel was 18,770 British Thermal Units, giving a boiler efficiency of 83·9 per cent.

Thornycroft Oil Fuel System.

In this system, fig. 30, the oil is sprayed under pressure into the furnace by means of a special patent sprayer having both edges of supply grooves tangential to the whirling chamber, the spray being produced within a steel cone of special construction which introduces and mixes the air and the oil-spray in such a manner as to produce perfect combustion. The system can be applied to either water-tube or marine type boilers. Water-tube boilers can be arranged for either oil only or coal combined with oil.

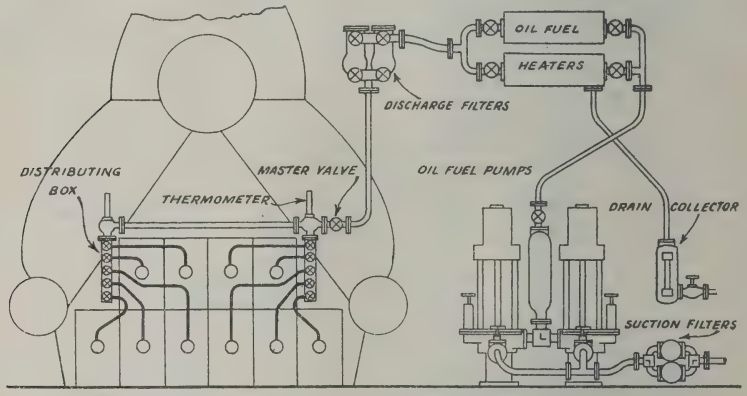

FIG. 30.—The Thornycroft Oil Fuel System.

The oil, which may be of any crude description such as Texas, Borneo, Mazout, or Shale, is stored in tanks in any part of the ship, and is drawn to the stokehold by a pump which forces it through the necessary strainers and the tubular steam-heater to the sprayers.

Lighting up is effected with crude oil by means of a U tube and hand-pump. Steam can be raised in from half to three-quarters of an hour.

When fitted in conjunction with Thornycroft boilers of latest design and fairly large size the makers are prepared to guarantee that the equivalent evaporation will be at least 16 lbs. of water from and at 212° F. per lb. of oil per hour, if the rate of evaporation does not exceed 4 to 5 lbs. per sq. ft. from and at 212°, and they can guarantee a maximum output of 18½ lbs. per sq. ft. from and at with an evaporation of 14 lbs. per lb. of oil from and at. This rapid rate of evaporation has no detrimental effect on the boiler if the arrangement is properly designed, while the combustion is smokeless up to moderate powers, and smoke is only just visible at the highest powers.

These results enable very large powers to be developed on small weight, and with the highest efficiency, and at small cost. The number of men necessary for a stokehold developing 16,000 h.p. is only 3.

Air required for Oil Fuel Combustion.

The amount of air required in practice at normal atmospheric temperature for the combustion of 1 lb. of oil fuel is from 250 to 450 cub. ft.; this is 1·6 to 2·5 times the theoretical amount.

British Admiralty Specification for Oil Fuel for the Navy.

(*Abstract.*)

'The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil or (*b*) petroleum, as may be required, or (*c*) a distillate or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures, percentage of sulphur, presence of water, acidity, and freedom from impurities.

'The flash-poin ishall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·05 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with deci-normal alkali the amount of acid extracted by the water, methyl orange being used as indicator. The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The viscosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel). The oil supplied shall be free from earthy, carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.'

British Admiralty Specification for Oil Fuel for use in Diesel Engines.

'Quality :—The oil fuel supplied shall consist of liquid hydrocarbons, and may be either (*a*) shale oil, or (*b*) petroleum, as may be required, or (*c*) a distillate, or a residual product of petroleum, and shall comply with the Admiralty requirements as regards flash-point, fluidity at low temperatures, percentage of sulphur, presence of water, acidity and freedom from impurities.

'The flash-point shall not be lower than 175° Fahr., close test (Abel or Pensky-Martens). (This compares with a flash-point of 200° Fahr. in 1910.)

'The proportion of sulphur contained in the oil shall not exceed 3·00 per cent. (as against 0·75 in 1910).

'The oil fuel supplied shall be as free as possible from acid, and in any case the quantity of acid must not exceed 0·05 per cent., calculated as oleic acid when tested by shaking up the oil with distilled water, and determining by titration with deci-normal alkali the amount of acid extracted by the water, methyl orange being used as indicator. (In 1910 it was required that the oil should be free from acidity.)

'The quantity of water delivered with the oil shall not exceed 0·5 per cent.

'The viscosity of the oil supplied shall not exceed 2,000 secs. for an outflow of 50 cubic centimetres at a temperature of 32° Fahr., as determined by Sir Boverton Redwood's standard viscometer (Admiralty type for testing oil fuel).

'The oil supplied shall be free from earthy, carbonaceous, or fibrous matter, or other impurities which are likely to choke the burners.

'The oil shall, if required by the inspecting officer, be strained by being pumped on discharge from the tanks, or tank steamer, through filters of wire gauze having 16 meshes to the inch.

'The quality and kind of oil supplied shall be fully described. The original source from which the oil has been obtained shall be stated in detail, as well as the treatment to which it has been subjected and the place at which it has been treated. The ratio which the oil supplied bears to the original crude oil should also be stated as a percentage.'

Special Oil Mixtures used for External Combustion.

Pitch-Creosote Mixtures.

Recently the use of mixtures of pitch and coal tar creosote has become common for furnace firing.

The pitch creosote oils are marketed in three grades containing 25 per cent., 50 per cent., and 75 per cent. pitch respectively. As pitch is but little lower than creosote in heat value, and generally commands about half the price, there is a pronounced economic advantage in burning pitch mixtures wherever possible.

Petroleum-Tar Mixtures.

The addition of tar or tar products to heavy petroleum oils causes a thick semi-solid deposit of pitch to separate, and this has till recently prevented the use of such mixtures. This difficulty has recently been overcome by the use of emulsifying agents which are capable of maintaining the constituents in a state of emulsion for prolonged periods.

Coal Dust-Petroleum Mixtures.

The U.S. Navy authorities have met with success in preparing fuel mixtures from very fine coal dust mixed with petroleum fuel oil. The coal is prevented from settling by the action of emulsifying agents. Such oils are claimed to have given satisfaction for boiler firing on the U.S. warships.

Safety in Use of Oil Burners.

Serious accidents to engineers and firemen have frequently occurred from the practice of improper methods of lighting and handling oil fires.

In starting a new fire the steam should be turned on and the bypass opened in order that the oil and steam passage may be cleaned out and warmed up. The bypass should then be closed and the steam shut off. Then the damper must be opened ; on no account try to start a fire with a damper closed. Next light a torch or bunch of oily waste and place about 10 ins. to 12 ins. in front of the burner, turn on a small amount of steam (just enough to carry the oil from the burner tip to the torch) and crack the oil control valve a little. As it generally takes some little time for the oil to fill the burner passage, do not turn on more fuel but wait until the passage is filled, when the fire will light easily.

The moment the fire is out, either intentionally or accidentally, the oil should be shut off and the door opened. After a few minutes the gases (which are violently explosive) will have passed off and the fire may be rekindled.

In regulating a fire the attendant should hold the door open just enough to enable him to watch the flame and be in a position to duck his head in case of a flare back. To increase the fire the oil valve should be operated first, then the steam turned on until the flame is clear. If not enough steam is used, the flame will appear red and smoky ; too much steam will cause the fire to look ragged and will have a tendency to extinguish it. In reducing the flame the steam is throttled down first, then the oil is reduced.

Once the fires have been set, they may be regulated over quite a range by increasing or decreasing the pressure applied to the oil supply without opening the fire-door or changing the steam supply. This can be done by manipulating the pump throttle or a bypass valve between the suction and discharge lines.

When extinguishing a fire, the flame should be cut down as low as possible ; then by opening the bypass immediately after shutting the oil valve, the oil passage will be blown out without danger, as the flame will not be extinguished until the passage is clear.—*A. C. McHugh.*

Notes on Oil Fuel.

At a large London factory at which some Lancashire boilers were converted from coal to fuel oil firing, the water evaporation per lb. of coal, having a calorific value of 11,451 B.Th.U., was 7·22, whereas when working with the pressure system of oil burning, using an oil having a calorific value of 18,750, the evaporation per lb. of oil reached 14·44 lbs. The quantity of water evaporated per sq. ft. of heating surface with coal was 3·3 lbs., whereas, according to Mr. A. F. Baillie in a paper read before the Manchester Association of Engineers, the quantity evaporated with oil was over 7 lbs., thereby increasing the boiler rating by over 100 per cent.

In most engines of the hot-bulb type, oil fue commonly known as gas oil or residuum is employed, this having a specific gravity of between 0·86 and 0·9. In some motors Tarakan crude oil has been used with success, whilst the other Mexican fuel oil, in spite of its relatively high percentage of sulphur, has operated very successfully. Paraffin is, of course ,also suitable for these motors, but owing to its high price it is not often made use of.

GASEOUS FUELS.

The more important gaseous fuels used commercially are generally mixtures. The combustible gases found in such mixtures are hydrogen, carbon monoxide together with the three hydrocarbons—methane, ethylene, and acetylene—also higher hydrocarbons of the series of which these are examples, together with benzene vapour, and occasionally other hydrocarbons.

Calorific Values, etc., of Gaseous Fuels.

In the table on page 1825 the calorific values per lb. of the usual fuels are given, together with the weight of the products of combustion, both when burnt in pure oxygen and also when burnt in dry air. The 'higher value' is that obtained when the water produced in the combustion is considered as having been condensed to the liquid condition, thus yielding up heat at the rate of about 970 B.Th.U. per lb. produced.

Usually in calculations relating to internal combustion engines it is found more convenient to deal with the volume rather than the mass of the gaseous mixture ; accordingly in the

† Of mixture with air. * Lower values.

Hydrogen.

From the above table it will be noted that a hydrogen-air mixture contracts after combustion to only ·853 of its initial volume, the pressure of the explosion being correspondingly reduced. Further, notwithstanding the very high calorific value of hydrogen *per pound*, its excessive bulkiness results in a heat evolution of only 82 B.Th.U. *per cubic foot* of its admixture with air at 60°F. and atmospheric pressure. Hydrogen-air mixtures are also very sharply explosive and trouble is experienced in engines from pre-ignition at the compression pressures usual in practice when hydrogen is present in large proportion in a gaseous fuel. Thus it is clear that hydrogen alone would be a comparatively poor and very troublesome fuel to employ for power purposes, though its presence is often beneficial in conferring sufficiently prompt inflammability upon dilute mixtures of other gases. For heating purposes a large hydrogen content is advantageous on account of the high temperature obtained in its combustion. Hydrogen constitutes about 45 per cent. by volume of modern coal gas, on the average.

Marsh Gas.

Marsh Gas (Methane) is an excellent fuel for power purposes; it has a greater heat value per cubic foot of air mixture than hydrogen, and the volume of the products of combustion is equal to that of the mixture before combustion.

The 'natural gas' so largely used in the United States consists principally of marsh gas, that of Olean (N.Y.), for example, containing no less than 96½ per cent. of this constituent. In 1908 more than 100,000 horse-power was developed by engines operated by natural gas in the United States; the gas usually issues from the wells at high pressure, occasionally approaching 1,000 lbs. per sq. in. The Snow engine of the N.Y. & Penn. Traction Co. at Olean is supplied by natural gas issuing at a pressure of 200 lbs. per sq. in., which is reduced down to 1·8 lb. per sq. in. before being admitted, mixed with air, to the engine. With natural gas compression pressures of 150 lbs. per sq. in. are common, and mean effective pressures of 80 lbs. per sq. in. are often attained.

Acetylene.

Acetylene has so far been but little used as a fuel for internal combustion engines. It is very violently explosive when mixed with air, and owing to its endothermic nature the pressure developed is unusually high.

The range of explosive mixtures with air is also considerable; Grover found that at atmospheric pressure explosive mixtures were produced with one volume of acetylene to from 4 to 18 volumes of air; at a compression of three atmospheres even a 30 : 1 air-acetylene mixture was found to be explosive.

Acetylene is soluble in water to the extent of 1·1 volume; in alcohol to about 6 volumes; while acetone at 60°F. and atmospheric pressure absorbs about twenty-five times its volume of the gas, and at a pressure of about 180 lbs. per sq. in., about 300 volumes. A solution of acetylene in acetone contained in a porous matrix under a pressure of 150 lbs. per sq. in., is sold commercially as dissolved acetylene ('D. A.'); the 'D. A.' cylinders contain 100 times their own volume of acetylene at 60°F. and ten atmospheres. Commercial calcium carbide on addition of water usually yields about 4½ cubic feet of acetylene per lb.

If bubbled through petrol, acetylene gas becomes heavily 'carburetted'; 100 cubic feet of acetylene thus treated will produce about 150 cubic feet of 'carburetted' acetylene. According to Dr. Caro, as a heating agent this exceeds pure acetylene about in the ratio of 3 : 2.

Used as a fuel for internal combustion engines some remarkable results have been obtained with acetylene. Some early tests on a 2 h.-p. engine showed that only 8¾ cub. ft. of the gas were required per b.h.p. hour, as against 35 cub. ft. of coal gas. In another case 6·35 cub. ft. of acetylene yielded 1 b.h.p. hour. And with a 6 h.p. engine using a 20 : 1 mixture, and a compression pressure of 115 lbs. per sq. in., Cuinat found that only 6·26 cub. ft. of acetylene were consumed per b.h.p. hour, the consumption by volume of coal gas being about three times as great. Specially designed acetylene engines of from 1 to 10 b.h.p. are built; these are mainly employed in pumping water for the generators of large village installations. The average consumption is about 7 cub. ft. of acetylene per b.h.p. hour, costing about 2¼*d.*; it is thus an expensive fuel for power purposes, as at present produced.

Several types of acetylene self-starting devices for the engines of motor vehicles have appeared during recent years, but unless caution be exercised in their use the extreme suddenness and violence of the starting explosion may result in damage to piston or cylinder.

See also Index.

Carbon Monoxide.

Carbon Monoxide yields the large return of 95·2 B.Th.U. per cubic foot of mixture with air, notwithstanding its low calorific value per lb.; this results from its weight being fourteen times that of hydrogen. The products of combustion occupy, however, only 0·835 of the volume of the original mixture; it is the principal combustible constituent of producer and blast furnace gas. Carbon monoxide is extremely poisonous, forming with the red corpuscles of the blood a stable chemical compound of a bright red colour termed carboxyhæmoglobin; care must always be taken to prevent any leakage of the gas into the atmosphere, and all engine and producer houses should be freely ventilated.

Olefiant Gas.

Olefiant Gas (Ethylene) is usually present to a small extent (up to about 4 per cent. by volume) in coal gas, and is a valuable producer of heat.

Owing to Government restrictions on the use of petrol, many trials were made in the use of coal gas as a fuel for motors designed for the use of liquid fuels. Large gas-proof bags have been attached to the roofs of taxi-cabs, or placed underneath motor buses, and good running obtained by filling up with coal gas at frequent stopping stations. Needless to say, the mileage of such an arrangement is very limited. Otherwise its performance is quite satisfactory, and, at present prices, considerably more economical than the use of petrol.

GASEOUS FUELS EMPLOYED IN GAS ENGINES.

1. Natural Gas.
2. Coal Gas.
3. Coke-oven Gas. (See page 1829.)
4. Acetylene Gas. (See page 1829.)
5. Producer Gas. (See page 1830.)
6. Blast Furnace Gas. (See page 1844.)

NATURAL GAS.

Natural Gas.—Large quantities of natural gas are evolved in most petroleum oilfields. The composition of the gas varies in different localities, but it always contains a high percentage of methane. The net calorific power is usually 750 to 950 B.Th.U. per cubic foot. It is used in gas engines and for heating and illuminating purposes.

2. COAL GAS.

Coal Gas is still almost exclusively used in the smaller sized stationary gas engines, especially in towns; it is an admirable fuel for internal combustion engines of any size, however large, but its use for considerable powers is usually precluded by its relatively high cost. The introduction of the Welsbach mantle, and the largely increased use of gas for domestic heating and cooking, has enabled the gas companies within recent years to supply a gas of lower intrinsic illuminating power than formerly at less cost to the consumer, and this reduction in cost has done much to encourage its use for power purposes.

The composition and properties of coal gas have been considerably affected by war conditions. The following table gives the pre-war composition and heat values of coal gas from several centres :—

CONSTITUTION AND CALORIFIC VALUE OF COAL GAS.

Place of Manufacture.	100 Volumes of Gas contain of :—							B.Th.U. per Cubic Foot at 60°F. and 1 Atm.
	H	CH_4	CO	Heavy Hydro-carbons.	CO_2	O	N	
Column :—	1	2	3	4	5	6	7	8
								(Lower)
Cambridge . .	47·2	35·2	7·15	4·8	0	0·25	5·4	585
Sheffield . .	46·86	35·6	7·35	5·42	0·25	0·43	3·21	620
London . .	45·2	29·9	10·3	5·1	0	0·5	10·0	538
Birmingham . .	43·4	33·67	9·46	4·48	0·16	0·13	8·7	553
Manchester . .	42·9	30·93	14·99	6·8	2·14	0·0	2·24	578
Average . . .	45	33	10	5·3	0·5	0·3	5·9	575

The average composition by volume from these five analyses is given in the bottom line; from table on page 1826 the corresponding calorific value per cub. ft. at 60° F. (15·5° C.) and 1 atm. (lower) is estimated as follows :—

Item.				B.Th.U.
Hydrogen	0·45	×	279	= 125·5
Marsh gas.	0·33	×	924	= 308·0
Carbon monoxide	0·10	×	323·6	= 32·3
Heavy hydrocarbons (say)	0·053	×	2000	= 106·0
Total B.Th.U. per cub. ft.				= 571·8

Say, roundly, 572.

The volume of air theoretically just necessary for complete combustion of this gas is estimated by aid of the second table on page 1826 as follows :—

Item.				Cub. Ft. of Oxygen necessary.
Hydrogen	0·45	×	0·5	= 0·225
Marsh gas	0·33	×	2·0	= 0·660
Carbon monoxide	0·10	×	0·5	= 0·050
Heavy hydrocarbons (say)	0·053	×	5·0	= 0·265
Total vol. of oxygen necessary				= 1·200 cub. ft.

The corresponding volume of air needed, as the gas contains 0·003 of its vol. of free oxygen, is : (1·200—·003) × 4·8 = 5·75 cub. ft.

BRICK AND FUEL ECONOMY

ON the authority of Sir Charles Ruthen, President for 1922 of the Society of Architects, no less than ONE MILLION HOUSES are needed to meet urgent demands.

If these million houses are built to use gas in lieu of coal for heating and cooking purposes, no less than *5,000 bricks in each house can be saved* owing to the substitution of small flues in the walls for chimney stacks and chimney breasts.

The consumption of gas in the house in preference to solid fuel conserves the nation's coal and secures for the consumer the maximum of efficiency, economy and convenience.

This question has been specifically discussed in Issue No. 81 of an illustrated monthly for business men and women entitled 'A Thousand and One Uses for Gas,' which will be orwarded post free, on receipt of 6d. in stamps, by the Secretary—

The British Commercial Gas Association

30 Grosvenor Gardens, S.W. 1

F. 1828

5. PRODUCER GAS.

In normal combustion, when an excess of air is present in the combustion space, the carbon of the fuel is burnt to form carbon dioxide according to the reaction

$$C+O_2 \rightarrow CO_2.$$

Nitrogen from the air passes through the combustion space into the resulting gas without entering into the reaction. By this reaction one pound of carbon generates 14,647 B.Th.U.

By restricting the air supply and arranging to maintain a comparatively great depth of fuel upon the grate the carbon may be burnt into carbon monoxide according to the reaction

$$2C+O_2 \rightarrow 2CO,$$

nitrogen again passing through the grate without being affected.

By this latter reaction, 4,400 B.Th.U. are generated for each pound of carbon gasified, the residual heat value obtainable from the carbon by complete combustion, i.e. 14,647 − 4,400 = 10,247 B.Th.U., remaining in the resultant gas.

The greatest quantity of heat obtainable in the form of cool carbon monoxide from the air-carbon reaction is therefore only $\frac{10,247}{14,647} = 70$ per cent. of the heat originally available in the carbon.

Of the 30 per cent. of heat given out during the reaction, a large portion leaves the producer in the form of sensible heat.

The heat generated in the producer is sufficient to cause a temperature too high for satisfactory working.

In order to cool the producer and to utilise this excess of heat, steam is introduced into the combustion space, when, if conditions are favourable, the following reaction takes place:

$$C+H_2O \rightarrow CO+H_2,$$

For each pound of fuel entering into the reaction 4,320 B.Th.U. *are absorbed* from the heated fuel.

By the use of air and steam in certain proportions, it is possible to absorb the excess heat generated by the air reaction and maintain a practically constant temperature in the producer.

By alternately blowing the producer with an excess of air and raising its temperature by the combustion of carbon, either to the monoxide or to the dioxide, and then cutting off the air supply and passing steam into the hot fuel until the producer temperature has again fallen it is possible to generate water gas (the result of the steam-carbon reaction) which may be collected separately.

Water gas in conjunction with oil gas (generated by the cracking of heavy petroleum distillates) is largely used for the preparation of illuminating gas in normal times.

As the fuel used is not pure carbon, other considerations than those mentioned in the above theoretical outline affect producer design and working. As coals undergo a destructive distillation in the producers it is necessary to make use of special devices for the removal of tar from the producer gas. The recovery of ammonia generated from the nitrogen of the coal is also of the greatest importance in the economics of producer gas plants. These particulars are treated in greater detail in the following descriptions of various types of plant.

(*a*) Pressure producer gas from anthracite (Dowson).

Gas Producers.

Some account of producers and producer gases from material supplied by manufacturers of gas plant is given hereunder :—

Dowson Gas.

The Dowson gas is made by passing a mixture of superheated steam and air through incandescent fuel. There is no external fire, as in ordinary gas retorts, and no skilled labour is required to work the apparatus.

The original type of Dowson plant included a small steam boiler, to give the steam required and to work an air injector. Excellent results have been obtained in this way, and for some purposes it is still the best plant to use. It is now known as the 'Dowson Steam-jet Pressure Plant,' and is used when gas is required from one apparatus to serve several gas engines or one or more engines and heating appliances.

Another type of Dowson gas-making plant is the 'Dowson Suction Plant,' which has been installed in large numbers in this and many other countries. This type of apparatus requires no boiler or gasholder, and the engine itself draws the air required through the fire in the gas generator : the engine, therefore, governs the rate of producing the gas to suit its varying consumption, and there can be no waste of gas. Moreover, the dry steam required is produced by waste heat, and the fuel which is to be converted into gas is also heated by waste heat before it reaches the combustion zone. Throughout the apparatus the loss of heat is therefore reduced to a minimum, and the efficiency is exceptionally high. Sir Dugald Clerk's 'James Forrest Lecture,' delivered in 1904 to the Institution of Civil Engineers, refers to exhaustive tests made by him with this suction plant, the heat efficiency being proved to be about 90 per cent.

In both types of the Dowson apparatus anthracite peas or nuts, charcoal, or coke can be used. The consumption depends somewhat on the type of plant and the kind of fuel used. With the suction plant the Dowson Company guarantee that the consumption of small coke of good quality will not exceed $1\frac{1}{8}$ lb. per b.h.p. per hour, at full load, with any good gas engine suitably adjusted for working with the plant.

If anthracite peas (from $\frac{3}{8}$ in. to $\frac{3}{4}$ in. cube) are used, the consumption is guaranteed not to exceed 0·9 to 1 lb. per b.h.p. per hour.

As regards stand-by losses, careful independent investigations have shown that at four different places Dowson gas generators, ranging from 100 to 375 b.h.p. each, during long stand-by hours, consumed an average of only 3 lbs. per generator per hour, while gas of good quality could be ready for use in about ten minutes. With steam power the stand-by loss is far greater.

A further important advantage of the gas is that it does not condense or lose power on its way to the engine ; on the contrary, the more the gas is cooled the better it is for the engine, as each charge of gas which enters the cylinder is more dense, and has consequently greater energy. With steam the condensation in the pipes, etc., is considerable ; with gas there is no such loss. It is easy to prevent leaks of gas from the piping, owing to the low pressure of the gas, whereas with steam there is often much loss and inconvenience on this account.

With the suction plant there cannot be a leak of gas when the engine is working, but piping, scrubbers, etc., must be absolutely tight to avoid air leaks.

The wages of firemen are about the same for the gas plant as for a steam boiler of equal power. The quantity of water per b.h.p. per hour in the gas plant is about 1 gall. ; with steam power it is usually two or three times as great. The cost of repairs (pre-war period) is approximately as follows :—

For 100 b.h.p.	£4 per annum.	For 400 b.h.p.	£12 per annum
,, 200 ,,	6 ,, ,,	,, 500 ,,	15 ,, ,,
,, 300 ,,	9 ,, ,,		

As regards labour, with the suction plant the usual allowance is one man for about an hour each day to start the fire, clean, etc., and about one hour per day to put fuel in the generator. When the plant is worked with a boiler the labour required is greater, but not more than for steam power of equal size.

Although about four volumes of Dowson gas are required to do the same work in a gas engine as one volume of town gas, yet Dowson gas is produced so cheaply that the equivalent of 1,000 cubic feet of ordinary town gas costs only seven to twelve pence, according to the scale of working and price of fuel.

With Dowson gas 1 lb. of coal will produce ·70 cubic feet of gas, and 1 cubic foot of this gas requires only 1·1 cubic foot of air for complete combustion, against 6 to 8 cubic feet for ordinary gas.

A complete Dowson apparatus does not occupy more space than that required for the boiler of a steam engine of the same power.

The Dowson gas is used for heating and furnace work of all kinds, as it is a cheap and cleanly fuel, under perfect control. Many large manufacturers using Dowson gas lead part to gas engines and part to heating apparatus. Thus the well-known B.S.A. Company of Small Heath serve several

large engines, over 30 hardening furnaces, and 20 tempering vats—all taking gas from the same gas-holder. The Home, Canadian, and Indian Governments have adopted Dowson apparatus for heating purposes in various military establishments. At the Royal Arsenal, Woolwich, and elsewhere, the gas is used for annealing cartridge cases.

The following comparative estimates (pre-war period), for 25 and 50 b.h.p., show that it is much cheaper to use gas power than electricity, even where the latter is sold at 2*d.* per unit :—

25 B.H.P.	Per week. £ *s.* *d.*	Per annum. £ *s.* *d.*
Electricity—25 B.H.P.=18¾ B.Th.units×50 hours =937½ units at 2*d.*	7 16 3	390 12 6
Town Gas Power.—25 B.H.P.×20 cubic ft.×50 hours=22,500 cubic ft. at 2*s.* 6*d.*	2 16 3	140 12 6
Dowson Gas Power.—25 B.H.P.×85 cubic ft.×50 hours=106,000 cubic ft. at 3*d.*	1 6 6	66 5 0

50 B.H.P.	Per week. £ *s.* *d.*	Per annum. £ *s.* *d.*
Electricity.—50 B.H.P.=37½ B.Th.units×50 hours =1,875 units at 2*d.*	15 12 6	781 5 0
Town Gas Power.—50 B.H.P. × 20 cubic ft. × 50 hours=45,000 cubic ft. at 2*s.* 6*d.*	5 12 6	281 5 0
Dowson Gas Power.—50 B.H.P.×85 cubic ft.×50 hours=212,000 cubic ft. at 3*d.*	2 13 0	132 10 0

A trial of Dowson plant with gas engines was made by Messrs. Handcock & Dykes, electrical engineers, at the printing works of Messrs. Harmsworth Bros. at Gravesend. The general results are as follows :—

Length of run, 36 hours. Mean load, 40·85 kilowatts Mean B.H.P., 64·4

Total anthracite weighed out during run	2,520 lbs.
Total actually added after clinkering	532 ,,
Add allowance for clinkering the third time	266 ,,
Total anthracite	3,318 ,,
Less amount recovered	577 ,,
	2,741 lbs.

2,741 lbs. equals total anthracite consumption for one generator and engine for three days of 12 hours each, including 'standing by' losses of another generator for 36 hours, and loss whilst both engines were running together whilst changing over.

Anthracite per k.w. per hour=1·86 lbs. Anthracite per b.h.p. per hour=1·18 lbs. Total coke consumed=448 lbs. Coke per k.w. per hour=·3047 lbs. Coke per b.h.p. per hour=·193 lbs.

Making total fuel in generator and boiler { Per k.w. per hour=2·16 lbs. / Per b.h.p. per hour=1·37 lbs.

N.B.—It should be noted that the load 60 b.h.p. was only 75 per cent. of the normal working load of engine and producer. Messrs. Harmsworth have since made large additions to their Dowson gas plant.

More recently Mr. Dowson has introduced a new type of producer, to work with bituminous coal, which is a new departure in several respects. In producers which are worked with bituminous coal the tarry vapours from the hydrocarbons in the fuel mix with the gas, and the tar is usually afterwards extracted in separate apparatus. Mr. Dowson has always held the opinion that the tar should be got rid of in the producer itself, and he has succeeded in doing this.

The producer is double-acting—i.e. air is drawn in through the top and through the bottom of the fuel column. The coal is put in at the top, and the upper part of the fire burns downwards. The hydrocarbons are distilled off and various reactions occur, the coke which remains sinks downwards into the lower part of the producer. The coke is there converted into ordinary producer gas by the upward current of air (accompanied by steam), which is drawn in at the bottom. The mixture of gases leaves the producer through an outlet about halfway between the top and bottom. There is no external fire, and the gas is made as quickly as it can be consumed, as in the other types of Dowson gas plant.

When working with ordinary bituminous coal, or with lignite and several other varieties of fuel, there is no tar ; it is removed altogether in the producer, and no mechanical or other tar

extractor is required. After leaving the producer the hot gas passes through a vaporiser to cool the gas, and to raise the steam required for making the gas. It then passes through suitable scrubbers and is ready for use in the engine to be worked with it.

This bituminous plant is worked by suction, and consequently there is no escape of gas; it is also easy to work, and the cost of labour is about the same as with an ordinary plant working with anthracite or coke.

When the plant is to be worked by the suction of an engine as in the smaller powers, viz., 25 up to 100 h.p., there is a fan to start it, as in ordinary suction plants, and this is stopped when the engine is running. For powers 100 h.p. and upwards there is a fan or blower to draw the gas from the plant and deliver it to the various engines or heating apparatus requiring gas. Each fan or blower produces the suction on the plant and governs the make of gas. Of course with all heating work and where there is more than one engine requiring gas, even for the small powers, a fan or blower is always installed to deliver the gas under pressure.

The quality of the gas made in this plant is about the same as that of gas made with coke in ordinary suction plants. The heat efficiency of the new plant is exceptionally high, and with a good engine under full load the consumption of fuel is little over 1 lb. per b.h.p. hour. The stand-by losses are small, and after standing over-night or during meal hours, good gas can be ready for the engines in a few minutes.

A well-known firm in the Birmingham district, who used Dowson anthracite gas for many years, started one of their bituminous plants for 500 h.p. in October 1908, and have used it regularly ever since. The results were so satisfactory that in October 1909 they started a second plant of this type for 700 h.p., and they now use both plants to serve thirteen gas engines of different powers. They have stated that the gas made from local bituminous coal containing as much as 30 per cent. of volatile matter is as clean as the anthracite gas previously used. The consumption of bituminous coal, including all stand-by losses, does not exceed the previous consumption of anthracite under like conditions.

At first it was thought that these bituminous plants would not be suitable for small powers; but with slight modifications they can be made in any size from 25 h.p. upwards.

The Moore Producer.

Messrs. The Dowson & Mason Gas Plant Co. Ltd. manufacture also the Moore patent water-jacketed producer with by-product recovery.

The characteristic feature of this producer is that the fuel is treated continuously in three zones. (1) In the lowest, a firebrick-lined high-temperature zone, the bulk of the gas and ammonia is generated with only such an excess of steam as will prevent the temperature rising too high; (2) a water-jacketed or low-temperature zone in which the gas is cooled with the object of preventing the decomposition of the ammonia formed without the necessity of a large excess of steam; and (3) really a continuation of the second zone, an upper or air-cooled zone.

In order to insure a graded cooling effect the internal diameter of the producer, which is slightly conical, is less in proportion to its height than usual; and to get the best effect from the water jacket and air-cooled surfaces, the producer is elliptical in form with rounded corners in cross-section.

The producer is continuously fed with fuel through a gas-tight feeding device, whilst the ashes are withdrawn without the use of a water bottom by means of two circular coned tables, one on either side of the grate, which is built up in halves. By this arrangement the producer is always approximately full, whilst the fuel is kept in slow but steady movement downwards, the tendency for the fuel to jamb being prevented by its conical form. At the same time the necessity for poking is reduced to a minimum, as the gradual heating combined with the constant movement tend to prevent caking.

The water jacket, in addition to cooling the gases, supplies the bulk of the steam necessary for operating the plant; the remainder of the steam furnished by an outside source, calculated upon the total coal gasified in the producer, amounts to only about 8·5 per cent. of the total; the steam from outside sources required for the producer is at most ½ lb. per lb. coal, which is stated to be but one-third of the quantity required by ordinary recovery producers.

The temperature of the gas leaving the producer is only about 250° C. A dust-catcher fitted before the air condensers removes any dust carried forward from the producer.

The gas, after extraction of tar and ammonia, leaves the plant about atmospheric temperature and is practically free from suspended water. The whole of the by-products, both tar and ammonia, being recovered centrally there is no further deposition of tar in mains or flues, and no periodic cleaning is required.

The calorific value of the gas, working under conditions which allow a recovery of from 80 to 90 lbs. sulphate of ammonia per ton, varies from 155 to 160 B.Th.U. net per cubic foot at N.T.P. The average analysis of the gas is as follows: CO_2 10 per cent., CO 20·0 per cent., H_2 20·0 per cent., CH_4 3·0 per cent. The comparatively small percentage of carbonic acid and large percentage of carbon monoxide render the gas specially suitable for furnace work, whilst the percentage of hydrogen is not in any way detrimental to the successful operation of gas engines for central power stations and under varying load conditions.

SPECIALISTS IN PRODUCERS FOR EFFECTIVELY GASIFYING BAD FUELS.

(*See also page* 1835)

By reducing the quantity of steam added to the blast, it is possible to obtain a gas containing 25 per cent. or more of carbon monoxide, but the ammonia yield is reduced by about 20 per cent. In cases where the quality of the gas is of less account than a high yield of ammonia, it is economically possible to obtain a much greater yield than 80-90 lbs. sulphate of ammonia per ton of coal.

It is claimed that the net available quantity of gas is 20 per cent. more than that obtained from ordinary recovery producers, and that the first cost of the producer plant is less than that of ordinary recovery plants, whilst the ground space required is very much less.

The Kerpely Revolving Grate Gas Producer.

(E. G. Appleby & Co. Ltd., 70 Victoria Street, Westminster, London, S.W. 1.)

The Kerpely grate, a sectional view of which (dimensioned for the standard 3-metre diameter producer) is shown by fig. 31, is of polygonal shape and is placed eccentrically on the water trough. It has a continuous and not an intermittent action in crushing any formation of clinker that may occur. The water-cooled jacket in the fire zone prevents the formation of clinker on the walls of the producer. The clinker, when entering the ash zone, is caught by the numerous edges of the revolving grate and pressed horizontally sideways against the seal apron, and is consequently broken or crushed into small fragments, which, dropping into the water trough, are removed

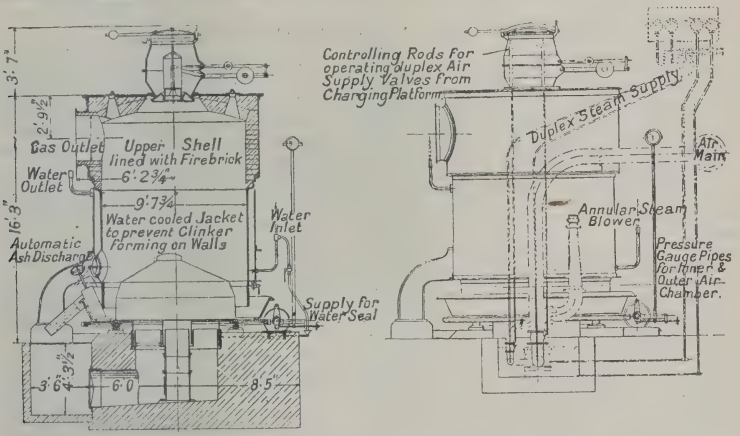

Fig. 31.—The Kerpely Revolving Grate Gas Producer.

by the ash scraper. The latter automatically discharges the ash and clinker accumulating in the bottom of the producer, and, being constructed to suit the shape of the ash trough, the ash is not only pushed aside, but is piled up and continuously discharged into an ash shoot. The automatic discharge of the ash and clinker from the Kerpely producer results in considerable saving of labour in the removal of ash, and ensures continuous working of the producer and gas of uniform quality. Labour is saved in poking, a small amount only of steam is required, and a dry gas is obtained, which ensures a prolonged life of the furnace linings. The supply of air steam to the Kerpely producer is separately conveyed to the inner and outer sections of the grate, and, being transmitted through spaces between the plates of the revolving grate, ensures uniform combustion over the whole grate area, the maximum gasification capacity per square foot of grate area, and effective control of the fuel bed.

The Kerpely producer can be fitted with the Appleby-Bentley Patent Mechanical Rotary Fuel Feed and Distributor, or this mechanical feed combined with patent balanced and adjustable fuel agitators and levellers, as the fuel conditions may determine.

Campbell Gas Producers.

The Campbell Gas Engine Co. are makers of several types of suction producers. They were among the pioneers of the enclosed type, which is still their standard for anthracite or coke and—with certain modifications—for charcoal.

Another type, first introduced by the Campbell Gas Engine Co., is the open-hearth suction gas plant, which is particularly suitable for inferior anthracite, collie coal, and small coke. It

also works successfully with locomotive smoke-box char, and plants to use this fuel have been supplied to the leading British railways and to railways abroad.

A third type of gas plant built by this company is designed for working with bituminous non-caking coal, lignite, etc. This plant works on the double draught principle in order to convert a considerable proportion of the tarry matter from the fuel into a fixed gas in the producer, and thus dispense with complicated scrubbing and cooling apparatus.

A fourth type of suction gas producer with which this firm has achieved success is their wood refuse plant. This as its name indicates is used for gasifying all descriptions of chips, shavings and sawdust. Plants of this type have been operated for considerable periods on sawdust alone with entirely satisfactory results. The consumption of such fuel varies considerably according to its quality, but averages about 3 lbs. per b.h.p. per hour.

These gas plants are supplied from 35 to 750 h.p. Several large plants have been supplied to leading British railway companies in conjunction with vertical gas engines and run entirely on the refuse produced in the wood-working shops, developing more than sufficient power to drive the whole of the machinery in these shops.

With certain modifications the producers are also supplied for using such fuels as rice husks, cotton seed, sunflower seeds, olive husks, etc.

Ample 'scrubbing' capacity is provided in all types, and careful provision is made for easy access to all parts for cleaning, thus keeping running costs at a low level.

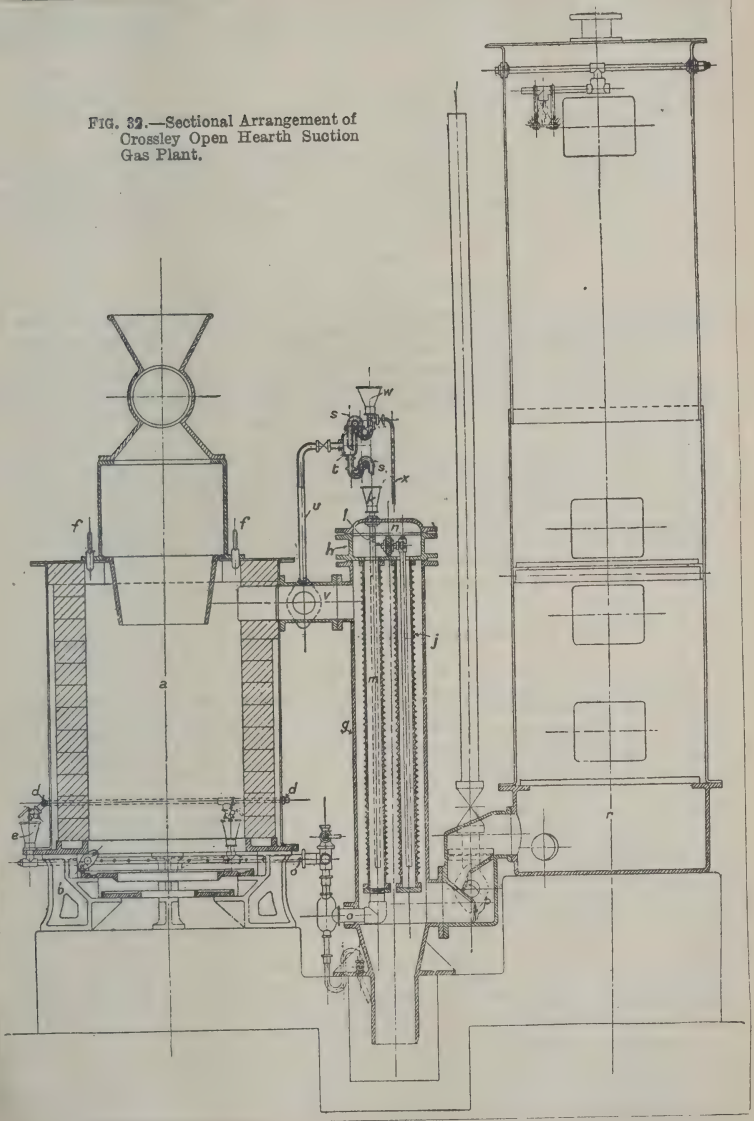
The Crossley Patent 'Open Hearth' Suction Gas Plant.

Crossley waste fuel suction gas plants are designed to work on a variety of refuse fuels, including waste wood of all kinds, spent tan, rice husks, olive refuse, sugar-cane refuse, cocoanut shells, coir dust, cocoa and coffee refuse, etc. Particular attention has been given by the designers to the removal of impurities from the gas and to allow of the continuous working of the plant by unskilled labour. The distinctive features are: open hearth fire grate, air-lock feed hopper, and sound construction, which give the advantage of easy cleaning, regular quality of gas, freedom from stoppages and reduce the amount of attention required.

In this producer, illustrated in fig. 32, the fire is always in full view of the operator. The fire-brick-lined generator *a* is supported by legs *b*, which also carry the circular cast-iron plates forming the patented stepped grate, so inclined as to exceed the natural angle of repose of the fuel and thus prevent any of this falling from the grate; at the bottom the fuel rests on its own bed of ashes.

Water delivered by a small pipe *d* running round the generator casing, passes into the funnels *e*, and so to the grate plates, overflowing from upper to lower; the grate is thus prevented from becoming burnt, while steam is generated which assists in the gas production. The absence of the usual vaporiser at the top of the apparatus enables the poker to be passed through the fuel from above in a direction parallel to that of the firebrick lining, the clinkers being thus very easily removed without risk of injury to the brickwork.

With this stepped grate every part of the fire is readily cleaned; thus section No. 1 may be cleaned by raking from the top stepped plate; No. 2 by raking from the lower plate; and No. 3 by raking straight across the ash pile supporting the central fuel column. It is to be noted also that with the open hearth stepped grate there is no variation in the quality of the gas produced arising from the opening of fire doors, which might cause slowing down, or even stoppage, of the engine. From the generator the hot gas passes to an external vaporiser *g*, consisting of a casing supporting a box *h* with gilled tubes *j*, exposing a large absorbing surface for extracting heat from the gas for vaporising the water. This water passes through an automatic regulator and thence into the tube *k* which is open at the bottom; the water rises in the gilled tube to the overflow *l*, to which the feed pipe of the next gilled tube is connected in series, and so on throughout this system of tubes, excepting the last, *m*. The tube *m* forms the connection between the steam space *n* of the vaporiser, and the steam distribution pipe *o* to the producer, and the water overflowing from the adjacent gilled tube passes down *m* and is flashed into steam.



In this producer the gas to be cooled is *external* to the water to be heated, so that both the cooling and heating are most effectually provided for.

The partially cooled gas next passes through two cascades of water, *p*, produced by the overflow from the scrubber; these remove the grosser impurities of the gas. It is next passed through a cast-iron coke scrubber, *r*, containing two coke-charged trays and fitted with doors so arranged that the coke in the bottom of the scrubber—which is the first to become fouled—can be renewed without interfering with that in the upper portion; from this scrubber the gas passes on to a combined drier and expansion box.

Instead of the usual pressure fan for blowing up the fire, a hand-operated exhausting fan is here employed which draws air and water vapour through the producer in a manner similar to that of the engine itself; this confers the advantage that the fan can be placed close to the engine gas supply cock so that when good gas comes over (as tested by lighting at the small test cock) the engine may be started at once by the assistant at the fan.

The automatic water regulator to the vaporiser above referred to consists of two tubes *s* connected to a small vacuum chamber *t*, which in turn is connected by the pipe *u* to the gas outlet pipe *v* from the generator. Water is fed from a tap into the funnel *w* and when the engine is not taking gas this water overflows from the pipe *x* into the seal box. When the engine takes

FIG. 32.—Sectional Arrangement of Crossley Open Hearth Suction Gas Plant.

gas, however, a vacuum is created in the chamber *t*, and the water is accordingly sucked over the upper tube *s* and runs into the lower funnel and so to the vaporiser; the simplicity and effectiveness of the device are noteworthy. The leading features of this patent producer of Messrs. Crossley are claimed to be :—

1. Its simplicity of construction.
2. The fire is always in full view of the operator.
3. The easy removal of ash and clinker without affecting the quality of the gas made.
4. The poke-holes are parallel to the fire-brick lining.
5. The cast-iron water-cooled stepped plates are not liable to get burnt out.
6. The absence of moving parts in the automatic water-supplying device to the vaporiser.
7. The large use of cast iron to avoid corrosion and thus prolong the life of the plant.
8. The exhausting hand fan alongside the engine valve enabling one man to start up the plant.
9. The practicability of using small fuel, as fine anthracite peas or grains, or low-grade coke.

Mond Gas.

(*The Power-Gas Corporation, Ltd., Stockton-on-Tees.*)

The Mond Gas Producer Plant was originally developed by the late Dr. Ludwig Mond for the conversion of bituminous fuels into power and heating gas, along with the simultaneous recovery of the nitrogen in the form of sulphate of ammonia.

The plants are constructed by The Power-Gas Corporation, Ltd., and in the course of time mechanical details have been improved and various parts of the plant modified. Within the last few years The Lymn Chemical Engineering Co. has been absorbed, and characteristic features of this Company's designs are now embodied in plants offered to operate under the Mond and Lymn system.

Plants of both the recovery and non-recovery type are constructed for power and for heating purposes, but considerations of economy rarely justify the installation of the recovery type in units of less than 2,000 h.p. or equivalent capacity. The non-recovery type, however, is installed in much smaller units.

Both types of plant can be adapted for utilising inferior fuel, such as the waste products from collieries and coke ovens, and the gas used for gas-engine driving, industrial furnace heating or boiler firing, and in such cases with the recovery plant the return from the sulphate of ammonia will go a good way towards meeting the running expense of the plant.

The Mond Non-recovery Water-cooled Gas Producer Plant.

(*Mond and Lymn System.*)

The modern type of Non-recovery Water-cooled Gas Producer Plant, as installed for generating gas from bituminous producer coal of suitable grading, quality, and condition for use in gas engines or for other purposes where cleanliness equal to gas-engine practice is required, may be considered as composed of two sections: the 'Gas Generating Section'—comprising the producer and its accessories—and the 'Gas Cooling and Cleaning Section'—comprising vertical static cooler and washer, centrifugal cleaners, and sawdust scrubber.

The producer is of the central blast type, with steel casing designed to sit on concrete foundations (provided by purchasers) and dip into a water-lute, formed in the foundations, and from which the ashes can be removed evenly all round without interrupting the working of the producer. The grate is conical in form, built up of two or more C.I. sections, and provided with air slots. It is located concentrically with the producer shell, and is connected up to the blast pipe which passes through the foundations to the outside of the producer. The lining of the producer is built of special quality firebricks and fireclay. The producer is fitted with a series of horizontal poke holes about the level of the air slots in the grate, and also with poke holes on the top giving access to the whole of the fuel bed, these top poke holes being fitted with spherical closers.

A fuel hopper is fitted on the top of the producer, with sliding cover and inner cone valve operated by lever and balance weight. The fuel in the hopper is discharged into a fuel container or inner bell, the top of which is provided with suitable poke holes, and from this container, automatically on to the fuel bed; this method of charging ensuring a more constant quality of gas. The gas outlet branch is fitted on the side of the producer casing close to the top.

A steel chequer plate operating platform is arranged at the level of the top of the producer shell with suitable protecting handrailing and ladder giving access from ground level.

Fuel handling plant is frequently included, and the type usually recommended comprises a power-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into a bunker, which is mounted on substantial supports over the producer and fitted with a shute furnished with lever-operated discharge valve leading down to the producer hopper.

The air-blast for the producer is provided by a blower of the steam-jet type, arranged so as to ensure a thorough intermixture of air and steam before the blast reaches the grate, but in some installations a steam-driven Roots or turbo-type blower is included, the exhaust steam from the blower engine or turbine being led into the blast pipe.

Leaving the producer, the gas enters the cooler and washer, which is of patented design, and provides an effective means of gas washing by the employment of a novel and efficient method of utilising the momentum of upward flowing gases to atomise liquid falling in thin sheets, with a resultant intimate contact between gases and liquid without the use of any mechanical spraying device.

The apparatus consists of a cylindrical casing of mild steel, fitted with top and bottom plates, gas inlet and liquid outlet at the bottom, and with gas outlet and liquid inlet at the top. When desirable, the bottom of the casing can be arranged for water-luting.

A vertical stationary shaft is located in the centre of the apparatus, extending the height of the casing. At suitable distances from each other, a series of discs or distributing devices for the liquid are fixed on this shaft, and attached to the casing are a corresponding series of inverted truncated cones which serve as collecting devices, the design of these internal parts being varied to suit particular requirements.

Falling by gravity alternately from the distributors to the collectors and *vice versa*, the thin sheets of liquid are atomised, and in the form of fine spray actually driven by the gas—itself flowing in zigzag path in the opposite direction—on to the collectors and distributors, where the spray again forms into thin sheets of descending liquid. Each particle of gas is thus brought into contact with the liquid many times before it leaves the apparatus.

The distributors are constructed with diameters considerably smaller than the lower diameters of the collectors, and thus the gas passage is not restricted, and the loss of pressure occasioned is very small.

Packing or filling materials, such as coke, earthenware tiles, or wooden boards, which baffle the passage of the gas, are dispensed with, and the troubles of stoppage and renewals attendant upon such materials getting choked with tar and dust are thus eliminated.

This type of washer is of established efficiency, and the absence of moving parts, together with the freedom from possibilities of blockage, which is a feature of the design, make it a thoroughly reliable apparatus requiring a minimum of attention, with no upkeep charges for labour and material for packing or filling renewals such as have to be met with in other types of washer.

From the washer the gas passes to the first of two centrifugal cleaners. These two cleaners are normally arranged to work in series, but where desired, the requisite cross connections and valves can be added to enable either cleaner to be cut out of operation and by-passed for purposes of overhauling should such be necessary. Each cleaner has a tar drain water-sealed in a lute in the foundations, and the gas delivery branch of the second cleaner is joined up to a sawdust scrubber, to the outlet of which the gas main leading to the gas engines, etc., is connected.

The scrubber is a rectangular cast-iron box fitted with wooden grids, on which are spread layers of wood chips, shavings, and sawdust. The gas enters at the bottom, and passing up through these layers receives its final drying and purification.

The scrubber requires very little attention, only needing to be cleaned out and refilled a few times per year, according to the load on the plant. A special lifting arrangement is provided to facilitate the removal of the cover, and all the spent material taken out can be burnt under the boiler which provides the steam for the plant.

The drains from the various parts of the plant are run to the settling tank, which takes the form of a concrete pit with iron or reinforced concrete partition plates, so arranged as to keep back the tar and allow only the water to run to the drains. The tar is then scooped or run off and disposed of in the most convenient manner, either being sold, used for boiler-firing purposes, dehydrated, or distilled, according to the quality and quantity available and local conditions.

The auxiliaries of the plant—elevator and centrifugal cleaners—can generally be most advantageously and economically driven by electric motors if electric supply is available, a direct or continuous current being preferable to an alternating current supply

Where requirements call for a minimum fluctuation in the gas supply pressure, an automatic governor can be added to plants in which a power-driven blower is installed. Such a governor would be of the gasholder type, but of small capacity, and hence of negligible storage value. The bell of the holder would be so arranged that as it approaches its top position it actuates a relief valve connected to the air-blast main, reducing the blast supply to the producer when the gas make is in excess of the requirements, and thus automatically controlling the gas production.

In installations where the gas generated is used to supply gas engines and also to fire furnaces, it is advisable that a non-return valve should be provided in the gas main to the furnaces.

A suitable and sufficient supply of steam is required for blast saturation purposes, also a suitable and sufficient supply of cold water to the washer, cleaners, and producer lute. Where

cold water is scarce, water-cooling and circulating plant may be installed, and a considerable portion of the water required can be used over and over again. Suitable motive power for the auxiliaries is also required, in the form of electricity or steam.

This description is typical of units up to about 1,100 b.h.p. capacity, larger units being generally similar but having two or more producers, gas main connections between producers and washer, to suit, and additional scrubber units.

The labour required on such a plant is small; it is easily understood, simple in operation, and will run for long periods without requiring replacements or renewals.

The Mond Bye-product Recovery Gas Producer Plant.

(*Mond and Lymn System.*)

Under normal circumstances, the installation of this type of plant is not, generally speaking, justified in units smaller than 2,000 b.h.p. in capacity, and local conditions and values may even require a larger unit, to afford an economical proposition. Thus, the usual plant of this type comprises more than one producer unit with corresponding superheaters, etc., but, except for plants of unusually large capacity, the washing, etc., vessels are installed in single units, with the scrubbers in multiple units, according to requirements.

This plant is made up to a certain extent of similar parts to the non-recovery type, but the design of several of these parts is modified to suit the different working conditions, and additional apparatus is included.

The plant may be considered as composed of four sections :—

(1) The Gas Generating Section, comprising producers and superheaters.
(2) The Gas Washing and Cooling Section, comprising dust washer, ammonia absorber, gas coolers and air saturator.
(3) The Gas Cleaning Section, comprising gas cleaners and scrubbers.
(4) The Sulphate Recovery Section, comprising sulphate of ammonia, evaporating and drying plant.

If the gas from the plant is required only for heating purposes, then Section (3), or, in some cases, the scrubber portion of this section, is not required.

The producers are similar to the non-recovery type, but with increased depth and other constructional modifications.

A steel chequer-plate operating platform common to the battery of producers is arranged at the level of the top of the producer shells, with suitable protecting handrailing and ladder giving access from ground level.

Fuel-handling plant is generally included, and the type usually recommended comprises a power-driven enclosed bucket type elevator, lifting the fuel from a boot at ground level into an overhead bunker, together with push-plate conveyor. The bunker, constructed of steel, is generally of parabolic section, extending over the whole of the battery and suspended from substantial supports, which also carry the producer platform. The bunker is provided with discharge shutes leading down to the fuel hoppers of the producers, each shute being provided with a lever-operated discharge valve. When required, a light iron framing and corrugated sheet-iron covering is supplied to cover in the coal conveyor and bunker top. For large installations, fuel-handling plant of the travelling overhead crane and grab type offers advantages which merit its adoption.

The air-blast for the producers is provided by blower or blowers of the steam-driven type, and on its way to the producers passes through the air saturator, where it is brought in intimate contact with water previously used for cooling the gas in the cooler built above the saturator, and from this hot water picks up a large proportion of the vapour required for blast saturation purposes. Leaving the saturator, it then passes forward through the superheaters into the producers, the additional steam required to complete the saturation being added on the way.

Leaving the producer, the gas enters the superheater, and passes through counter-currentwise to the air-blast.

The gas from each producer and superheater set passes into the gas-collecting main which joins up the various producer and superheater units, and from which it enters the dust washer, where intimate contact with falling sprays of water washes out a large proportion of the dust. From this vessel the gas passes on to the ammonia absorber, which is the same type of vessel as the washer used with the non-recovery gas-producer plant.

From the absorber, the gas passes to the first gas cooler, which is built above the air saturator. Both saturator and cooler are of similar construction to the absorber, but their relative position permits the cooling water pumped to the top of the cooler, after exercising its function in this vessel, to pass through into the undermounted vessel, where it is brought into contact, as previously mentioned, with the air-blast. Draining from the saturator into the water tank below, the water is from there again pumped to the top of the first cooler, and thus kept in circulation through the two vessels.

From the first cooler, the gas passes forward into the final cooler, which again is a vessel of the patented washer type.

For certain heating purposes the gas may be taken off for use from the exit of this cooler, but if further cleaning is required, it next passes forward to the first of two centrifugal cleaners, which in detail and arrangement are exactly similar to those described as part of the non-recovery plant.

Where the gas is required to be of gas-engine cleanliness, the delivery branch of the second cleaner is connected to a bus-pipe joining up to the inlets of the scrubbers, the outlets of these vessels being connected with a bus-pipe, from which the main for the gas engines may be taken.

Where for special purposes the final cleaning in scrubbers is not required, then the gas may be taken off from the exit of the second centrifugal cleaner.

The scrubbers are formed in separate sections in a rectangular cast-iron box, each section being provided with wooden grids on which are spread layers of wood chips, shavings, and sawdust. The gas enters at the bottom, the various sections working in parallel, and the operation, etc., being generally similar to this portion of the non-recovery plant.

The fourth section of the plant, in which the sulphate of ammonia is made in crystal form from the liquor obtained from the absorber, is generally housed in a building to itself. The plant comprises stock liquor tanks, into which the liquor at suitable saturation is withdrawn from the circulating system of the absorber and stored. From these tanks the liquor is pumped up to overhead feed tanks, from which it is fed into the vacuum evaporator, which operates in conjunction with a condenser of the ejector-jet type. Here the liquor is evaporated and the crystals discharged from the base into a specially designed aspirator, and from thence passed on for final drying in power-driven hydro-extractor. The dry salt is then delivered into the store, usually arranged in the basement of the building, where it is packed in bags ready for distribution or shipment.

A steel circulating tank is provided for use in connection with the absorber, and located closely adjacent thereto, to contain the weak sulphuric acid solution which is used as the circulating liquor in this vessel, and a pump, constructed of acid-resisting metal, is provided for circulating this liquor, with the repuisite connections between the tank, pump, and absorber, and from the tank to the stock liquor tanks. It is necessary for purchasers to provide acid and water supply pipes to this tank, to supply the make-up for the liquor withdrawn from circulation. Suitable pumps are also provided for supplying the circulating water to the dust washer and to the gas cooler and saturator, but it is usually left for purchasers to supply the cold water supply and pipe-line to the top of the final cooler, to the centrifugal gas cleaners, and to the jet condenser, as also the requisite drain connections for the disposal of the waste water from condenser and settling tanks.

The drains from the washing and cleaning sections of the plant are run to the settling tanks, as in the non-recovery plant, and the tar similarly dealt with.

The auxiliaries of the plant—elevator and conveyor, centrifugal cleaners, pumps, and hydro-extractor—can generally be most advantageously and economically driven by electric motors if electric supply is available, a direct or continuous current being preferable to an alternating current supply, but it is the usual practice to couple up the blowers to steam prime movers, the exhaust from which, as before mentioned, is utilised for blast saturation.

Automatic governor and non-return valve are provided when required to meet the same conditions as in the non-recovery type of plant, while steam, water, and motive power supplies will similarly be required.

In addition to the types of producer plant described above, The Power-Gas Corporation Ltd. design and construct :—

Heating producers for hot raw gas.

Rotating grate mechanical ash discharge water-cooled gas producers.

Rotating grate mechanical ash discharge gas producers with automatic coal feed and stirring gear.

Suction type producers, gasifying anthracite, coke, or charcoal (for power), 10 h.p. up to 450 b.h.p. single units.

Suction-pressure type producers for gasifying anthracite, coke, or charcoal (for power and for heating), 10 h.p. up to 450 h.p. single units.

Steam jet pressure type producers for gasifying anthracite, coke, or charcoal (for power and for heating).

Suction-pressure semi-bituminous type producers for gasifying wood, lignite, semi-bituminous coal, cocoanut shells, peat, etc. (for power and for heating).

'H.G.' (high grade) type producers for gasifying free-burning, non-caking fuels (for high temperature heating purposes).

All these types embody well-known features of this firm's Mond bituminous pressure plant —substantial construction, simplicity in design and working, reliable and economical operation, and a high efficiency under even severe running conditions.

Mond Gas for Industrial Heating Purposes.

Mond gas is extensively adopted for a great variety of industrial heating purposes, especially in connection with the heat treatment of metals and other materials, drying, melting, etc., displacing town gas and oil fuel on the score of the substantial economies in running costs, and direct solid fuel firing by virtue of the many advantages of gaseous fuel, such as :—

1. Higher temperature and more complete combustion.

2. Furnace temperature under absolute and easy control.

3. By recuperation, a large amount of heat, otherwise lost in the waste gases, returned to the furnace, etc.

4. Smoke nuisance eliminated.

5. Labour (coal and ash handling, etc.), by being centralised, much reduced.

6. A reducing or oxidising flame obtained at will, and, being clean and free from dust or dirt, the most delicate materials can be treated without fear of contamination.

7. Output of furnace, stove, etc., owing to the uniformity of temperature, is increased.

8. Stand-by losses greatly reduced, as, if desired, the gas can be shut off immediately the charge is drawn.

9. A saving of 20 per cent. to 30 per cent. in weight of fuel is readily obtained by efficient gas-firing, whilst the producer will also utilise generally a cheaper quality of fuel.

The gas is delivered cool, clean, and dry within practical limits and at any reasonable pressure required, the gas being of uniform quality and reasonably free from fluctuations in supply.

If the temperature is attainable by Mond gas, it may be assumed that the work will be done with equal satisfaction as compared with town gas or oil fuel, and, of course, on much superior lines to the direct use of solid fuel.

Bituminous Suction Producers.

The production of a satisfactory suction plant using bituminous fuel has proved a problem of very great difficulty, but several types of such plant have recently appeared, and they are now built commercially by Messrs. Dowson, Messrs. Crossley, and others. In these the leading idea is to destroy any tar produced by distillation of the fuel *in the producer* before the crude gas enters the coolers and scrubbers. This is usually accomplished by taking the gas from the hot zone of the producer, and arranging the supply of air and steam from both above and below ; the fuel enters from a hopper on top, and the gases coming off from the fresh coal pass down together with some air and steam to the hot zone where reactions take place which destroy the tar by converting it into useful gases. The fuel, now largely carbonised, passes slowly downwards towards the grate supporting the whole mass, and being traversed by a current of mixed air and steam passing upwards yields carbonic oxide and hydrogen as usual. Engines driven by these plants frequently require only about 1·2 lb. of slack to the producer per b.h.p. hour. Messrs. Farnham, of Glasgow, manufacture a bituminous suction producer of a different type to the above, the bituminous fuel being fed to the usual fire-brick lined iron shell *below* an incandescent zone of coked fuel, the products of distillation passing upwards, with air and steam, and becoming decomposed before arriving at the top of the fuel bed. With this arrangement the tar is so completely removed that less ' scrubbing ' of the crude gas is required than is necessary even in a normal anthracite suction producer.

A prolonged trial of a Farnham producer using a mixture of a highly bituminous caking coal and coke was made by Sir Dugald Clerk in 1910, who reported that the results were in every way satisfactory ; the consumption of total fuel amounted to only 1·13 lb. per b.h.p. hour, including stand-by and starting losses, and there was practically complete freedom from tar in the gas supplied to the engine by the producer. The fuel consisted of 78½ per cent. caking bituminous coal, and 21½ per cent. of coke ; the dried bituminous coal contained from 31·7 per cent. to 34·8 per cent. of volatile gases and tarry matter.

The ' Ruston ' Suction Gas Plant for Anthracite, Coke, Charcoal, etc.

The latest improved producers of Messrs. Ruston & Hornsby, Ltd., are designed for long working life, and also to be capable of operation with fuels of quality inferior to those usually employed in suction gas plants so as to ensure low working expenses; a sectional view is given in fig. 33, of a recent design.

The gas generator has an improved ash box with water-sealed bottom, enabling clinker and ashes to be removed while the engine is running and without weakening the gas. The vapour chamber is of steel plates with the outer casing removable for cleaning purposes, a vital necessity if dirty water be used. Before entering the vapour chamber the water is raised to a high temperature in an external feed water heater, by which means much of the sensible heat of the outgoing gas is recovered; high efficiency and an abundant supply of steam are thus attained, and the formation of clinker is reduced to a minimum.

Poking holes are provided in the top plate, in line with the inside of the firebrick lining, through which any clinker adhering to the bricks may be readily detached.

By taking off the gas at four points from the top of the generator a uniform draught is induced throughout the fire zone, and an equal distribution of heat to the vapour chamber; the fuel chamber is of such capacity that the plant can run for several hours without attention.

A patented three-way valve is fitted for shutting off the scrubber from the gas generator during stand-by periods of the plant; the possibility of an explosion occurring is thus eliminated.

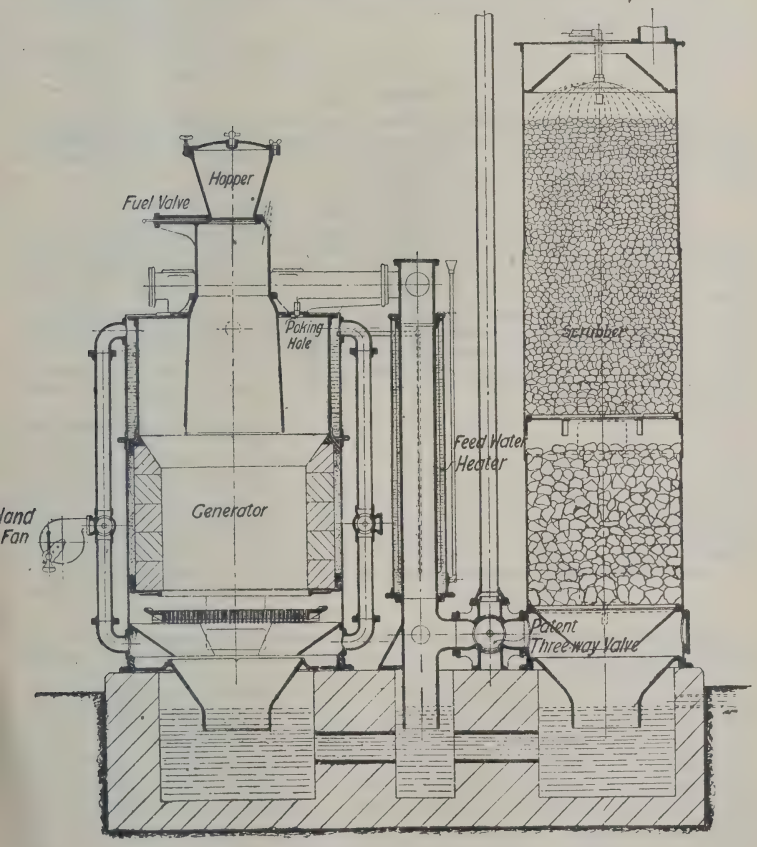


FIG. 33.—'Ruston' Improved Suction Gas Producer.

The 'Ruston' Wood-Refuse Suction Gas Producer.

Many gas producers have been made to deal with wood refuse from sawmills, such as sawdust, wood blocks, chippings, bark, etc., and similar fuels, a successful design being that made by Ruston & Hornsby, Ltd.

The chief endeavour has been to obviate the stoppages for cleaning usually necessary when working on such fuels. The little cleaning that is required is at the gas outlets from the generator, and this can be easily performed in a few minutes while the plant is in operation by means of special scrapers, so that the usual week-end cleaning is done away with, and the plant can be worked continuously if required.

Other advantages claimed are as follows:—small space occupied, very little attention required, no coke scrubber to become clogged with tar, simple in design and construction, and gas free from grit, dust, or tar. The consumption of wood refuse is from 2½ to 3½ lbs. per b.h.p. according to the amount of moisture in the fuel, and the plant will produce four or five times the power as when the fuel is burned for direct steam raising.

The producer is also suitable for working efficiently on anthracite, coke, charcoal, peat, lignite; as well as various waste materials, including cocoanut husks and shells, olive refuse, sunflower seeds, tea prunings, etc. etc.

A large number of these producers have been supplied at home and abroad for all classes of fuel.

Water Gas.*

In 'Water Gas' producers the action is intermittent, the fuel being alternately raised to incandescence by an air blast which is then shut off and steam alone passed through the glowing mass; the steam is dissociated into free hydrogen and oxygen, and the oxygen combines with the carbon present in excess and forms CO; thus:—

$$H_2O + C = H_2 + CO$$
$$2 \text{ vols.} + 1 \text{ vol.} = 2 \text{ vols.} + 2 \text{ vols.}$$

In theory, therefore, water gas should contain 50 per cent. by volume each of hydrogen and carbon monoxide; practically a small quantity of CO_2, N and O generally appears, as shown in the analysis given below. The passage of the steam through the mass of incandescent coke soon cools it down, when the steam is cut off and the air blast again turned on; the cycle of operations is then repeated.

Water gas plants are frequently installed in gas works, and the water gas is often enriched or 'carburetted' by admixture of heavy hydrocarbon vapours and in this condition used either alone or mixed with coal gas for lighting, heating, and power purposes.

The following results of analyses suffice to give a general idea of the characteristic constitution of water gas, carburetted water gas, mixed gas (i.e. mixed water gas and coal gas), and normal coal gas:—

	H.	CH_4.	CO.	Heavy Hydrocarbons.	CO_2.	O.	N.
Water gas	48·6	0·4	44·0	—	3·3	—	3·7
Carburetted water gas . .	29·35	20·48	33·19	11·32	—	—	5·66
Mixed gas	46·73	24·57	14·46	4·91	1·45	0·73	7·15
Normal coal gas . . .	45	33	10	5·3	0·5	0·3	5·9

6. BLAST FURNACE GAS.

In 1895 the late Mr. B. H. Thwaite showed that the hitherto waste gases from blast furnaces could be used in gas engines, and his discovery has stimulated the construction of the very large gas engines now becoming common.

The gas is taken from the gas main and forced by a blower through a scrubber into a holder regulator, and then to the engine. About 180,000 cubic feet of gas are produced per ton of fuel consumed in the furnace, and about 124 cubic feet of gas are used in the engine for each horse-power hour. From tests made on Mr. Thwaite's first plant at Wishaw by Mr. W. H. Booth, it is estimated that for each ton of fuel used per week in a blast furnace, 10 horse-power may be continuously obtained by gas engines. It is proposed to thus utilise the gases of all blast furnaces and so produce several millions of horse-power for distribution for railway, lighting, canal, traction, and general power purposes. Table I., page 1845, gives the analyses of blast-furnace gas in two cases where the Thwaite system is in use, and a comparison with producer gas, while Table II., page 1845, gives results of a volumetric analysis of the Wishaw gas.

* See also Section XXXIV.

						7·9038	

From 80 to 100 cubic feet of gas are obtained from each pound of fuel used. The foregoing table shows about 98 cubic feet of gas per pound of carbon, but some of the carbon comes from the limestone flux and from the ore, and even from the blast itself. In the gas engine, with the necessary enlargement of the gas inlet as compared with that necessary for town gas, and with a fair amount of initial compression, the action of blast-furnace gas is perfect, and no misfires are found to occur. The poverty of the gas is, in fact, no bar to its employment for power purposes. In fact the blast furnace is described in Mr. W. H. Booth's report as an ideal gas-producer. The employment of blast-furnace gas for power purposes enables cold-blast iron to be made, for with a sale for gas the economy of fuel per ton of iron ceases to be of importance.

Approximately each pound of carbon in the fuel used will produce about 98 cubic feet of gas, and each 100 cubic feet of gas produced weighs nearly 8 lbs. The tests on the small engine at Wishaw showed only about 1¼ lb. of coal per electrical horse-power, or 1·12 per i.h.p., assuming an efficiency of 75 per cent. between the cylinder and the terminals of the dynamo and allowing for temperature. Approximately each ton of fuel used per week in a furnace would give continuously 10 horse-power.

There has been a very considerable extension of the use of blast-furnace gas in Germany, where full advantage was promptly taken of Thwaite's teachings, and after a period of attempting to work with uncleaned gas Thwaite's method of cleaning was practically adopted. It is very important that the gas should be cleaned of its dust. Failure has occurred at an American iron-works where the engine valves became heavily loaded with dust. Fans may be employed through which the gas is circulated, jets of water being entered at the side of the fan casing. Rotating gas washers also are employed, and washer boxes in which the gas is passed under diaphragms which project an inch or two below water and compel the gas to bubble up through the water.

Large scrubbers with cellular work of light lathwork with water trickling over them will arrest much dust. Thwaite employed a sawdust filter as a final catcher, arranged so that the sawdust could be rapidly changed. Thwaite relied much on sawdust for removal of the tar of which it is difficult to get rid. Though blast-furnace gas may contain as little as 27 per cent. of combustible gas it presents no ignition difficulties when electrically fired in a state of compression in the cylinder. A. Witz has shown that the average calorific value of the gas from twenty-seven Belgian furnaces was 111 B.Th.U. per cubic foot, while nineteen Luxembourg samples showed 114 B.T. .U., twenty-three German furnaces showed 108 B.Th.U., and nine French and Spanish furnaces 107 B.Th.U. He takes a general average of 110, but the value may fall to 97 with an acid flux. Such poor gas will bear high compression, and will safely bear 7 to 9 atmospheres. No matter how poor a gas it will ignite if sufficiently compressed, and at Seraing as high as 11 atmospheres were employed in 1901. Hence the excellent efficiency that is obtained with blast-furnace gas.

Blast-furnace gas contains but little hydrogen, as no steam is used in the blast furnace ; it approximates, in fact, closely to the gas that would be given by an ordinary producer supplied with air only. The small hydrogen content enables very high compression pressures to be used without danger of pre-ignition ; when well cleaned, this gas is an excellent fuel for large engines, the heat evolved per cubic foot of maximum mixture at 60° F. and 1 atm. being about 57 B.Th.U. as an average lower value ; as already pointed out in an earlier part of this section, with cylinders of 30 ins. in diameter and over, in order to avoid overheating troubles it is found desirable in practice to introduce only from 35 to 40 B.Th.U. per cubic foot of piston displacement ; thus, although low in comparison with most other gaseous fuels, the heat evolution per cubic foot of blast furnace gas mixture is fully adequate to the needs of large gas engines.

Some average results for the principal gaseous fuels used at the present day are given in the following table :—

HEAT VALUE AND COMBUSTION OF USUAL GASEOUS FUELS.

(*From Sir Dugald Clerk.*)

THE KIRKE PATENT GAS-FIRED BOILER.

The original Bonecourt Surface Combustion Boiler has now been superseded by the Kirke Patent Gas-fired Boiler, invented by Mr. P. St. G. Kirke, M.A., A.M.I.C.E., A.M.I.M.E., and manufactured by *Spencer-Bonecourt, Ltd., Parliament Mansions, Victoria Street, S.W.* 1, and *Hitchin, Herts.*

Fig. 34 is a section of a Kirke Patent Gas-fired Steam Boiler. The design is based on the discovery that, if such gases as coal gas, coke-oven gas, blue water gas, producer gas, and natural gas are induced into empty tubes of great length relative to their bore, together with the air theoretically required for combustion, or some 10 per cent. in excess thereof, they can be completely burnt in the tubes without being previously mixed, and the resulting products of combustion reduced to 70° C., or less, above the temperature of the water in the boiler. Further, that this can be done either with natural draft or with high induced draft of 4 ins. of water and over, provided that the length of the tubes is greater relative to their bore, the higher the draft adopted.

The Kirke Patent Gas-fired Boiler in its simplest form consists of a drum traversed by a number of long tubes with nothing in them, which function as combustion chambers, as mixing chambers, and as extractors of the sensible heat remaining in the resulting products of combustion.

Recover Your Waste Heat

The two Boilers shown are effecting a reduction in coal consumption to the extent of £4,000 per annum; without counting the saving in labour charges. If you have steel furnaces, retorts, coke ovens, or large gas engines, instal a

'Kirke' Patent Waste-Heat Boiler

and your boiler house expenses will be reduced materially, for this fuelless boiler will provide you with steam *free of cost*.

SPENCER-HOPWOOD

Patent Water-Tube Vertical Boilers

ADVANTAGES:

Quickest steam-raising vertical boiler on the market. High evaporative capacity, fuel and upkeep economy, complete accessibility, easy to clean, no leakage or priming. : :

STANDARD, SQUAT, MARINE AND LAUNCH PATTERNS.

—

Also patentees and makers of the 'Kivke' High-efficiency Boiler for gas firing, oil firing, and utilisation of waste heat.

Works: HITCHIN, HERTS. Telephone: VICTORIA 5563.

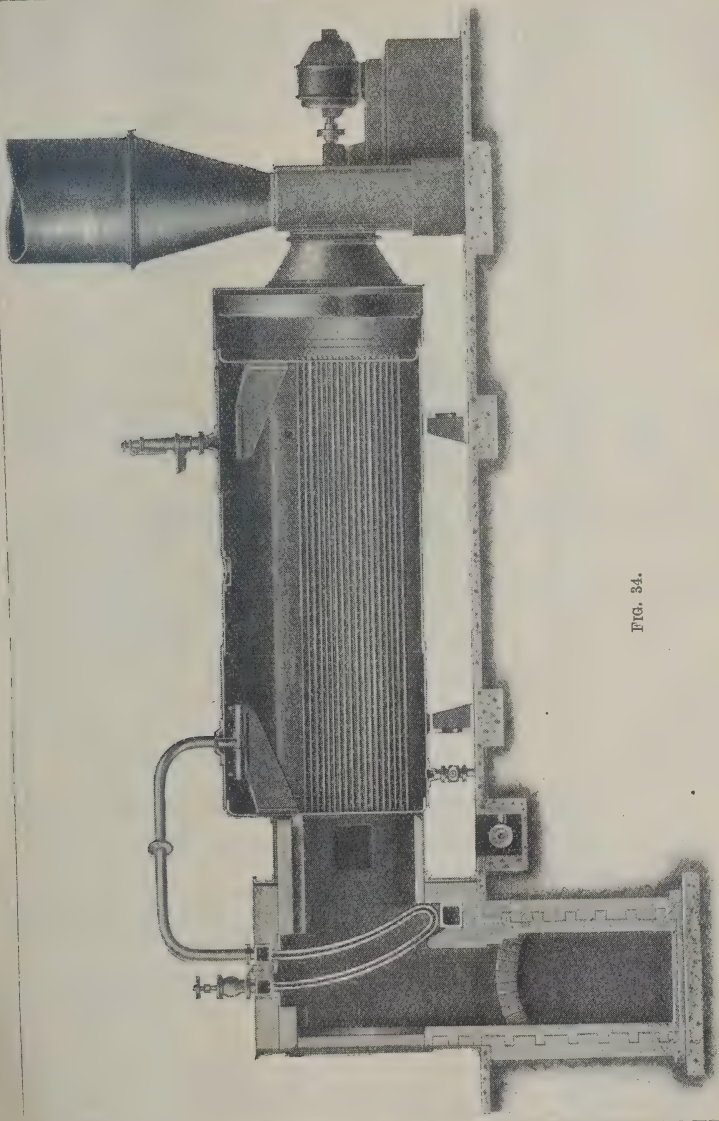

FIG. 34.

At the inlet end of the tube is a patent gas burner or distributor which discharges a jet of gas into each tube, the amount of which is determined by the size of the holes from which the gas issues and the pressure of the gas in the burner, the latter being controlled by the large gas inlet valve shown at the bottom of the burner. The requisite air for combustion enters each tube from the atmosphere, the quantity being controlled by the amount of draft which is varied to suit the load.

The following are figures obtained from a single tube evaporating water in an open wood tank lined with zinc :—

Gas burnt in cubic feet per hour	230
Steam raised from and at 212° F. in lbs. per hour	104
Cubic feet of gas per lb. of steam from and at 212° F.	2·21
Temperature of gases leaving the boiler	188° C.
Suction in inches of water	8
Gas pressure in inches of water	4
Evaporation per sq. ft. of heating surface in lbs. from and at 212° F. per hour	18
Net calorific value of the gas in B.Th.U.'s.	480
Thermal efficiency without economiser	91 per cent.

A single drum boiler of this type 7 ft. diameter by 21 ft. long, fired with coke-oven gas, will evaporate 21,000 lbs. of steam per hour with a suction of 4 ins. ; 16,000 lbs. with a suction of 2½ ins. ; and 10,500 lbs. with a suction of 1 in. The radiation loss from the shell when completely lagged (except for the front tube plate) is only ½ per cent. at full load and under 3 per cent. when unlagged.

The following table gives the power required by the fan, assuming 15½ lbs. of steam from and at 212° F. are required to generate 1 b.h.p.

Nature of Fuel burnt in Kirke Patent Fuel-fired Boilers.	Draft.	Percentage of Boiler Output required to create 4 in. suction.	Approximate B.H.P. required by the Exhauster for an Evaporation of 10,000 lbs. of steam from and at 212° F. per hour.
	Ins.	Per Cent.	
Water gas	4	0·93	6
Coke oven gas	4	1·00	6½
Producer gas	4	1·25	8
Crude oil	4	1·35	8¾
Coal	4	1·71	11
Blast-furnace gas	4	2·00	13

There are two ways of superheating the steam. The first is to insert larger tubes to accommodate superheaters of the locomotive type, as is universal in locomotive practice.

The second method, which appears to be preferred, is to divide the drum into two halves and insert the superheater between them, or to halve the length of the drum and make the gases pass through the boiler, first in one direction and then through return tubes in the other, placing the superheater in the chamber connecting the two sets of tubes.

When the floor space is very restricted, it is easy to put one drum on the top of another and, if desired, to couple them together in the steam and water space. In this way, for a given evaporation, only one-fifteenth of the floor space required by Lancashire boilers for the same evaporation is required.

The cleaning of the tubes on the water side is made easy by division of the tubes into two nests. A man can enter the boiler through the manhole and walk along the whole length of the boiler between the two nests, so that he can scrape the surface of all the tubes for their entire length, the distance between the tube centres being sufficiently great to enable him to get a suitably shaped scraper to all the tubes. This, however, is better avoided by softening the water or using a suitable boiler fluid.

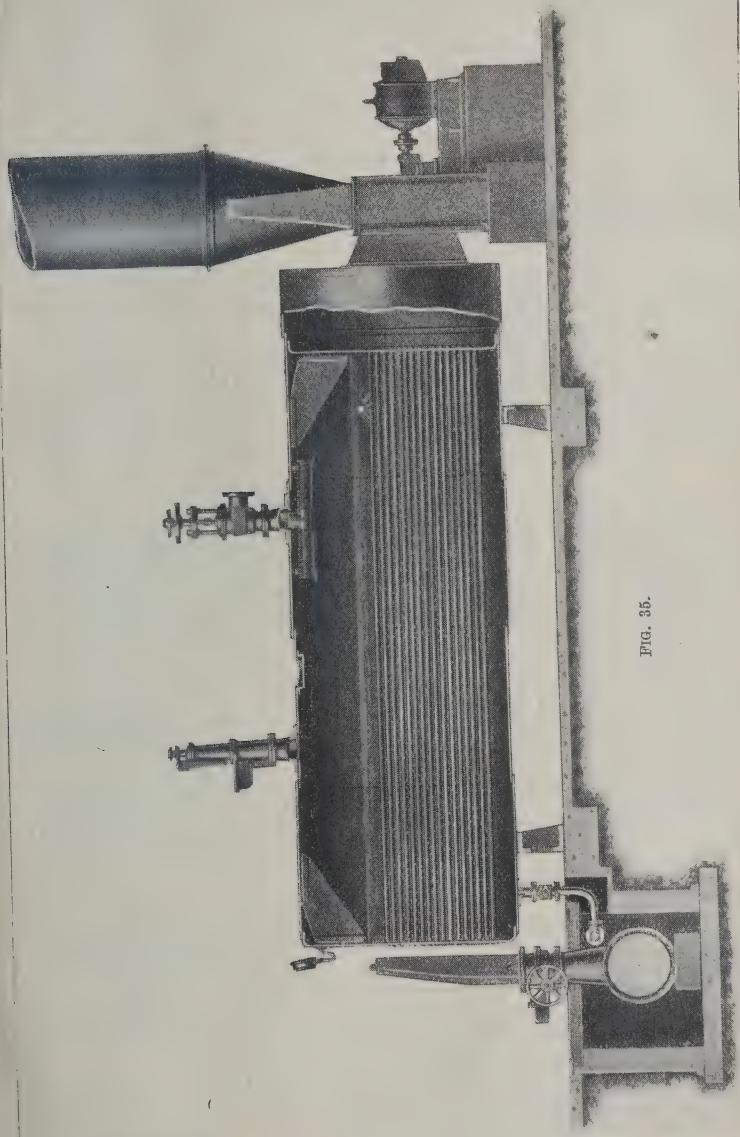

FIG. 35.

The following are the approximate fuel consumptions per lb. of steam raised from and at 212° F. for various fuels burnt in Kirke Patent Boilers without economisers:—

Producer gas	8 cubic ft.	Poor coal gas	2·7 cubic ft.
Coke oven gas	2½ ,,	Natural gas	1·2 ,,
Water gas	3⅜ ,,	Crude oil	1/17th lb.
Rich coal gas	2·2 ,,		

Kirke Patent Waste-Heat Boilers.

There are two types of Kirke Patent Waste-heat Boilers, a very short or squat one for dealing with clean gases which are at a positive pressure exhausted from large gas engines or Diesel engines, and an entirely different and very long one for dealing with dirty gases usually found at a negative pressure.

Internal Combustion Engine Pattern.

In the short or squat type for internal combustion engines, the tubes are very short and in them are placed twisted metal spirals.

The short or squat Kirke Patent Waste-heat Boiler has been evolved and put on the market to obtain the many advantages which may be obtained with twisted spiral cores, the twisting of which to a sufficient degree requires special machinery and special material. A short vertical boiler for a fairly large National Gas Engine which has been working for years was found to save its whole cost in twelve months. A short boiler of the horizontal type working on another gas engine was found to raise steam from cold in 30 minutes from the starting up of the engine.

Industrial Furnace Pattern.

In the long pattern Kirke Patent Waste-heat Boiler, made for large industrial furnaces, there are *no spirals placed in the tubes*. By using a high velocity of flow through the tubes a small boiler can be made for a big output and the capital cost kept low. The high velocity is compensated for by having the tubes very long relative to their bore, the length depending on the velocity chosen and the temperature of the hot gases in the boiler. Tube efficiency is usually about 90 per cent., and can be raised to 95 per cent. In this way the gases leaving the boiler are made cool enough to enter the exhauster, the boiler being so efficient that in many cases it is hardly worth while going to the expense of installing an economiser at all. Except when the water in the boiler is cold, it is impossible for the gases leaving the boiler to corrode the tubes or the fan impeller, because the water in a steam boiler is always above 212° F., and therefore the steam in the products cannot condense and combine with any sulphur in the gases to form sulphuric acid. If an efficient boiler is installed and an economiser inserted between the fan and the boiler, the gases may easily be reduced to such a temperature as to corrode both economiser and fan, and stop the whole plant. For this reason, if it is required to add an economiser, it should be put on the exhaust side of the fan, so that if the economiser is eaten away the boiler and fan remain intact.

If the gases entering the boiler are at a very low temperature, and an inefficient boiler needing an economiser is installed, the waste heat in the gases leaving the boiler will often heat far more water in the economiser than the boiler can use. It is very important, therefore, that the boiler should be a very efficient one, so that all the water heated in the economiser can be used and not wasted.

Fig. 35 shows a section of a Kirke Patent Waste-heat Boiler and Superheater without economiser.

When dealing with dirty gases containing very large quantities of dust—such as are obtained from cement kilns—Messrs. Spencer-Bonecourt have protected an arrangement for enabling boilers to be cleaned while they are running. The fan is arranged at the top or at the side of the boiler so as to leave the cover plate of the outlet products chamber unobstructed. In this cover plate small holes are drilled large enough to pass a tube brush or steam lance through for pushing through the whole length of tubes. One of these little holes will allow some nine tubes to be cleaned, and while leakage of air into several of the holes is not sufficient to reduce the draft, it is not necessary to open more than one at a time for cleaning purposes.

There are cases where gases are 1,000° C. or more, and in them a type of armoured superheater is recommended and arranged in the roof of the inlet products chamber. The superheater tubes are protected by cast-iron covers, so that with temperatures up to 1,000° C. and over, oxidation of the tubes themselves is entirely prevented. When dealing with such hot gases the boiler tube ends also are protected by ferrules.

The Kirke Patent Waste-heat Boiler can be adapted to burn blast-furnace gas. The usual inlet products chamber is replaced by an ordinary combustion chamber with any form of burner on the market which may be preferred. There is a place for the usual coke fire for relighting the gas after a temporary lull in the supply, so often experienced, but coal gas or coke-oven gas pilot jets are far simpler, and provision is also made for them.

The Kirke Patent Waste-heat Boilers are claimed to have a number of advantages over water tube boilers. First, air leakages which are troublesome in many types of water tube boilers, are avoided. If too much draft is put on to a water tube boiler with brick setting, the setting is apt to leak and spoil the performance of the boiler by reducing the temperature of the gases before the heating surfaces are reached, and by also adding uselessly to the volume of the products and, consequently, to the power absorbed by the fan. Also, the gases travel through these tubes of Kirke Boilers in an absolutely straight path, changing their velocity but gradually, and their direction not at all; consequently, for a given evaporation, the power required by the fan is much less than in a water tube type of boiler where the gases have to repeatedly change their direction of flow, and repeatedly accelerate and retard their velocity.

The following table gives the power required to create a draft of 4 inches of water for a Kirke Patent Waste-heat boiler evaporating 10,000 lbs. of steam from and at 212° F. per hour, assuming 15½ lbs. of steam from and at 212° F. per b.h.p.:—

Temperature of Waste Products.	Draft.	Percentage of Boiler Output required to create said Draft.	Approximate B.H.P. required by Exhauster for said Draft.
	Ins.	Per Cent.	
Blast-furnace gas	4	2	13
Waste products at 1,000° C.	4	2	13
Do. 800° C.	4	2·71	17½
Do. 600° C.	4	4	26
Do. 400° C.	2	4	26

The following test results have been obtained from Kirke Patent Waste-heat Boilers working on large industrial furnaces running 24 hours per day. In No. 3 the boiler was unlagged.

	1	2	3
Length of boiler	18½ ft.	18½ ft.	18½ ft.
Diameter of boiler	6 ft.	6 ft.	5 ft.
Temperature of products entering the boiler	850° C.	650° C.	383° C.
Duration of test in hours	4	3¾	6
Temperature of the gases leaving the boiler	219° C.	—	192° C.
Steam pressure	62 lbs.	62 lbs.	100 lbs.
Steam from and at 212° F. per hour	5,830	3,700	1,466
Draft at fan inlet in inches of water	2½	2½	2½
Draft at boiler inlet in inches of water, i.e. taken by the furnace	⅝ in.	½ in.	½ in.
Temperature of the exhaust gases above that of the steam	64° C.	—	29° C.
Tube efficiencies	90·8 %	—	89·6 %
Steam per sq. ft. of heating surface from and at 212° F. per hour	4	2·53	1·43
Coal saved per annum in tons, due to boiler running night and day at constant load	2,380	1,450	575

In case 1 the value of coal saved would pay for the boilers in a few months, in case 2 in a year, and in case 3 a little over a year.

When desired, these boilers can be fitted with extra tubes for separately firing with gas to increase the output of the boiler when the waste heat is insufficient.

By fitting a second drum containing one or more large firing flues in front of the Kirke Patent Waste-heat Boiler, the latter can be adapted for burning liquid fuel (or coal) and for recovering

waste heat alternatively or simultaneously. The following is an independent test on one of the boilers fired with oil in which the large flue and waste heat tubes were fitted in a single drum:—

Oil	Mexican fuel oil.
Temperature of oil . . .	200° F.
Calorific value of oil in B.Th.U.'s per lb.	18,550
Specific gravity of oil . . .	0·95
Oil burnt per hour in lbs. . .	215
Diameter of boiler in ft. . .	4½
Length of boiler in ft. . . .	16½
Heating surface in sq. ft. . .	230
Water evaporated per hour in lbs. actual	3,130
Steam from and at 212° F. per hour in lbs.	3,702
Steam pressure in lbs. per sq. in. .	26
Induced draft in ins. of water	1
Temperature of steam. .	134° C.
Temperature of products .	282° C.
Temperature of feed water .	53·6° F.
Pounds of steam from and at 212° F. per lb. of oil .	17·1
Pounds of steam from and at 212° F. per hour per sq. ft. of heating surface .	16·1
Combustion . . .	Smokeless.
Thermal efficiency of boiler *without* economiser .	89 per cent.

Electrical Units.

Unit.	Symbol.	Name.	Value in C.G.S. Units.	Dimensions in terms of	
				Length Time Mass.	Length Time Force Velocity.
Electromotive force	E	Volt	10^8	$L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}$	$V\sqrt{F}$
Current	I	Ampere	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}$	$\sqrt{F}$
Quantity	Q	Coulomb	10^{-1}	$L^{\frac{1}{2}}M^{\frac{1}{2}}$	$T\sqrt{F}$
Resistance	R	Ohm	10^9	LT^{-1}	V
Capacity	C	Farad	10^{-9}	$L^{-1}T^2$	TV^{-1}
Inductance	L	Henry	10^9	L	L
Power or rate of working	P	Watt	10^7	L^2MT^{-3}	VF
Energy	W	Joule	10^7	L^2MT^-	LF

The values of these units are as follows :—

One Volt is equal to 0·9818 of the E.M.F. of a Weston normal cell at 15° C.

One Ampere is the current which will deposit silver from a solution of nitrate of silver in water at the rate of 4·025 grammes per hour.

One Coulomb is the quantity of electricity represented by 1 Ampere passing for 1 Second.

One Ohm is the resistance at 0° C. of a column of mercury of uniform cross-section and length equal to 106·3 cm. whose mass is 14·4521 grammes.

One Farad is that capacity which is charged to a potential of 1 Volt by a current of 1 Ampere flowing for 1 Second.

One Henry is the inductance of a circuit in which an E.M.F. of 1 Volt is induced by a current variation of 1 Ampere per Second.

One Watt is the rate at which work is being done when a current of 1 Ampere passes through a resistance of 1 Ohm.

One Joule is the amount of work done, or heat generated, by 1 Ampere flowing for 1 Second through a resistance of 1 Ohm.

The following multiples and sub-multiples of these units are in common use :—

One millivolt	= one-thousandth of a volt.	**One microhm**	= one-millionth of an ohm.
One milliampere	= one-thousandth of an ampere.	**One microfarad**	= one-millionth of a farad.
		One millihenry	= one-thousandth of a henry.
One megohm	= one million ohms.	**One kilowatt**	= one thousand watts.

The following relations will be found useful :—

***One horse-power* is equal to 746 watts.**

***One foot-pound* is equal to 1·356 joules = 0·323 calorie.**

One calorie is the work done in raising 1 gramme of water 1° C., = 4·2 joules.

One joule is equal to 0·238 calorie.

One joule is equal to 0·7373 foot-pound.

One dyne is the force which, acting horizontally on a mass **of 1 gramme for 1** second, will give it a **velocity of 1 cm. per second.**

One erg **is the work done by 1 dyne acting through 1 centimetre.**

One watt = 0·00134 horse-power = 0·7373 ft.-lb. per second = 44·24 ft. lb. per minute = 0·0573 British thermal unit per minute = 1 joule per second.

One kilowatt-hour = 1,000 watt-hours = one Board of Trade Unit = 1·34 horse-power-hours = 2,656,400 ft.-lb. = 3,440 British thermal units = 867,000 calories.

The practical standard of electromotive force is the Weston Normal cell, which has an E.M.F. of 1·0185 volts at 15° C., decreasing by 0·00004 volt per degree C. rise of temperature.

The Clark cell, formerly used as the standard, has an E.M.F. of 1·433 volts at 15° C., decreasing by 0·078 per cent. per degree C. of temperature rise.

Laws of Currents in Conductors.

Ohm's law states that : Electromotive force = Current × Resistance, or $E = I \times R$.

Kirchhoff's first law states that : The algebraic sum of the currents meeting at any point of a network of conductors is zero.

Lenz's law states that : The current induced in a conductor flows in such a direction that its reaction opposes the change of position or state by which it is produced.

The power represented by a current of I amperes flowing under a difference of potential of E volts through a conductor of resistance R ohms $= I \times E = I^2R = E^2/R$ in watts.

The heat energy generated by a current of I amperes flowing through a conductor of resistance R ohms for t seconds $= I^2Rt$ in joules.

Resistivity of Pure Annealed Metals, and Alloys, at 0° C. (32° F.).

The resistance of metals increases with the temperature in accordance with the approximate formula

$$R_t = R_0 (1 + kt)$$

where k is the coefficient given in col. 5 or 6 (according to the temperature scale employed) divided by 100.

At 15·5° C. (60° F.), the resistance of a copper conductor is accurately given by the formula

Res. in microhms = 8 × Length in feet/Cross-section in square inches.

BRITISH STANDARDS FOR INSULATED ANNEALED COPPER CONDUCTORS FOR ELECTRIC LIGHT AND POWER.*

(No. 7—1919.) (*Abstract.*)

The International Standards of Resistance for Copper are as follows :—At 20° C. (68° F.), the resistance of a wire of standard annealed copper 1 metre long and of 1 sq. millimetre cross section is $\frac{1}{58}$ (0·017241) ohm. The density of such copper at 20° C. is 8·89 grams per cub. centimetre, and the temperature coefficient of resistance is 0·00393 per degree C. At 60° F. (15·56° C.) the resistance of a solid conductor of standard annealed copper 1,000 yards long and of 1 sq.in.

* By permission of the British Engineering Standards Association.

Electric Wiring in a Modern Works—YOUR Works—

to be efficient demands a high standard of Cable manufacture as a first essential

It calls for a type of cable having at least some of the following merits :—

Waterproof.
Stands Rough Usage.
Resists Corrosion.
Not affected by Electrolysis.
Unkinkable.
Resists Acids, Oils, etc.
Low Cost and Upkeep.
Very Neat.
Extremely adaptable.
Minimum of Skilled Labour Required.
No Special Fittings or Tools needed.

C.T.S. Cable (Patent No. 3996/11) possesses *all* the above points—how many can be placed to the credit of the type of cable *you* are using *to-day* ?

SILK COVERED WIRES.

ENAMEL INSULATED WIRES.

FLEXIBLE CORDS.

Platinoid, Eureka, and other Resistance Wires.

F. 1859

cross-section is 0·0240079 ohm; the density is 8·892015, and the temperature coefficient of resistance is 0·0022221 per degree F.

For the purposes of the specification an increase of 2 per cent. in the length of each wire in the stranded conductor has been assumed, and the area of the stranded conductor has been taken to be that of the solid wire which has the same resistance. In the case of multicore cables, an increase of 2 per cent. has been taken, to allow for the laying-up of the cores.

Tolerances allowed on solid conductors are, in weight, 3 per cent.; in resistance, 3 per cent. plain, 4 per cent. tinned (0·036 in. diameter upwards), 5 per cent. (below 0·036 in.). On stranded wires, in weight 2 per cent.; in resistance, 2 per cent. plain, 3 per cent. tinned (0·036 in. diameter upwards), 4 per cent. (below 0·036 in.).

The resistance of hard-drawn copper is about 3 per cent. higher than that of annealed copper conductors.

The resistance of a copper conductor 1,000 yards long and 1 sq. in. cross-section at various temperatures is given below, with the constant by which the value at 60° F. must be multiplied to give this figure :—

Temperature.	Resistance.	Multiplier.	Temperature.	Resistance.	Multiplier.
°F.	ohm.		°F.	ohm.	
40	0·02294	0·9556	90	0·02561	1·0667
50	0·02347	0·9778	100	0·02614	1·0889
60	0·02401	1·0000	110	0·02668	1·1111
70	0·02454	1·0222	120	0·02721	1·1333
80	0·02507	1·0444	—	—	—

The pressure test is to be carried out with alternating current of sine wave form at any frequency between 25 and 100 periods per second, at the r.m.s. values specified, for fifteen minutes continuously; the works test is to be made after twenty-four hours immersion in water.

660-Volt Paper or Jute Insulated Cables.

D is the thickness of the dielectric between any one conductor and the next conductor or the lead sheathing. Test for paper, at works, 2,500 volts for 15 mins.; when laid and jointed, 1,000 volts for 15 mins. Test for jute, at works, 1,500 volts for 15 mins.; when laid and jointed, 1,000 volts for 15 mins.

* Circular conductors; with segmental conductors the thickness of lead is generally slightly less.

D is the thickness of the dielectric, as follows :—

Paper cables : (1) Concentric cables, not earthed ; between the conductors, and between the outer conductor and lead sheathing. (2) Concentric cables earthed ; between the conductors. (3) Twin cables ; and Three-core cables, centre point not earthed; between the conductors, and between any conductor and lead sheathing.

Rubber cables : (1) Single-conductor cables ; on the conductor. (2) Concentric cables, not earthed ; on each conductor. (3) Twin and three-core cables ; on each core.

OC is the thickness of dielectric on the outer conductor of concentric cables with the outer earthed.

E is the thickness of the dielectric between any conductor and the lead sheathing of three-core cables when the centre point is earthed.

When the outer conductor of a concentric cable is to be earthed, the pressure test between the outer conductor and earth (irrespective of the working pressure) is : at works, 2,500 volts ; laid and jointed, 1,000 volts.

The foregoing particulars, summarised from ten tables in the British Standard Specification, relate to eight sizes of cable ranging from 0·0225 sq. in. to 0·25 sq. in. Where segmental conductors are used, the thickness of lead sheathing is sometimes slightly less than in the case of circular conductors.

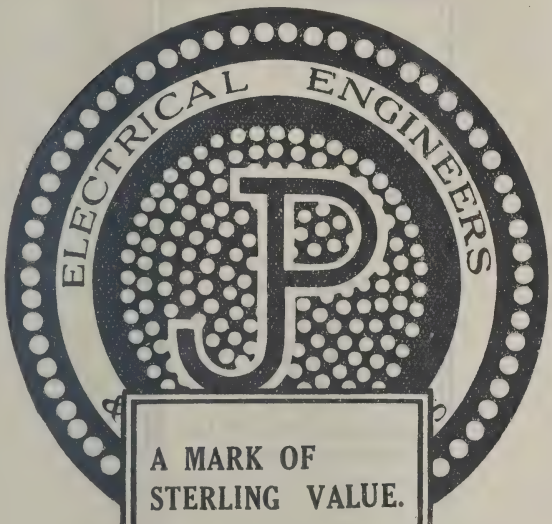
ELECTRICITY SUPPLY CABLES.

The figures in the table on page 1864 apply to single cables run in pairs and touching one another, and refer to situations where the maximum temperature of the air does not exceed 80° F. (26·7° C.).* The figures in columns 3 and 4 are the currents corresponding, in the case of rubber-insulated cables, to a rise in temperature of 20° F., and, in the case of paper-insulated cables, of 50° F. above that of the surrounding air. The lengths in circuit given in columns 3*a* and 4*a* when working at the currents given in columns 3 and 4 are calculated on the assumption that the temperature of the cable will be 100° F. in the case of rubber insulation and 130°F. in the case of paper insulation. For thickness of dielectric, see page 1859 *et seq.*

* The figures in columns 3 and 4 may be multiplied by the following constants for the classes of cable shown: Concentric, 0·93; 3-core, 0·88; 4-core, 0·82.



ELECTRICITY SUPPLY CABLES.

Cab Tyre Sheathed Cable.

This well-known type of protected cable patented by *The St. Helens Cable & Rubber Co. Ltd.*, Warrington, is manufactured under licence by most of the large British cable makers. It is generally known as C.T.S. It was designed for use in positions where ordinary protected cables often give trouble, principally as trailing or portable cables, and has since been found of value in all kinds of dangerous situations.

The conductors are usually insulated in accordance with the standards of the C.M.A., the whole then being sheathed with the same tough rubber material as is used in the manufacture of cab tyres. The principal characteristics of this rubber are durability, non-corrodibility, and non-absorbence. This type of cable is, therefore, now used in the numerous places where corrosion, moisture, hard wear, climatic or temperature changes are likely to be met with.

An advantage for some classes of work is that the elastic flexibility of the material prevents it from being kinked.

This class of cable is being largely used for general wiring. Being a portable solid system, not needing any further protection, it is easily and cheaply run.

The use of C.T.S. without further protection of any kind is authorised by the Wiring Rules of the Institution of Electrical Engineers (see p. 1950, *re* 'Tough Rubber Compound' Protection).

The following specification for this class of cable is based on the British Admiralty Specification Tests for Cab Tyre Sheathing :—

Revised Specification for Cab Tyre Sheathed Cable.

The cab tyre sheathing shall contain not less than 35 per cent. and not more than 40 per cent. of first-grade plantation rubber or other rubber of not less good quality.

The surface of the sheathing shall not be treated or dressed without the consent of the Admiralty Overseer.

The acetone extract of the vulcanised sheathing shall not exceed 5 per cent. calculated on the weight of the complete sheathing as manufactured.

Bending Test.—A test length of the complete cable containing the conductor shall be bent round a hard rod having the same diameter as the external diameter of the cable to form a loop. The unbent portions of the test piece shall be bound together so that the two parts touch one another closely throughout their length from their ends up to the beginning of the loop.

In cables of large size when this method is not practicable the test piece shall be bent in a loop so that the maximum extension of the external surface at the curvature at the bend reaches 50 per cent.

The sample in either case shall be left untouched for a period of 48 hours and at the termination of this time shall show no signs of cracking.

Immersion Tests. (*a*) *Chemical.*—Test pieces 6 ins. long shall be prepared, and after the conductor and dielectric have been removed they shall be dried at a temperature of 100° C. for one hour in an air oven ; they shall then be cooled in a desiccator for two hours, and at the end of this period shall be weighed. The ends of the test pieces shall be plugged with rubber bungs and sealed with paraffin wax for a length of half an inch from each end. The test pieces thus prepared shall be completely immersed in a vertical position in the following solutions for a period of 48 hours at normal temperature ; they shall then be removed and washed in running water for a period of two hours, afterwards being wiped dry and the wax and plugs removed. The samples shall then be dried in an air oven for one hour at a temperature of 100° C. and shall be cooled for two hours in a desiccator ; they shall then be reweighed. The difference in weights before and after immersion shall be calculated as grammes per 100 sq. ins. of surface exposed to the solution.

(1) *Acid Test.*—The solution shall be hydrochloric acid having a specific gravity of 1·045. The figure calculated as stated above shall not exceed 1·0.

(2) *Alkali Test.*—The solution shall be sodium hydrate having a specific gravity of 1·116. The figure calculated as stated above shall not exceed 1·5.

(*b*) *Oil Test.*—A test piece shall be prepared 6 ins. long ; one end shall be sealed so as efficiently to prevent access of oil to the interior. The test pieces shall be immersed in pure rape oil of the best quality to such a depth that not less than 2 ins. of sheathing is exposed to the action of the oil. The immersion shall be continued for six hours, the oil during that time being maintained at a temperature of 100° C. After immersion the sample shall be removed and rolled dry between blotting paper ; the seal shall then be removed and the sample reweighed.

The difference in weights shall be calculated as grammes per 100 sq. ins. of surface exposed and the figures so obtained shall not exceed 15.

The cable should be generally in accordance with Patent No. 3996/1911.

See also 'Maconite,' p. 1967.

Directions for Making Joints in Electric-Light Conductors.

(Silvertown Instructions.)

Preparing Ends and Making Metal Joints.

The braiding should first be removed, the tapes unlapped, and the conductor exposed for a length of not less than eight to ten times its diameter (for small wires the length should not in any case be less than 2 ins.). With vulcanised or similar cables the rubber should then be cut off at a right angle, care being taken not to nick the wires. With pure rubber cables the pure rubber should be unwrapped, not cut.

In making all joints resin should be used, either raw, or a little powdered resin dissolved in spirits of wine to a thin paste.

The soldering-bit should always be kept clean. This is best done by dipping it into a saturated solution of sal ammoniac and water.

The copper conductor to be jointed should always be carefully cleaned; and when the joint is finished, all rough points should be removed by means of a file, so that the surfaces may be smooth for insulating.

For a Single-conductor Wire.—The ends of the copper should be filed to a long bevel—i.e. scarfed—and the two ends so filed laid one on the other, the object being to get a long surface of contact. The scarf should then be carefully soldered and whipped with small binding-wire, and the whole again soldered and cleaned up with emery cloth or a file; the finished diameter should now not greatly exceed the original diameter of the conductor.

For a 7-strand Cable.—The whole of the strand should first be soldered up solid; then scarfed and jointed as a solid wire, in the same way as above.

For a 19-strand Cable.—The conductor should be bared to a suitable length, and a small binder tied round the ends next to the rubber to keep the strand in place. The 12 outside wires should then be unstranded and turned back. The central 7-strand should then be soldered up and jointed as a solid conductor. To joint the 12 wires over this, every alternate wire should be cut off short, and the two sets of 12 married—that is, the long wire from the one end jointed to the short wire on the other, and so on round the central strand; thus half the joints on the single wires will be on the one side of the joint in the central strand, the other half being on the other side. The joints in these single wires need not be scarfed, but only butted together at each end of the joint, where the long and short wires are soldered together. A narrow whipping of binding-wire should be put on at each end and soldered, the whole being then filed down smooth.

For a 37-strand Cable.—If flexibility is required, the same method is followed out, with the addition that the 18 wires surrounding the 19-strand joint are married in the same way.

If flexibility is not essential, the 19-strand should be scarfed and jointed in the same way as the 7-strand, and the 18 remaining wires only are to be married.

For a 61-strand Cable.—The joint should be made the same as the 37-strand, with the addition that the remaining 24 wires surrounding the 37-strand should be married in the way previously described.

Directions for Making T-Joints in Conductors.

To Joint a Single Wire to another Single Wire.—The smaller wire should be scarfed and laid along the surface of the other wire, and then whipped with binding-wire and soldered and finished smooth; the binding should, however, not be continued up to the point where the smaller wire is bent.

To Joint a Single Wire to a Strand.—The surfaces should be carefully cleaned, and the single wire wound spirally round the strand at the end, but lying flat with the strand at the point of junction; this flat part should be whipped, and the whole soldered.

To Joint a 7-strand on to a larger Cable.—The 7-strand should be unstranded, and, after cleaning the wires separately, the wires should be twisted round the larger cable, three being twisted parallel in the one direction and four in the reverse direction, and on the other side of the T, and a light whipping of copper wire round each end; and the whole should then be carefully soldered together.

For Large T-Joints.—Each conductor should be soldered up solid. The smaller one should then be scarfed and a recess filed in the other, about halfway through, the shape of the scarf; the whole should then be soldered together, and whipped with binding-wire, and soldered again. Where the joints are heavy strong binding-wire should be used.

F. 1867

DIRECTIONS FOR INSULATING JOINTS.

Vulcanised Rubber Joints.—When the conductor joint is finished the rubber should be carefully trimmed and cut with as long a bevel as possible, according to the thickness of the rubber; the copper conductor and the bevelled ends should then be rubbed with pure benzol and slightly heated with a spirit lamp. The conductor and the bevelled edges of the rubber should then be lapped with a pure rubber strip laid on as tightly as possible in one or two layers according to size: this pure rubber should then be covered with special rubber solution, rubbed in so as to exclude air as much as possible; the joint should then stand until thoroughly dry. When the solution is sufficiently dry, and will not adhere to the fingers, a special rubber strip should be lapped on spirally, forming a uniform covering over the first coat of pure rubber, care being taken, by lapping tightly and evenly, to exclude all air. This rubber should be put on in two or more layers, until the diameter is equal to that of the original insulation, and over this a layer of proofed tape should then be applied, the whole joint so made slightly exceeding in diameter that of the original insulation. When so completed the next process is that of vulcanisation. To do this it is necessary to cover the joint with special sheeting cut to the whole width of the joint and firmly rolled round it, making a longitudinal seam, binding the sheeting over all by a strong cotton selvedge tape applied spirally, and as tightly as possible by hand. The sheeting thus will serve as a mould to keep the joint together during the process. The joint should then be fixed in the 'cure' (a cast-iron box) and the cover bolted on; and, to prevent damage to the original insulation and to make the box tight, the insulation on each side of the joint, for the proper distance to fit the cure, should be lapped with two or more coats of tape, to cover the original insulation down to the point of junction. When the cure has thus been made tight molten sulphur compound, previously melted in a suitable pot, should be poured into the cure round the joint through the small hole in the top of the cure, and a suitable thermometer afterwards inserted in this hole, to enable the temperature of the sulphur compound to be noted. This temperature should be kept as constant as possible between 290° and 300° F. by means of spirit lamps.

After the joint has been kept at the full temperature for about half an hour the molten sulphur is run out and the cure-cover unbolted. The joint should then be taken out, the wrappings stripped off, and it will then be found to be vulcanised. A rough test of the degree of vulcanisation may be made by trying with the thumb nail (when the joint is cool) to indent it. If the mark of the nail remains in the rubber, or if the rubber is too hard, the joint is a failure, and should be cut out and remade. If the joint thus examined is found to be in good order, it should be finished off by lapping over all special tapes, extending, say, over about 2 ins. each side of the braiding; this taping to be then painted with shellac varnish.

When insulating with rubber the hands should be kept dry and perfectly clean. When solution is used, it should only be used in small quantities, and the spirit allowed to evaporate before the whole is again covered up. The spirit used should be of the best quality, so that it evaporates quickly and leaves little or no residue behind. Special care should be taken that the rubber applied be brought into immediate contact with the prepared ends, and that no tapes of the original insulation, or foreign material which would conduct moisture, should intervene between the two surfaces to be joined. Unless everything used is perfectly clean, and all air excluded by careful and tight lapping, the joint may be found to have blown, even though the rubber is properly vulcanised. Special attention, therefore, is required to these points.

If, during vulcanisation, the temperature should drop below 290°, the heat will require to be maintained for a longer time; say, if at 280°, the cure would last for about three-quarters of an hour instead of thirty minutes; but it is important that the temperature should be kept as constant as possible between the limits of 290° and 300° F.

If the pure rubber appears hard and brittle it should be slightly warmed before using. Should the compound tape become dirty or too hard, it can be softened by wiping with benzoline.

The Electrical Testing of Electric-Supply Mains.

The accurate testing of electric-light mains before and after laying, and periodically during use, is a matter of great importance if the efficient working of a system is to be obtained and maintained. For the purpose of accurate testing each station should be provided with a sensitive high-resistance mirror galvanometer, a shunt box, a resistance coil of not less than 10,000 ohms (if possible, a megohm), a condenser, keys, and a battery of not less than 100 Leclanché cells. For tests during laying this battery should consist of 400 to 600 cells. It is often possible, however, to use the current from the mains at the normal supply voltage, on a direct-current system.

The shunt boxes usually supplied with the mirror galvanometers are fitted with shunts having for that particular galvanometer multiplying powers of 10, 100, and 1,000. For the varying insulation resistances which have to be measured in electric-light testing a resistance box having coils of units, tens, hundreds, and thousands is most convenient for use as a galvanometer shunt box, as it enables work to be done between very wide limits, and the obtaining of the deflection upon any part of the galvanometer scale. The Ayrton-Mather 'Universal' shunt-box can be used with advantage, as the multiplying powers are independent of the resistance of the

galvanometer. The instruments should be erected and adjusted before the work of laying or pulling is commenced, so that tests may be taken on the arrival of the drums of cable and the specified insulation resistance assured.

The test should be taken with the drums of cable immersed in water wherever possible; but where this cannot be done they must be well wetted, except in the case of lead-sheathed cable.

The preparation of both ends of the cable is of the utmost importance if the real insulation resistance of the dielectric is to be obtained, the difference in the results given with properly and improperly prepared ends being very great. For vulcanised rubber cables the tapes, braiding, or other covering should be removed for at least 6 inches from the ends, and the tape next the rubber

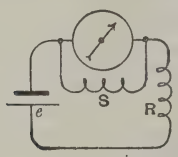

FIG. 1.

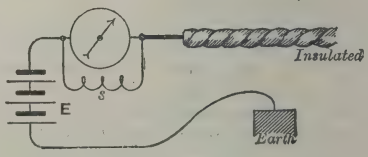

FIG. 2.

should be carefully removed, and the surface of the rubber washed with naphtha, and well scraped to remove any fragments of the tape. The rubber should be tapered off with a pair of clean, bent scissors, the length of the taper being 1 to 2 inches. Next thoroughly dry the whole of the prepared end by means of a spirit lamp, allowing the flame to play round the rubber, care, however, being taken not to burn it. If the test cannot be taken immediately, the prepared end should be well warmed and lapped with clean, warm, pure indiarubber tape, well stretched.

The most accurate method of obtaining the insulation resistance of a highly insulated cable is the direct deflection method—i.e. by a comparison of the deflection of the galvanometer needle produced by a given battery power working through a known high resistance with the deflection produced by the same battery power working through the insulation of the cable. This method is as follows :—

A small battery (usually 1 cell) is first connected up, as shown by fig. 1, with the galvanometer and with a resistance, R, of 10,000 ohms, the galvanometer being shunted by a shunt, S (usually the $\frac{1}{1000}$th shunt), so that a convenient deflection, D, is obtained; this is called taking the constant. The connections are then altered as shown by fig. 2, a large battery, E (about 100 or more cells), being used, and the wire whose insulation is to be measured being joined up as shown. Let the deflection be d, and the shunt s on the galvanometer be the $\frac{1}{n}$th (usually $\frac{1}{10}$th $\frac{1}{100}$th or $\frac{1}{1000}$th—i.e. $n = 10$, 100, or 1,000); also let the shunt used when the constant is taken be the $\frac{1}{N}$th shunt; then

$$\text{Insulation resistance of wire in megohms} = \frac{D \times N}{n} \times K \times R \div d \times 10^6,$$

where K is the ratio between the number of cells used in taking D and in taking the constant; thus, if d is given by 100 cells and D by 1 cell, then K = 100. When great accuracy is required the exact ratio of the electromotive force of the large to the small battery has to be determined, for it is seldom that 100 cells have exactly 100 times the E.M.F. of 1 cell, though in a large number of cases it is sufficient to consider it as such, care being taken that the cells are all in good condition. If a megohm resistance (1,000,000 ohms) is available, the constant may be taken with the same battery as is used for testing the insulated wire, the megohm being used in the place of the 10,000 ohms; in this case K = 1. A short-circuit key must be connected across the galvanometer terminals, and must always be closed so as to short-circuit the galvanometer at the beginning of each test, otherwise the rush of current from a high battery power will probably demagnetise the needle. For testing short lengths of highly insulated cable a battery of at least 400 Leclanché cells should be used. If the battery is kept on for fifteen minutes, during which readings are taken every minute, it will be noticed that the deflection falls rapidly the first two or three minutes, the fall per minute becoming gradually less, till, at the end of fifteen minutes, the deflection is falling very slowly. It would thus appear as if the insulation resistance rises during the test; but the chief reason is, that when the battery is first connected, and after the first rush of current, the dielectric electrifies or absorbs current, and this absorption naturally becomes less and less as the cable becomes fully charged. The great use of this test is that it shows the existence of minute faults in a cable which on a one-minute test would pass the specification, as, if there is little or no electrification, or the existing electrification proceeds unsteadily, it is certain the dielectric contains undeveloped faults. For this test it is absolutely necessary that the cable should be in water,

as no reliable results could be obtained even from a well-wetted drum ; and of course it cannot be taken on a system connected up to transformers, etc., though frequently before connecting up the electrification is very pronounced. It is customary to take the reading of the deflection d at the end of one minute's electrification.

In order to avoid error due to leakage from the lead between the galvanometer and the cable, the galvanometer key should be depressed before the lead is connected to the cable ; any deflection

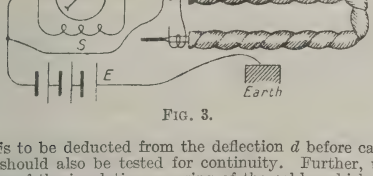

FIG. 3.

that may be observed is to be deducted from the deflection d before calculating the insulation resistance. The leads should also be tested for continuity. Further, to prevent error due to leakage over the surface of the insulating covering of the cable, which is often of considerable importance, especially when the length of cable under test is short and the insulation resistance very high, a 'guard wire' should be connected at one end to the junction between the battery and the galvanometer, the other end being wrapped round the prepared insulating surface at each end of the cable (if both ends are accessible) : this device (fig. 3) by-passes round the galvanometer any current due to surface leakage, and greatly improves the conditions of testing.

All insulated conductors should be tested after at least twenty-four hours' immersion in water, and none but those giving the specified insulation resistance should be accepted. When laid or drawn in, but before jointing, the section having one end in the station should have its ends prepared, the distant end being well warmed and lapped, and a careful test taken ; if all right, prepare section 2, and having by means of a short piece of fine wire connected it to section 1, test both sections together. If the insulation resistance per mile is found to be correct, the two sections may be jointed, after which they should be again tested, and if not up to the previous tests the joint must be remade. Sections 1 and 2 being jointed and passed, section 3 may be temporarily connected and tested, jointed, and the three sections tested, and so on till the entire system is jointed and the final test taken. If this method is carried out the engineer in charge will have a record of tests—1st, upon each section in water ; 2nd, upon each section after laying ; 3rd, upon the system as each length is jointed on—and he will feel satisfied that the cables are up to the specification, that they have not been damaged in laying, and that the joints are all well made.

With vulcanised indiarubber joints in a vulcanised indiarubber insulated cable there is no difficulty in keeping the completed system up to the specified insulation resistance per mile of the cable. It is manifestly absurd to lay down high-class mains and, by means of inferior joints, reduce the insulation resistance to a few thousand ohms. If a section cannot be tested from the station, or if the jointing cannot be commenced at the station end of the mains, a portable testing set should be employed ; and when all the sections are jointed up a final test should be taken with the station instruments.

With portable testing apparatus it is not possible to attain the same degree of accuracy as by the method outlined above ; but, on the other hand, the insulation resistance of cables and wires when laid or installed in position is usually very much lower than in the former case, and therefore does not call for equally refined methods of testing. The most convenient portable instrument for testing insulation resistance is the 'Ohm-meter,' of which several patterns are obtainable, each combined with a generator which gives the necessary testing pressure without the aid of a battery. These instruments are capable of applying a testing pressure of 500 or even 1,000 volts, and of measuring to a sufficient degree of accuracy insulation resistances up to 1,000 megohms.

Testing sets are also made for carrying out tests of insulation resistance by the direct deflection method, using a galvanometer of the pivoted type, and a battery ; these instruments in some cases are so designed as to be capable of being applied also to the measurement of direct currents and pressures, low resistances, etc., and for localising faults on cable networks. The Evershed ohmmeters are described on p. 1940.

Metallic Resistance Materials.

Metallic resistance materials are classified by the British Engineering Standards Association for maximum temperatures of 60, 200, 300, 700, and 1,000° C. respectively. According to Report No. 115—1921, the resistivity at 20° C. is not to differ more than 5 per cent. from that declared by the supplier, and the material must be uniform in resistance within 5 per cent. ; the temperature coefficients in the two low-temperature classes must not exceed 0·00002 and 0·00004 per degree C. respectively, and these classes must withstand temperatures of 60° and 150° C respectively for ten hours without the resistance changing more than 0·01 per cent. Lists of standard sizes of wires, sheets, and tapes are given in the Report.

Cable Soldering Sockets.

Specification No. 91—1921 of the British Engineering Standards Association gives the standard dimensions of cast and wrought lug sockets, clamp sockets, and clamps, for cables from 0·0018 to 1·000 sq. in. sectional area. Cast lug sockets are of brass containing 70 per cent. of copper, and wrought lug sockets are of solid-drawn copper tubing; clamp sockets are of brass or other suitable non-ferrous metal. Sweating surfaces are to be drilled and tinned ,and contact surfaces machined.

Cables for Installation Work.

As far as electrical installation work, and particularly conduit work, is concerned, the type of cable with which the contractor has mostly to deal is that known as a rubber insulated cable. The real properties of rubber insulated cables are more or less obscure, and the question as to what constitutes a good cable is almost impossible to answer with any degree of accuracy. To give some indication as to the quality of the rubber compound covering, a careful chemical test is required, and this combined with a stretching test will give a distinct clue as to the possible durability of the material.

The following specification for high-grade electric power and lighting cables for working pressures up to 500 volts is based on the British Admiralty Specification.

Specification for Vulcanised Rubber Insulated Wires and Cables.

Conductor.—The conductor is either to be a single wire or is to be composed of a strand formed of the number of wires specified. Each wire is to be of high conductivity copper and drawn as accurately as possible to the specified gauge. In no case shall the weight of any wire in any foot length of the wire or cable vary more than 2 per cent. either way from the standard weight of such length. The several wires in the cable shall be stranded together to form a compact strand, the lay on each ring of which shall be uniform throughout the length of the cable, except in the case of conductors in which great flexibility is required, when they shall be twisted uniformly. All wires are to be British drawn.

Copper.—Each wire is to be of solid well-annealed copper, having a conductivity of not less than 98 per cent. of annealed high conductivity commercial copper, which is to be taken to have a resistance of 0·66788 microhm per cubic inch at a temperature of 60° F. The copper must be capable of elongating at least 15 per cent. in a length of 6 ins.

Tinning.—Each wire is to be double tinned uniformly and efficiently, and must be thoroughly cleansed before stranding or covering. The tinning is to be free from lead or other impurity, the minimum thickness of the tin being such that the conductor shall show no signs of sulphide of copper after vulcanising.

Joints in Conductors.—Not more than two joints are to be made in any one of the single wires forming 1,000 yds. of completed cable and no joint is to be within 12 ins. of any other joint in the same ring. Joints should be avoided altogether if possible, but where made they are to be brazed or electrically welded. No joint may be made in the conductor after it has been stranded.

Stranding.—All wires are to be stranded right and left-handed. The lay is to be uniform in each ring throughout its length and must be such as not to increase the resistance of the stranded conductors more than 2 per cent. above that of a conductor of the same length with parallel wires.

Dielectric.—The conductor is to be covered with three layers of indiarubber, viz. :—first a layer of pure indiarubber (the pure rubber shall not contain more than 0·35 per cent. of sulphur), then a separator, and lastly, a jacket. The first covering is to be of the finest Brazilian Para rubber. The separator and jacket are to be composed of the finest Brazilian Para rubber mixed with sulphur and mineral matter only. The quantity of rubber which is to be used in the separator and jacket mixtures must not be less than 40 per cent. (forty per cent.). No re-manufactured rubber or rubber substitute is to be used.

The pure rubber is to be applied to the conductor by being lapped around it, care being taken that each successive turn amply overlaps the last so as to leave no possibility of an opening in the covering. The separator and jacket are to be applied longitudinally, great care being taken that the conductor is accurately centred in the dielectric.

The conductor insulated as described is to be spirally lapped with an indiarubber proofed tape, and the whole vulcanised together into a compact homogeneous body.

Thickness of Dielectric.—To be not less than that specified in the published list of the Cable Makers' Association.

Stretching Test of Dielectric.—Samples of the vulcanised rubber from which the conductor has been removed are to return to within 25 per cent. (twenty-five per cent.) from original length within 6 hours after being stretched for 24 hours at or about 60° F. to three times its length.

Insulation Resistance.—The insulation resistance of each length of cable is to be measured by means of the direct deflection method, employing a battery giving not less than 500 volts. The cable is to be negatively electrified for one minute, during which the electrification is to progress steadily, and at the end of this time the insulation resistance shall not be less than that specified.

Immersion in Water.—All cables are to be immersed in fresh water, making efficient electrical connection with earth for a period of not less than 24 hours immediately preceding the tests.

The foregoing details give some indication of the main features which are to be looked for in

a high-class rubber insulated cable. As regards the conductors, the conductivity question is one of considerable importance, but it should be mentioned that trouble in this direction very seldom arises, because there is little difficulty in maintaining a standard purity in electrolytically refined copper. The phrase ' to show no sign of sulphide of copper after vulcanising ' refers to the appearance of the wire when it is stripped of its insulating covering. It should then present a clean, bright appearance, free from blackening.

The building up of the rubber dielectric in three layers represents the usual English practice, and the wording of the specification is designed to exclude the use of adulterants and deleterious substances, these being practically synonymous so far as the life of the rubber insulation is concerned.

The specifying of a minimum percentage of Para in addition practically leaves no room for anything but legitimate compounding ingredients, the choice of which is left to the experience and skill of the cable manufacturer.

There is, perhaps, no industry so greatly dependent on detailed experience and skill in applying that experience as that of the manufacture of rubber, and when electrical conditions are involved this is doubly true.

Generally speaking, therefore, where consideration of quality and durability are paramount it will always be best to purchase rubber insulated cables, either to a specification such as that instanced above, or to agreed standards such as those of the Cable Makers' Association.

The provision of suitable outer coverings for rubber insulated wires and cables which are exposed to abnormal conditions is a point which should not be overlooked. Conversely, in a given situation, a certain method of installing may be unsuitable. For instance, condensation effects, which occur in tubes and pipes, are notoriously bad for rubber cables, and in such situations either the method of installing should be varied or special coverings, such as a bitumen sheath, should be applied to the cables. Many cable makers are prepared to advise as to the best type of covering and method of running or fixing cables under abnormal surrounding conditions.

A second quality of vulcanised rubber cable has been placed on the market to meet the demand of those users who are satisfied with a cheaper grade of cable. Such cable, known as ' non-Association ' cable, is quite satisfactory when properly manufactured, and may be safely used in cases where only a moderate insulation, combined with good mechanical properties, is required, and where the conditions do not require a permanent maintenance of high elasticity of the dielectric.

CONDUITS.

Simplex Conduits and Fittings for Electrical Installations.

(*Simplex Conduits, Ltd.*)

Simplex conduits, with the exception of the seamless or drawn varieties, are made from specially selected steel strip, varying in gauge according to the diameter of the tube. The strips are rolled to a circular section of exact external and internal diameter, by a method which ensures freedom from internal roughness and an even surface to facilitate the drawing of the wires into the conduit, thus preventing injury to their insulation. Exact sizes are essential in order to obtain a tight junction between the conduit and fittings with both socket and screwed junctions.

The conduits are made in two different types, viz., Light Gauge, for socket and continuity junctions, and Heavy Gauge for screwed junctions.

The applications of the various grades are as follows :—

Light Gauge Socket Conduits.

1. *Simplex Ordinary Conduit.*—This has a longitudinal seam, the edges of which, although abutting closely together, are not metallically united. It is suitable for general house wiring and dry situations generally, in which no extraordinary risks are incurred, but should never be buried under plaster or cement. Where price is the main consideration, Simplex Ordinary Conduit with socket junctions should be used, but in cases where electrical continuity is insisted upon by the Authorities the Continuity Junction should be employed.

2. *Simplex Light Elektroduct Conduit*—is a specially brazed tube, for use when the conduit work on the socket or continuity system is buried under the plaster of the building.

3. *Simplex Light Cableduct Conduit*—is used for superior surface work in which the socket or continuity junction is employed.

Simplex Heavy Gauge Screwed Conduits.

1. *Simplex Screwed Elektroduct*—is a specially brazed tube with extremely smooth interior and exterior surfaces. It is the cheapest of the Heavy Gauge Conduits, and should be employed for installation work where ' Heavy Gauge Screwed Conduits ' are specified.

2. *Simplex Screwed Wireduct*—is a welded tube drawn over dies to exact diameters, manufactured by a process which keeps the interior free from burrs and other obstructions.

3. *Simplex Screwed Cableduct*—is a high grade conduit, and is essentially a drawn tube. It is recommended for the best class of work where price is not of the first importance; it provides a high degree of security from fire risks, with long life, freedom from faults and security against breakdown to the installation.

Protective Covering of Conduits.

Simplex conduits are supplied in two standard finishes, as follows :—

(1) Stove enamelled (black); (2) Galvanised.

For all ordinary installation work in the interior of buildings, the enamelled conduits will be found satisfactory in working.

The enamel employed is flexible, acid-resisting, insulating, and durable.

The conduits are well cleaned before being enamelled, and are subsequently stored at an even temperature until the enamel is set, so that it is not liable to flake or break away when the conduit is bent. The enamel will resist any chemical action which is likely to be found in the plaster of buildings.

Where conduit is subjected to excessive chemical action, especially when buried in cinder-fill concrete, quick-drying chemical plasters, and the like, a more efficient protection is required, and this is afforded by the galvanising.

Simplex conduits have been supplied to Government Departments.

SELECTION OF TYPE OF CONDUIT.

Contract Price at which the Work has been accepted.—Where the price is cut very fine, ordinary conduit, being the cheapest grade, should be employed, as its low initial cost and low labour charges make it especially applicable. Where a higher grade conduit can be allowed for, then either 'Elektroduct' or 'Cableduct' may be used.

Condition of Building.—If the building is in course of construction, the conduit system will usually be concealed, and in wiring before the plastering is commenced it would be advisable to employ Elektroduct, except under floor boards, where the ordinary conduit may be used.

Circumstances entailing unusual risks.—(1) Risk of damage to protective covering, such as would be met with on steamships, in shipyards, collieries, breweries and engineering works; (2) Risk of damage due to excessive moisture, steam, water or vapour—such are present in boiler rooms, laundries, baths, etc. In these cases, electro-galvanised heavy gauge screwed conduit should be used.

JUNCTIONS FOR SIMPLEX CONDUITS.

There are three forms of junctions or unions used with Simplex conduits, viz. :—

(1) The *socket* junction for *light gauge* conduits.

(2) The *screwed* junctions for *heavy gauge* conduits only.

(3) The continuity or screw-socket junction for either light gauge or heavy gauge unscrewed conduits.

The Socket Junction is the simplest and cheapest, and secures proper alignment of the conduits—a feature of importance in surface work. It also requires a minimum of time, labour, and expense in erection, and is, therefore, the most economical junction, as no special tools or skilled labour are necessary.

Simplex couplings, fittings and boxes for use with this junction are accurately bored out for a distance depending upon the diameter of the outlet, and a slight shoulder is formed, against which the conduit abuts. Thus a good fit is secured.

The Screw Junction is the one used for connecting up heavy gauge conduits and fittings. The conduits are threaded on the outside, and this threaded portion screws into the tapped outlet or inlet of the fitting, forming an electrically continuous joint.

The Continuity Junction enables light gauge unscrewed conduit to be connected, and have electrical continuity throughout. Thus the Simplex Continuity System may be earthed as effectively as the Simplex Screwed System.

The advantages claimed for this system are :—

(1) No screwing tools required.

(2) No twisting of cables under any circumstances.

(3) Standard screwed fittings are used.

(4) Permanent continuity obtained on sound mechanical lines.

BRITISH STANDARD SPECIFICATION FOR STEEL CONDUITS FOR ELECTRICAL WIRING.*

(No. 31—1910.) (*Abstract.*)

Steel conduits for electrical wiring shall be either close-joint, brazed, welded or solid drawn They shall be of mild steel free from burrs, flaws or other defects. They and their accessories, when these are made of steel or iron, shall be stove enamelled or galvanised inside and out by an approved process.

* By permission of the British Engineering Standards Association.

Two classes of steel conduit for electrical wiring are recognised as standard :—

(A) Plain.

(B) Screwed.

Class (A) consists of light gauge conduit of the thicknesses and dimensions given in the annexed table. The socket joining the lengths of tubing is a sleeve and neither the ends of the conduit nor the socket are screwed.

Class (B) consists of heavy gauge conduit of the thicknesses and dimensions given in the annexed table. Both ends of the conduit are screwed with the Whitworth form of thread. The couplers are also screwed inside throughout their entire length with a right-handed thread of Whitworth form, but having the number of threads per inch given in the annexed table. The screwed portions of both conduits and couplers are not enamelled.

Both classes of conduit shall be manufactured in straight lengths of ten, twelve, or fourteen feet.

The thickness of any bend or tee shall be not less than that of the corresponding straight length.

Conduits and their accessories shall be gauged at the works of the manufacturer, before enamelling or after galvanising.

TABLE OF STANDARD DIMENSIONS OF STEEL CONDUITS.

Outside diameter in ins.			$\frac{5}{8}$	$\frac{3}{4}$	1	$1\frac{1}{4}$	$1\frac{1}{2}$	2
Threads per in.			18	16	16	16	14	14

The Henley Wiring System.

(W. T. Henley's Telegraph Works Co. Ltd.)

In this system the cables carry their own metallic protection, which is of a flexible nature : it is consequently very easily and speedily erected. The wires and cables are of very small diameter, and when painted, distempered, or stained and varnished to match existing decorations, they are to all intents and purposes indistinguishable. If desired, the cables may be buried in plaster and concealed generally. The cables may be run under floorboards, in lofts or cupboards, and dropped down between the faces of lath-and-plaster partition walls. The chasing of walls or cutting away of joists is very much less than is required with tubing.

The system covers two classes of wire : the earthed concentric for use on alternating-current systems through a double wound transformer, for private plant installations, and also for use in certain districts where the use of an earthed system has been approved by the Board of Trade. The other is the two-wire insulated type laid up in the form of a flat twin. This cable, of course, may be used on both direct and alternating current systems. In both classes of wire the insulation consists of pure and vulcanised indiarubber protected from mechanical damage by a seamless metallic sheath (of a special alloy) formed closely round the core or cores.

The fittings are arranged to be connected to the cables without a soldering iron or blow lamp.

The outer or earthed return conductor of the cables for the *Concentric System* is composed of copper tape which is wrapped round the core in a spiral manner, the whole being then sheathed with a solid-drawn tube of the special alloy.

For the *Twin System* the cables employed are of flat section of one, two, and three conductors, each conductor composed of tinned copper wires, insulated with pure and vulcanising india-rubber taped with proofed tape of a distinctive colour, the whole then vulcanised together, cores laid side by side and sheathed with a solid-drawn tube of the special alloy.

TABLE OF CONCENTRIC SYSTEM CABLES.

Class C.E.T.

Size of Conductor (Inner).		Minimum Guaranteed Insulation Resistance at 60° F. per Mile.	Amperes at I.E.E. Standard.	Approximate Overall Diameter.	Approximate Weight per 1,000 Yards.
Square Inch.	Number and Size of Wires.				
		Megohms.		Inch.	Cwts.

Test Pressure.—1,000 volts alternating for 15 minutes after 24 hours' immersion in water at 60° F. (15·6° C.).

FITTINGS.

Concentric System.

When the switch and light points have been chosen, the lower half of the H.W.S. screw fitting (*a*), fig. 4, is screwed into the wall or ceiling at the point fixed; the stud (*b*) is then screwed into its head, and a washer (*c*) is slipped on. The fitting is then ready to receive the outer conductor of the cable. The ends of the cables to be finished at this point are prepared in the usual way, the outer conductor (*d*) being unwrapped from the core, straightened out, and bent back at a point about 1 in. from the finish of the metal covering. A hole is punched through the double thickness of tape by means of a plier punch; the hole so made is then slipped over the stud, and

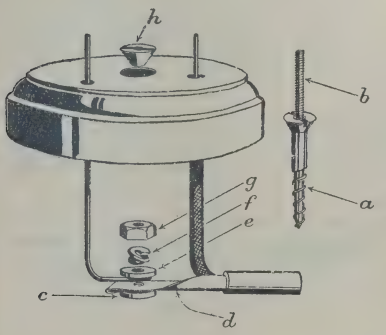

FIG. 4.

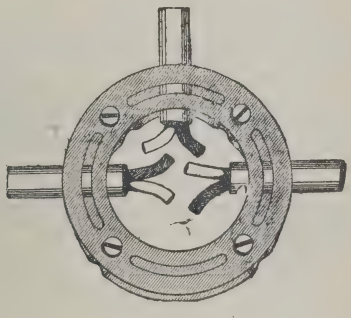

FIG. 5.

followed by a brass and a spring washer (*e*, *f*). The whole is then held securely by the hexagonal nut (*g*); the wood block being placed over all, and held in position by means of the cone-shaped nut (*h*). Where a connection to the external conductor is required, such as at light points, a piece of copper wire may be clamped between it and one of the washers.

Twin System.

For the purpose of bonding the sheathing at switch and light points the Universal Bonding Clamp is provided. This clamp, fig. 5, has been designed so that one clamp only, instead of

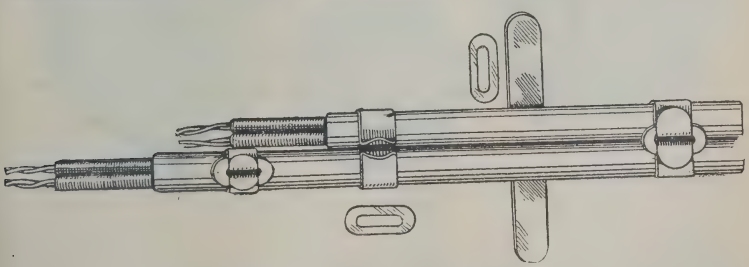

FIG. 6.

several, may be used at any point, thereby reducing to a minimum the necessity for stocking various sizes of clamps for various numbers and sizes of wires, etc.

In the case of electroliers controlled by two switches, in many instances it will be found most economical to use a 4-plate ceiling rose, taking both switch and light feeds to this rose, connecting the switches with a 3-core cable.

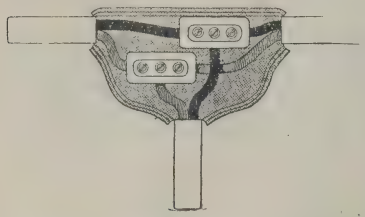

FIG. 7.

Straight through and tee joints are made with the use of the boxes provided under the system.

For fixing the cables, the 'Link' clip, fig. 6, is specially convenient. These clips are made from tinned brass, and may be fixed with either nails or countersunk-headed screws.

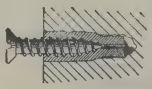

Fig. 7 shows a recent form of Tee and Joint box for the twin system. These boxes are manufactured from brass heavily tinned; the internal connectors are of the porcelain type, these being made in various forms according to requirements. The continuity of the metal sheathing of the cables is preserved by means of mechanical bonds that clamp the lugs on the boxes to the cables.

Figs. 8 and 9 show a plug (called a 'Rawlplug') for fixing link clips, saddles, protective covering or other articles, to plaster, brick, marble, slate, stone, etc. These plugs are highly suitable for soft plasters. They consist of a tube of stiffened fibres which expand when a screw is driven into them.

Section showing plug in position ready for screw.

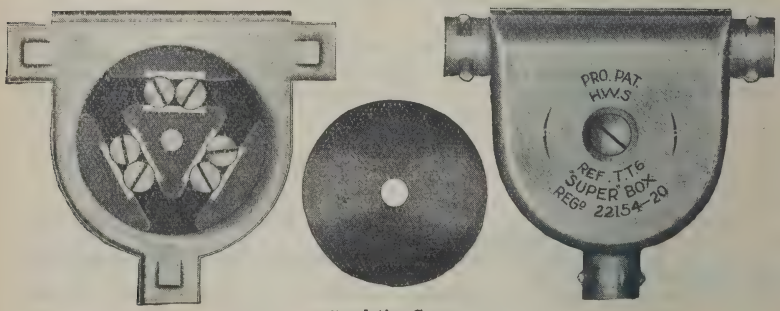

FIG. 8.

Screw entering, showing expansion of plug against sides of hole.

FIG. 9.

Recently a 'Super Box' (fig. 10) has been introduced in connection with the system. This box has no loose screws or nuts, requires no special tools, cannot possibly be fitted up wrongly, makes a perfect automatic bond, and has an unloseable screw in the cover, which is self-centring,

Insulating Cover.

FIG. 10.

The terminal screws and cover-screw fit only in their proper places, and are easy to fit. The cover is securely held in its correct position by means of one screw only, which also ensures efficient bonding, and it forms a spring washer grip which prevents subsequent loosening by vibration.

Electro-chemistry.

A current of I amperes will, in T units of time, deposit from a solution of any salt of a metal, under suitable conditions, ITa grammes of the metal (if time is reckoned in seconds), or ITb grammes (if time is measured in hours), where a and b have the values given below, due account being taken of the valency of the metal in solution. One 'gramme-equivalent' of any substance is dissolved, deposited, or decomposed by the passage of 96,494 ampere-seconds (coulombs) or 26·80 ampere-hours. This quantity of electricity is known as the 'faraday.'

In order to find the volume of gas evolved, multiply the weight in grammes by the volume occupied by one gramme of the gas at normal temperature and pressure. For the gases included in the table, the volumes in litres per gramme are as follows:—Chlorine, 0·3103; hydrogen, 11·12; nitrogen, 0·7990; oxygen, 0·6998.

To reduce the weights to pounds, multiply the weight in grammes by 0·0022. To reduce the volumes to cubic feet, multiply the volume in litres by 0·0353.

(*Kohlrausch & Holborn.*)

PRIMARY BATTERIES.

Siemens ' Dry Cells.

These cells (*Siemens Brothers & Co., Ltd.*), originally known as the ' Obach,' embody the result of many years of research and experience in this class of primary battery, and combine all the latest improvements. The cells are supplied in large quantities to the British and Colonial Post Offices and other Government Departments to comply with very rigid specifications. They are made round or rectangular in shape and in sizes to suit all requirements.

The following table gives the sizes, etc., and the output of a few of the standard sizes when discharged continuously through a resistance of 10 ohms until the P.D. has fallen to 0·75 volt on closed circuit, in each case :—

	Approximate Overall Dimensions (including terminal).	Approximate Weight.		E.M.F.	Internal Resistance.	Output.
		Lb.	Oz.	about	about	Amp. Hours.
M	$4\frac{7}{16}$ ins. × $4\frac{7}{16}$ ins. × $8\frac{1}{8}$ ins. high	10	0	1·5 volt	0·15 ohm.	260
N	$3\frac{5}{8}$ „ × $3\frac{5}{8}$ „ × $7\frac{1}{2}$ „	5	4	1·5 „	0·15 „	100
O	$2\frac{13}{16}$ „ × $2\frac{13}{16}$ „ × $6\frac{5}{8}$ „	3	0	1·5 „	0·20 „	37
P	$2\frac{1}{4}$ „ × $2\frac{1}{4}$ „ × $6\frac{1}{8}$ „	1	14	1·5 „	0·25 „	15

The cells are made up into batteries to give an e.m.f. of $4\frac{1}{2}$ or 6 volts. They are supplied in various shapes and sizes, and are extensively used for starting up on motor-cars, for small lights, cautery, and many other purposes.

Siemens Patent Inert Cell.

These cells (*Siemens Brothers & Co. Ltd.*), originally known as the ' Dura,' are similar in size and efficiency to the Siemens dry cell, and are also similar in construction, with the important exception that whilst the dry cells, as supplied, are in active condition, this cell is absolutely inert, and water must be added to bring it into activity. In the one case the exciting agent is in the form of a damp paste, and in the other in the form of a dry powder which, when water is added, also becomes a damp paste, and consequently the inert cell is converted into one having all the characteristics of a dry cell.

The special utility of this construction is that the cell will keep for an unlimited time in any climate without deteriorating in the least, and may be converted at any time into a newly made, so-called, dry cell.

ACCUMULATORS.

Storage cells should be placed in a well-ventilated room, preferably with louvres at the top to allow of the free escape of the gases evolved during charging ; and the room should also be well lighted, both naturally and artificially, provision being always made for a hand inspection lamp to enable cells to be examined individually. The room should not be exposed to undue draughts, as this promotes evaporation of the electrolyte, and it then becomes necessary to add an abnormal amount of water to keep the plates well covered with electrolyte.

Trays and Insulators.

When glass boxes are used, they should stand in separate trays containing sawdust, and these in turn should be supported on glass oil insulators, excepting in the smaller sizes, where indiarubber discs are used instead of trays, one of these discs being placed on top of each insulator between the latter and the glass box.

Stands.

The cells should stand on strong wooden shelves, protected with shellac varnish ; when in tiers, a space of not less than 30 ins. should be allowed between the shelves. The cells should be placed with the edges of the plates to view, and should only be arranged in double rows when they are accessible from each side. A space of about one inch should be left between adjacent boxes, or half an inch between trays.

Poles

The positive pole is painted red and is that to which the brown plates are connected : the negative pole is painted black and is that to which the grey plates are connected. The positive pole of each cell must be connected to the negative pole of the next cell throughout the battery, so that there will be a disconnected positive terminal at one end and a disconnected negative terminal at the other end of the battery. These are the battery terminals, which are

HART ACCUMULATOR Co. Ltd.

F. 1879

connected to the dynamo as indicated in the diagram of connections in fig. 16. Cells should never be connected in parallel so as to form single cells of larger capacity; but if necessary they may be formed into batteries, and the batteries connected in parallel by coupling their ends.

An automatic switch should be provided in the charging circuit.

Dynamo.

The dynamo used for charging should be shunt-wound, and the electromotive force required will be 2·6 volts for each cell in series. Before connecting up the dynamo it should be tested for polarity, which may be done as follows: Place two clean strips of sheet lead in a stone jar filled

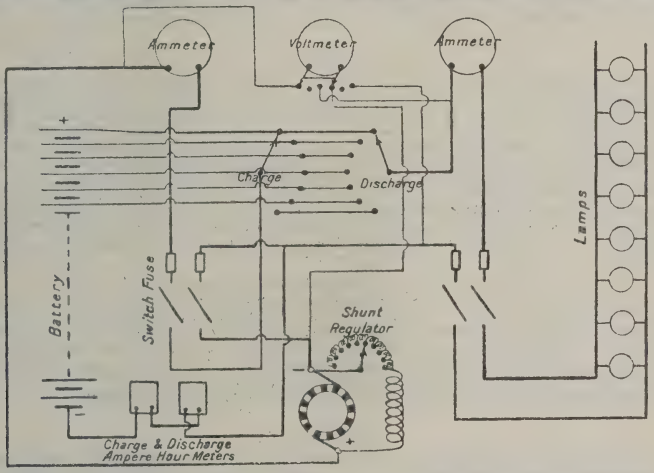

FIG. 11.

with dilute acid; separate them about two inches by means of a block of wood; connect one strip to one terminal of the dynamo and the other strip to an incandescent lamp which has its second terminal connected to the second terminal of the dynamo. After the dynamo has been running for a few minutes one of the lead strips will become brown, showing that the dynamo terminal connected to this strip is the positive terminal.

Instruments.

In addition to the voltmeter and to the ammeters in the charging and discharging circuits, it is very desirable to have in circuit a pair of ampere-hour meters, one to record the charge and the other the discharge. These may be connected in series as shown in the diagram of connections, and fitted with pawls which will prevent backward running, so that there will be a continuous record of both charge and discharge.

Water.

The water used for the cells should be distilled, as this avoids any danger of impurities entering the cell. Tap water should not be used.

Acid.

The Hart Accumulator Co. advises that the acid used for the electrolyte should be 'brimstone' sulphuric of 1·840 specific gravity, and free from impurities of all kinds, such as arsenic, etc. Before being poured into the cells it must be carefully diluted as shown below.

On the Continent, sulphuric acid prepared by the catalytic process is generally preferred for accumulators, on account of its great purity; this process originated in 1875 at the works of *Messrs. Spencer Chapman & Messel, Ltd.*, which firm likewise carry on the old process of manufacture from brimstone, and for both acids nothing but distilled water is used for dilution, the purity of the acids being thereby ensured.

Mixing Acid.

The acid must be poured slowly into the water in a separate vessel. This must be done with great care on account of the heat generated. The proportions by measure are five parts of water to one part of acid. The mixture should be well stirred and allowed to cool, when the specific gravity may be taken. This should be 1·190 as shown by the hydrometer.

Filling up.

When everything is ready for charging, the acid must be put into the cells to a height of not less than one inch above the plates. The acid must not on any account be allowed to remain long in the cells before charging, which must begin immediately after the electrolyte has been poured in. The specific gravity will drop slightly during the first few hours of charge.

Charging.

Before the battery is switched into circuit with the dynamo care should be taken that the field-magnets are properly excited and the proper e.m.f. generated. The initial charge should be continued for not less than 36–40 hours at the normal charge rate specified by the makers for the battery in use. The dynamo should on no account be stopped for the first twelve hours, nor should the battery be used to supply current until gas is being freely liberated from both positive and negative plates in each cell. The specific gravity will begin to rise slowly after the charging has commenced. If at the end of the first charge it rises above 1·210, pure water must be added to reduce it to 1·205–1·208. When, as in such a case, it may be necessary to add water, it should be introduced into the bottom of the cell by pouring through a glass or rubber tube with a funnel at its top end. The water will then be thoroughly mixed with the electrolyte. Any such addition of water should be made at the end of a charge whilst the plates are gassing.

Discharge.

The permissible rate of discharge depends upon the number of hours for which the discharge is required—the longer the time the smaller the rate. The product of rate into time is, however, not constant, but is greater with low rates of discharge than with high. Thus in the Hart Accumulator, 25 plate Lighting Type, the rates of discharge for 5, 7 and 10 hours are 126, 101 and 84 amperes respectively, giving discharge capacities of 630, 707 and 840 ampere-hours. The discharge rates for different times are always given by the makers, and should never be exceeded, the ampere-hours taken out being recorded on the discharge ampere-hour meter.

Recharging.

The cells should be recharged as soon as possible after each discharge. The normal charge rate is specified by the makers, and the time of charge will depend upon the previous discharge. The ampere-hours put in should usually be 10 per cent. in excess of the number taken out. If the battery is charged and discharged with great regularity every day this may be reduced to about 5 per cent. excess. A daily record of charge and discharge, as observed on the meters, should be kept on a form provided by the makers for the purpose.

Level of Electrolyte.

The level of the electrolyte must never be allowed to fall to less than half an inch above the top of the plates. Any loss due to evaporation must be made up by adding pure distilled water as above explained. Evaporation will be greatly retarded by the use of glass spray arresters covering the top of the plates. These must be so placed as to be easily removable for the purpose of examining the cells. Acid should not be added, except under the maker's advice.

Specific Gravity.

The specific gravity of each cell should be taken and recorded at least once a week, and if the consecutive readings so obtained are carefully compared, it is possible at once to detect a backward cell and take steps to remedy what is amiss. The hydrometer should be long enough to float in about two-thirds of the total depth of the electrolyte. The specific gravity varies to some extent with the temperature, and during the summer months will be rather lower than during the winter. The standard is taken at 60 deg. Fahr.; for every 2·7 degrees above this 1 degree of specific gravity may be added; for every 2·7 degrees below 1 degree of specific gravity may be deducted.

Cell Voltage.

Each cell should be tested at least once a week with a cell-testing voltmeter. This test should be made at the end of discharge, when the e.m.f. per cell should not be lower than 1·8 volts, normal current then passing. If any cell is lower than the others it should be at once examined for internal short-circuits or buckled plates. Low-voltage cells should be disconnected from the discharge circuit for a few days, but connected in charge in the usual way. This can

readily be done if the cells are of the type having bolted connections which can be easily undone The charge voltage will commence at about 2·20 volts per cell and rise to as much as 2·75 volts, the latter figure depending on the rate of charge. The discharge voltage will commence at about

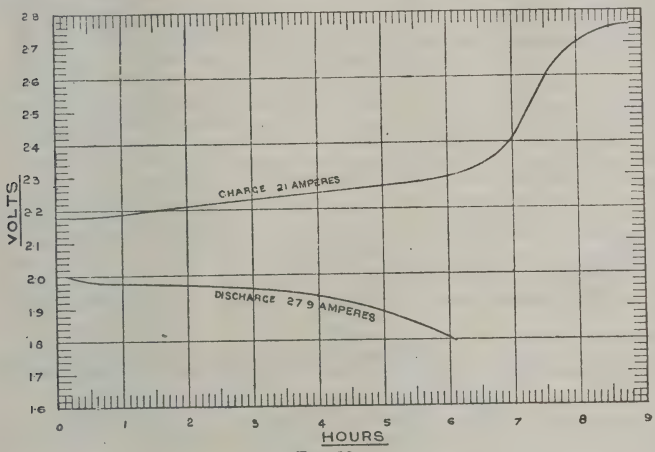

FIG. 12.

2·00 volts and gradually fall to 1·80 volts at the completion of the discharge. Fig. 12 gives typical charge and discharge curves of cell voltage of a seven-plate LL. type Hart accumulator.

Buckled Plates.

Buckled plates should be removed and straightened by pressing between thick boards. The positive plates are most easily straightened when fully charged, as they are then softer and not so liable to crack. The negative plates should be kept in dilute acid while the positives are being overhauled, as otherwise they may get heated by oxidisation with the air.

Idle Cells.

When a battery is not required for several weeks it should be thoroughly charged and the plates well covered with electrolyte. The cables should then be disconnected at the ends of each row to avoid any possibility of electrical leakage. Cells will remain in this condition for several months. If a charge can be given once every six or eight weeks it is best to do so; this should be given at 75 per cent. of the normal rate and continued until the full charge is completed, and the plates gas freely.

Battery Rooms.

SIZE OF BATTERY ROOMS REQUIRED FOR 25, 50 AND 100-VOLT HART BATTERIES.

Capacity in Amp. Hours.	25 Volt.		50 Volt.		100 Volt.	
	Single Tier.	Two Tier.	Single Tier.	Two Tier.	Single Tier.	Two Tier.
	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″	′ ″ ′ ″
140	6 6×3 9	3 6×4 3	6 9×5 0	7 0×4 3	13 3× 5 0	13 3× 4 3
280	9 3×3 9	5 0×4 3	10 0×5 0	10 0×4 3	12 9× 8 9	9 9× 6 0
420	6 9×5 0	6 9×4 3	13 0×5 0	13 0×4 3	16 6× 8 9	12 6× 6 0
630	9 0×5 0	9 0×4 6	11 6×8 9	9 0×6 6	16 9×12 6	16 9× 6 6
770	10 6×5 0	10 6×4 6	13 3×8 9	10 6×6 6	19 6×12 6	13 3×11 0
1,050	13 3×5 0	13 3×4 6	17 0×8 9	13 3×6 6	25 3×12 6	17 0×11 0

In preparing this Schedule the number of cells is as follows: 25-volt circuit, 13 cells; 50-volt circuit, 27 cells; 100-volt circuit, 54 cells. The height of room in each case should not be less than 8 feet.

Care of Storage Batteries.

Use only chemically pure acid (symbol CP).
Always pour the *acid* into the water.
Always cool electrolyte to 60° before pouring into cells. Stationary cells, sp. gr. 1·200.
Portable and automobile may go as high as 1·300.
High sp. gr. = low resistance, but danger to plates by sulphating if run too high.

Tests for impurities :—

Hydrochloric Acid (Chlorine).—To a small quantity of dilute electrolyte add a few drops of nitric acid, then add 3 drops of silver nitrate. The formation of a white, cloudy precipitate indicates the presence of chlorine in some form.

Nitric Acid.—Mix a solution of diphenylamine in concentrated sulphuric acid, and add it to the sample under test. Nitric acid will be indicated by a blue colour.

Iron.—Fill a test-tube with dilute electrolyte and heat to boiling point; add several drops of concentrated nitric acid and boil again. Repeat two or three times. When solution is cold add a few drops of potassium sulphocyanide, which will colour a deep red if iron is present.

Copper.—Add common ammonia until the resultant mixture gives an alkaline reaction; a deep blue indicates the presence of copper.

Arsenic.—Add an equal quantity of hydrogen sulphide solution ; a yellow precipitate indicates arsenic.

Chemically pure reagents only must be used.
Plates must not stand in acid longer than two hours without charging or they will sulphate.
Charging temperature should not rise above 100° F. ; if it exceeds this the current should be reduced.
The charging rate may be found by dividing the ampere hour capacity by 8.
The sp. gr. drops considerably at first, due to absorption by the plates, but will rise during the charge to slightly over the correct sp. gr. ; when charged it is about 0·025 higher than when discharged.
Never discharge below 1·8 volts per cell.

Edison Nickel-Iron Accumulator.

The Edison storage cell, which is largely used for propelling vehicles, has a positive plate of iron and a negative plate of nickel, immersed in a solution of potassium hydrate. The E.M.F. when fully charged is 1·5 volts, falling to 1·0 volt, or less, at the end of discharge. The output is 14 to 16 watt-hours per lb. of complete cell.

DIRECT-CURRENT GENERATORS.

Design of Direct-Current Generators.

The general design of the Westinghouse multipolar direct-coupled generator is as follows :—

A circular field yoke carrying inwardly-projecting pole pieces of laminated soft steel. The field ring is divided horizontally or vertically to suit variable conditions of service. When the machine is coupled at one end of a high-speed engine, and there is sufficient overhead room, the horizontal position is adopted. But when overhead room is restricted or if the machine be placed between the cranks of a cross-compound engine, the field ring is split vertically, the two halves being set on a guide plate. This vertical division of the field affords facility for inspection or removal of armature or field coils without the necessity of removing the outboard bearing or dismantling the engine. The opening of the field in a horizontal direction is of convenience where head room is limited and cranes or other devices for handling heavy castings are not available.

The armature core consists of punchings of carefully annealed steel held together between end-plates. This core is built upon an iron spider, which also carries the commutator. The spider is pressed and keyed upon the extended engine-shaft, and may be drawn off at will should that ever be necessary, without in any way interfering with the permanent arrangement of the commutator and winding. Ventilating spaces through the spider and armature core are so arranged as to give a constant circulation of air through the commutator and winding.

The generator field is over-compounded to compensate for drop of potential in the line. By means of a shunt on the series coils, the compounding may be adjusted for different degrees of over-compounding. The shunt and series coils are separately wound and removable at will. The series coils are composed of forged copper conductors of rectangular section.

The periphery of the armature is slotted. The armature winding of all machines of 50 kw. and over is made from bars of drawn copper, forged into proper shape on cast-iron formers.

It is important to buy THE RIGHT ACID for ACCUMULATORS and all Electrical purposes.

BOOKS FOR ELECTRICAL ENGINEERS.

***FUEL ECONOMY.** By W. H. BOOTH. A practical work of direct value to all Central Station Engineers and electricians in charge of steam-raising plant who are interested in the use of coal combined with economy and efficiency. Second Edition, revised and enlarged. Cr. 8vo, illustrated. **2s. 9d.** net, post free.

HANDY ELECTRICAL DICTIONARY. By W. L. WEBER. Thoroughly up to date. Contains definitions of over 4,800 distinct words, terms, and phrases. Cloth, **1s. 8d.** net; leatherette, **2s. 8d.** net, post free.

PRACTICAL ILLUMINATION. By JUSTUS ECK, M.A., M.I.E.E. A most useful pocket-book, full of information for lighting contractors, architects, consultants, etc. Highly recommended by experts. **1s. 2d.** net, post free.

ARMATURE WINDING. By C. SYLVESTER, A.M.I.E.E. An up-to-date and splendidly illustrated manual on this most important subject. It has been carefully prepared so as to give clear and full instruction to all interested in the various types of windings, and can be strongly recommended. Cl. 8vo. **8s.** net, post free.

***THE PRACTICAL ELECTRICIAN'S POCKET-BOOK.** An invaluable work of reference. Thousands sold annually. Recommended by all the electrical journals. **3s. 4d.** net, post free.

ELECTRIC BELLS, ALARMS, AND SIGNALLING SYSTEMS. By H. G. WHITE. A book of direct interest to all bell fitters, and to colliery signal engineers. Profusely illustrated. New and enlarged edition. **3s. 9d.** net, post free.

THE APPLICATION OF ARC LAMPS TO PRACTICAL PURPOSES. By JUSTUS ECK, M.I.E.E. A splendid manual for Contractors, Foremen, Trimmers, etc. Gives clear working diagrams and details of the leading types. Cloth 8vo, 101 pp., 92 illustrations. **2s. 9d.** net, post free.

***TELEPHONE ERECTION AND MAINTENANCE.** A Handbook for the Contractor and Wireman. By H. G. WHITE. Officially recommended by the C. & G. Examiners. Illustrated. **3s. 10d.** net, post free.

***DYNAMO AND MOTOR ATTENDANTS AND THEIR MACHINES.** By FRANK BROADBENT, M.I.E.E. A thoroughly practical and reliable work, of which over 35,000 copies have already been sold. **4s. 10d.** net, post free.

***THE PRACTICAL TESTING OF DYNAMOS AND MOTORS.** By CHAS. F. SMITH, M.I.E.E. A book of direct interest to all electricians concerned in the construction, installation, and management of continuous current machinery. Fifth Edition. Cl. 8vo, 292 pp., illustrated. **6s. 10d.** post free.

ROTARY CONVERTERS: Their Design, Construction, and Use. By C. SYLVESTER, A.M.I.E.E. A clear and eminently practical description of these machines, with numerous diagrams. Of direct value to all sub-station engineers, students, etc. Cr. 8vo. **2s. 3d.** net, post free.

QUESTIONS AND ANSWERS ABOUT ELECTRICAL APPARATUS. By J. W. CRAIG. A very handy work, containing more than 200 live practical questions and answers for central station operators and men in the repair and trouble departments. Limp cl. 8vo, illustrated. **7s. 6d.** net, post free.

***ELECTRICAL ENGINEERING PRACTICE.** By J. W. MEARES (Electrical Adviser to Govt. of India), and R. E. NEALE, B.Sc. Hons., A.C.G.I. A concise non-mathematical treatise, dealing thoroughly with fundamental principles and modern practice. An expert treatise of unique scope. Positively the only book of its kind. 642 pages, 86 figures and over 100 special tables. **26s.** net, post free.

*Books marked * are recommended by the City & Guilds Institute.*

WRITE FOR CATALOGUE No. 39.

After being thus shaped, the bars are thoroughly insulated and baked to remove all moisture. The coils are held in slots by means of retaining wedges of hard fibre driven into notches near the top of the slots, parallel to the shaft. These fibre wedges may be pressed out should it become necessary to remove any armature coil.

The brush-holder mechanism is carried by brackets projecting from a ring concentric with, and supported by, the field. A hand-wheel rocker arrangement accomplishes the adjustment of all the brushes simultaneously. The ring carrying the brush-holder brackets does not project over the commutator face ; the commutator face and brushes are therefore clear of obstructions, and may easily be inspected at any point. Carbon brushes are used in connection with all these machines.

A feature of particular importance in the Westinghouse engine-type generators is that all brushes of the same polarity are maintained at the same potential. Trouble has frequently been experienced in working with large multipolar direct-current machines owing to the difficulty of securing the same magnetic strength in all the poles ; the E.M.F. generated in conductors under one pole differed from that generated in conductors similarly situated under another pole of the same polarity, the result being a slight difference of potential between brushes of similar polarity. This caused currents to flow from one brush to another, and from one section of the armature winding to another, an occurrence attended by wasteful heating and the sparking of brushes. The difficulty is obviated in these generators by a particular method of electrical balancing. By the use of this method, the armature could be considerably out of centre and no injurious results occur, as the balancing currents flow, not through the brushes, but through specially provided connections. The pull exerted by one side of the field on a large armature out of centre by even the small fraction of an inch may become as high as several tons ; this method of balancing prevents such an increased pull.

Care of Direct-current Generators.

Steadiness.—It is important that the machine be firmly fixed to a good foundation. A machine may be run successfully on an upper floor, if supported on solid joists either of timber or iron. The machine will spark and the brushes and commutators wear unduly if there is vibration.

Commutator and Brushes.—These will always repay careful attention. If the brushes are left to wear unequally, and the commutator is not cleaned, the machine will soon commence to spark badly, and both brushes and commutator will wear rapidly. If, however, these parts are attended to in accordance with the following instructions, the wear and tear will be very small.

Adjustment of Brushes.—The brushes must be set truly on a diameter so that the point of one is diametrically opposite the point of the other. Gauze and metal brushes as they wear must be advanced to maintain the same distance, and consequently to bear the same angle on the surface of the commutator. They must be advanced frequently, even though the wear may be very small, otherwise the brush will not bed properly on the surfaces of the commutator when advanced. Each brush must always bed equally well at the point, or toe, and at the heel. If brushes are allowed to wear too much before advancing (but this should not be), they must be taken out and filed to fit truly. In filing a brush, clamp it firmly, and file by taking long strokes with a file always in one direction. If it is the toe that requires filing, after filing to fit take off the sharp edge, leaving the toe always $\frac{1}{16}$ inch thick. One brush often wears faster than its fellow (or fellows), and must be set up accordingly. Moreover, sometimes a whole set of brushes on one side of the commutator will wear faster than those on the other side, and this must be allowed for, or the brushes will cease to be on a diameter, and sparking and flatting of the commutator may result.

Carbon Brushes are usually set radially to the commutator and therefore require no diagonal adjustment. They require periodical inspection, adjustment and cleaning, as the toes or heels usually burn away and a new surface giving the full contact area of the brush must be again obtained. The best results with carbon brushes of ample contact area and good designs fitted with flexible tails are obtained by keeping the brushes absolutely clean and free from dust and the commutator true and polished with polishing paste.

Flats.—The most common source of the formation of little 'flats' upon the surface of the commutator is the brushes being out of adjustment.' Another cause is vibration of the brushes, due primarily to vibration of the machine, owing to improper foundations or a badly-jointed belt. Flats are sometimes caused by the pressure of the brushes being reduced to too low a limit.

Pressure.—It is well to have the pressure as light as possible, so long as no sparking and no vibration takes place at the brushes.

Oiling and Cleaning the Commutator.—In the case of metal brushes use a little good mineral oil or vaseline, applied with a piece of rag. Do not on any account apply oil with a feeder, or on a piece of waste. A commutator well looked after will acquire in time a dark-coloured, smooth polish. When this takes place run a piece of No. 0 0 emery cloth on the commutator occasionally before starting to work. In flour-mills and dusty places it is necessary to clean the commutator with a little benzoline every day before starting, or, if run continuously, during the run, taking care not to drench the commutator; also to apply emery cloth about once a week as just directed.

Belting.—Where practicable, the drive should be arranged so that the under side of the belt is the tight or driving side. A flexible belt should always be used. Leather-linked belting, arched on the face next the pulleys and flat on the outside, is very suitable. Such a belt should *not* be taken off after working. Single belting with double edges makes a good cheap belt for ordinary use, and may be jointed with a butt joint, secured by belt fasteners. If an ordinary single belt is used, it should be straight and of good quality. It should be jointed with a laced butt joint, until it has stretched, and then a proper spliced and cemented joint made. A dynamo belt must run evenly. A belt which lashes either up and down, or from side to side, should not be tolerated.

Oiling the Bearings.—Adjust the sight-feed lubricator to give about 3 to 10 drops per minute. The amount required varies with the quality of the oil used and the load on the machine. If the machine has been standing, give it a few extra drops before starting. Good castor-oil is the best lubricant. It is well to use an oil feeder made entirely of copper. Keep the machine clean—free from copper dust and waste oil.

Should the commutator wear out of truth or becomes very uneven (scored), take out the armature and turn up the commutator in a lathe, being careful to use a fine-pointed tool and not to take heavy cuts; afterwards polish with emery cloth. If the commutator should be only scored, it may be dressed in the machine with coarse, and afterwards fine, emery cloth, finishing with No. 0. Slight 'ringing' does not matter.

Mather & Platt Direct-Current Generators.

One of the latest phases of electrical engineering is the driving of large D.C. slow-speed generators, through gearing, by steam turbines, and a considerable number of these plants have been installed up and down the United Kingdom by Messrs. Mather & Platt, Ltd., of Park Works, Manchester.

A typical generator is shown in fig. 13. This machine is installed at the works of the Electro Bleach and By-Products, Ltd., Middlewich, Cheshire, and is driven by a steam turbine, of the 'Howden-Zoelly' Multi-Stage Impulse type, running at 3,000 r.p.m., manufactured by Messrs. James Howden & Co., Ltd., Glasgow. The generator is driven through double helical gearing and runs at a speed of 250 r.p.m. The substantial character and satisfactory operation of the plant—which runs day and night—cannot be better exemplified than by the fact that a further set of 1,000 kw., consisting of two 500 kw. machines in tandem, and a 1,250 kw. set have recently been installed, and set to work.

The details of construction of this machine is as follows:—

Carcase.—The frame is a plain ring of high permeability cast steel; the main poles consist of steel stampings accurately punched and assembled, and are bolted to the frame. Magnetic symmetry is thus ensured.

Bearings.—The bearings are of the self-lubricating, parallel bush, pedestal type; the bushes are of cast iron with white-metal lining, and all bushes and pedestals are split horizontally. Each bearing is lubricated automatically by means of two oil rings running in an oil well of large capacity.

Commutator.—The commutator is designed with a very high factor of safety. The segments, of hard-drawn copper, are insulated by megohmit, mounted on a strong cast-iron hub, and clamped between steel end rings. Before connection to the armature every commutator is subjected to an insulation flash test of 3,000 volts.

Armature Core.—The armature is built of thin steel slotted laminations of the highest electrical and magnetic quality, insulated from each other and clamped together under pressure on a strong cast-iron hub, an extension of which carries the commutator hub.

Armature Winding.—All wires and strips are thoroughly impregnated before winding, and the main insulation consists of mica sheet mechanically protected by leatheroid. The completed armature is finally dried and impregnated with varnish.

Field Winding.—All shunt coils are solidly built, dried, and impregnated *in vacuo*. Each coil is provided with stout terminals which relieve the last turns of wire from all stress, and the connections are made with bolted heavy copper strip.

Brush Gear.—The brush gear is of simple and rigid construction, split horizontally, and is supported by a separate frame. The brush-holders, which are of the direct-acting box type, are bolted to a carrier arm which keeps them in strict alignment, and are easily adjustable. The insulation is micanite throughout. When the brush rocker has been once set in the working position, it remains fixed for all loads up to the maximum permissible overload.

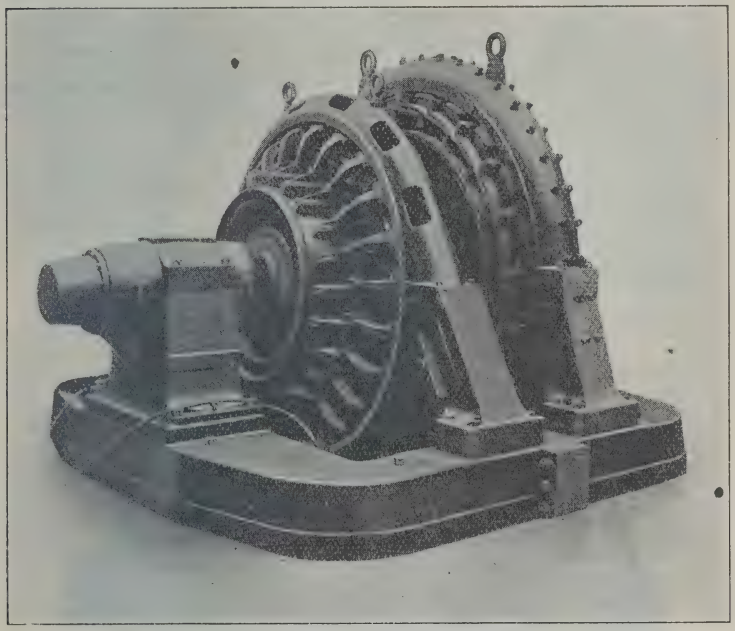

FIG. 13.—Mather & Platt D.C. Generator.

While many D.C. machines nowadays are driven by steam turbines through gearing, a similar arrangement is adopted with alternators in spite of the fact that it is not very difficult, either from an electrical or a mechanical point of view, to construct medium-size high-speed turbo alternator sets. The geared alternator is adopted from motives of economy, as the steam turbine can then be designed for speeds of over 3,000 r.p.m.

Fig. 14 shows a 1,250 k.v.a. generator, 2,200 volts, suitable for a speed of 500 r.p.m., and arranged for gear driving from a steam turbine of over, say, 4,000 r.p.m. Such a machine is constructed on the following lines:—

The stator consists of a cylindrical core, built up of thin steel laminations of the highest electrical and magnetic quality, insulated from each other, and firmly clamped together in a rigid cast-iron frame.

The windings are fully insulated before insertion in the slots, the latter being usually of the open type. High-tension coils are insulated with moulded mica, and low-tension coils with our standard mica sheet mechanically protected by leatheroid. In all cases the insulation forms a complete sealed tube completely enclosing the straight part of each coil, and extending

for a considerable distance beyond the stator core at each end. The coils are held in position by hard wood wedges.

In normal machines, the poles are completely laminated, the core and tip being stamped in one piece. The built-up poles are usually bolted to the rim of a cast-steel hub. In special cases, however, the above construction may be modified.

For small machines with few poles, the field coils consist of cotton-covered wire or strip. Each coil is provided with terminals which relieve the last turns of wire from all stress. The coils are thoroughly dried and impregnated in vacuo with an oil- and moisture-resisting varnish. For larger machines copper strip bend on edge is used in all cases where it is practicable.

The shaft is of mild steel of ample size and stiffness. Each bearing is of the pedestal type, with a cast-iron bush of large diameter and length, lined with white metal, and lubricated automatically by two oil rings running in an oil well of large capacity. The oil channels and escape grooves are carefully designed to eliminate oil-flinging and creeping, and the overflow is so arranged that frothing or churning of oil in the oil well does not cause any drip. The pedestal and bearing bush are split horizontally.

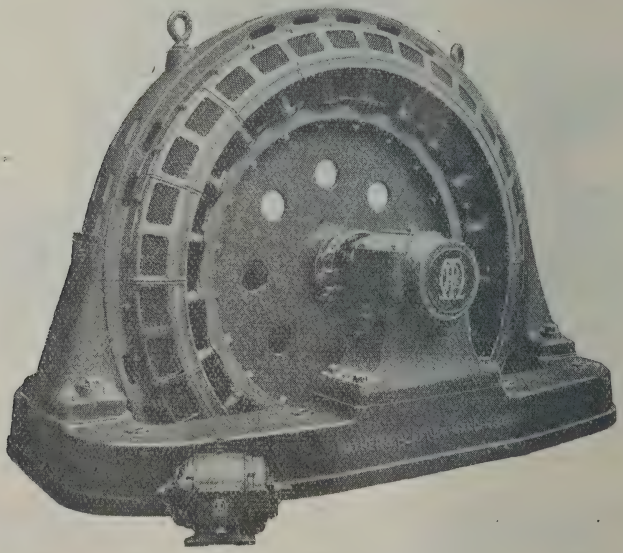

FIG. 14.—Mather & Platt 1250 k.v.a. Generator.

The slip rings are of bronze, insulated entirely by mica. The brush-holders are of our direct-acting box type, and the whole brush gear is simple and strong.

G.E.C. 'WITTON' DIRECT-CURRENT GENERATORS.

Fig. 15 shows three 1,000 kw. direct-current generators, driven through gearing by 'Parsons' turbines, as supplied to a large Explosives Factory. These sets deliver direct

current at a pressure of 220 volts, and run at a speed of 400 r.p.m. with the turbines operating at 3,000 r.p.m. The gearing is employed to enable the speed of the generator to be

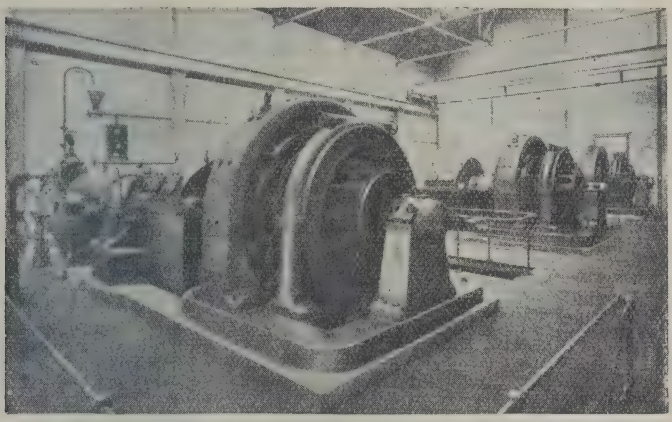

FIG. 15.—Three 1,000 kw. G.E.C. 'Witton' Direct-current Generators, Turbine driven through gearing.

reduced to such a point that the best commutation is obtained, and to enable the turbine speed to be raised to the point of highest efficiency.

ALTERNATING-CURRENT GENERATORS.

The following is a specification of a Class D alternator, made by *The English Electric Company, Ltd.*

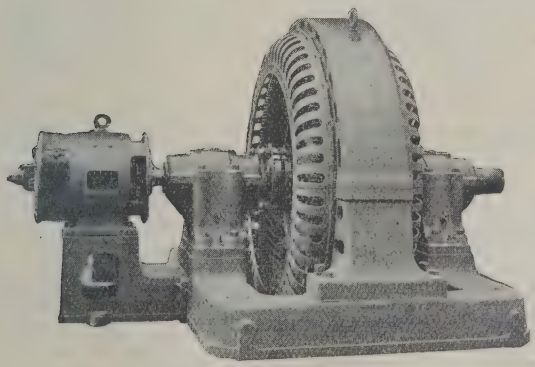

FIG. 15A.—English Electric Co.'s Class D Alternator.

These generators are supplied in various standard types as follows: the Protected Type, the Engine Base Type, the Sole Plate Type, the Bedplate and Two-Pedestal Bearing Type, the Bedplate and Three-Pedestal Bearing Type, and the Engine Shaft Type.

The 'Protected Type' (sizes up to D.16 inclusive) consists of a stator frame with feet, core, coils and terminals, two end-shields carrying the bearings, rotor with poles and field coils, slip-rings, shaft and half coupling and complete collector gear.

The 'Engine Base Type' consists of a stator frame with feet, core, coils, and terminals, one pedestal bearing, rotor with poles and field coils, shaft, slip-rings and coupling, complete collector gear, screws for fixing stator frame and pedestal to the engine base, and screws for adjusting the height of the frame.

The 'Sole Plate Type' is practically the same as the Engine Base Type with the addition of three sole plates suitable for building directly into the foundations.

The 'Bedplate and Two Pedestal Bearing Type' is similar to the Engine Base Type, but has a second pedestal bearing and a bedplate on which the stator frame and the two pedestal bearings are mounted. The shaft is suitable for coupling drive, or in certain cases for drive with belt or rope pulley.

The 'Bedplate and Three-Pedestal Bearing Type' is the same as the above, but has a third bearing with a correspondingly extended bedplate. The shaft is suitable for fitting with spur wheel, belt or rope pulley.

The 'Engine Shaft Type' differs from the Sole Plate Type by the omisssion of the shaft, coupling and the pedestal together with its sole plate, the rotor being suitably bored for forcing directly on the engine shaft.

Stator.—The Stator Frame is of cast iron, of great stiffness and substantial design, and is cast in one piece, not split. The ventilation of the stator winding and core is extremely good, the air being driven outwards by fan blades on the rotor and directed on to the winding and core by the end shrouds or end shields.

The stator core abuts directly on a surface turned in the frame. Up to size D.16 inclusive, it is held in place by clamping rings keyed to the frame, and for sizes above D.16 either by a similar arrangement or by through bolts. The core is built up of high quality sheet steel plates, insulated from one another by a heat-resisting material. The stator slots are of the overhung type and are accurately punched.

The stator coils are held in place in the slots by insulating keys. They are amply insulated, in the case of low-voltage machines by a combination of mica and fibrous insulation, and in the case of high-voltage machines by a carefully formed tube or covering of mica. The individual conductors are insulated with impregnated cotton. The out-hanging portions of the coil are protected from mechanical injury by the end shields or by the shrouds secured to the frame. The coils are thoroughly impregnated before putting into place.

Rotor.—The rotor consists of a cast steel wheel on which are mounted special cast steel poles rigidly bolted to the wheel, the securing bolts being locked to prevent their working loose.

In the smaller sizes the poles are cast as an integral part of the rotor wheel, and the pole shoes are rigidly secured thereto by screws.

Field Coils.—The field coils are usually wound on metal formers, from which they are carefully insulated.

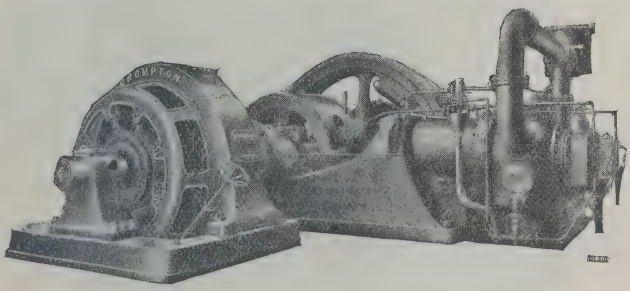
In the larger sizes and wherever possible the field coils consist of copper strip wound on edge and carefully insulated from the pole limb. Adjacent turns are insulated from one another by stout paper. Metal flanges are provided at the ends of the coil and are secured under heavy pressure. This form of winding is specially recommended owing to the excellent cooling it provides for the windings and its great mechanical strength and suitability to high peripheral speeds. It is advisable, whenever possible, to select a low voltage for excitation, so that a strip-on-edge winding can be used.

Slip-rings.—These are of gun-metal and are shrunk on to a sleeve, from which they are insulated with mica. The complete sleeve with rings is pressed on to the shaft.

Terminals.—In the Protected Type machines the terminals are carried in a terminal box mounted on the machine frame. In the larger Pedestal Bearing Type machines the terminals are arranged on the machine frame either at the side or at the lowest point of the frame.

Bearings.—On Protected Type machines with two end-shield bearings (viz. sizes up to D.16 inclusive), either sleeve bearings or 'Hoffman' heavy type ball or roller bearings are fitted, as required; this also applies to the pedestal bearing when a third bearing for these sizes is called for. For sizes above D.16 sleeve bearings are employed throughout, with bearing bushes of cast iron lined with white metal, the bearing bushes being spherically seated.

Fig. 16 (page 1889) shows a type of alternator made by Messrs. Crompton & Co. Ltd. These alternators are supplied for mounting direct on the engine crankshaft, for coupling direct, or for belt or rope driving. They are of the stationary armature type, with open parallel slots or semi-enclosed slots depending on the general design of the machine and the duty required. The coils are held in position by hard wood or fibre wedges. The magnets are of the rotating radial pole type, with the poles and shoes laminated or cast solid, according to the design. The field coils wound on insulated formers are held in position by the pole shoes.



When driven by slow-speed gas or oil engines, amortisseur or damping coils are often fitted.

The ventilation is a special feature of these machines. The armature coils are protected with metal covers, which assist in directing the air currents from the revolving field of the machine radially through the armature end windings to the back of the armature stampings, and thence through the ventilating holes in the cast-iron frame of the machine.

In the larger size machines the stationary armature is divided on the horizontal centre to facilitate transport and erection.

The exciter is of the usual standard construction for continuous current machines, and is usually arranged direct coupled to an extension of the alternator shaft, fitted with an outer bearing and mounted on an extension of the alternator bed plate.

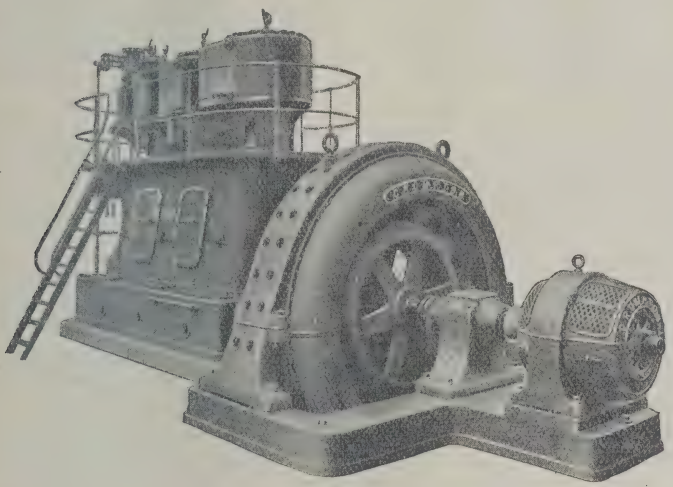

FIG. 16.—'Crompton' Alternator.

ALTERNATING-CURRENT TURBO-GENERATORS.

THE G.E.C. ALTERNATING-CURRENT TURBO-GENERATOR.

The following is the specification of a G.E.C. turbo-alternator of the standard type:—

The generator is of the enclosed type, fitted with drum-type rotor and forced ventilation. Shaft and exciter is included, but no pedestal bearings or coupling.

Stator Frame.—This is a massive cast-iron construction of box section, accurately bored to accommodate and clamp tightly the laminations. Stout end-plates are used for this purpose, and are secured in such a way that no bolts pass through the stampings, thereby avoiding a considerable amount of iron loss. All longitudinal ribs are dovetailed for keys to which the stampings are secured. The casting is fitted with two feet, which are connected with strong ribs to the main body to avoid flexure or vibration.

Laminations.—These are accurate stampings of best charcoal iron, punched out of large plates with the best tools to avoid burrs. They are re-annealed after punching, and insulated as a last operation. No filing or scraping takes place after the laminations are assembled, as it was found that this, owing to the length of the core, causes much higher iron losses due to eddies than in ordinary machines. For the same reason, the insulation between plates is increased by sheets of stronger paper placed at suitable intervals.

Stator Winding.—The winding, owing to special conditions of work, requires great care both from the designing and the manufacturing point of view. Whenever possible, strip copper is used in the slot and in the connections. The insulating tubes for the conductors are of micanite, and if possible they are moulded on to the coil itself. The complete coil with the insulation is then pushed through the slot from one end, one end of the coil being left straight for this purpose. Each conductor is then bent and connected up singly, thus making it absolutely certain that the insulation of the slot and also that between adjacent conductors is in perfect condition.

The arrangement of the conductors in the slot is also such that no high voltage can take place between adjacent conductors, so that the danger of breakdowns is entirely avoided.

Stator Ventilation.—A fan arranged at the coupling end of the rotor drives air from a duct, usually connected with the foundations, into the space enclosed by the guards. From here after cooling this side of the stator coils, the air is pressed through a large number of axial channels provided in the core. It escapes at the other end, and after cooling the coil connections, finds its way out of the machine through a funnel-shaped orifice. It should be particularly noticed that no air which is used for cooling the rotor is used to cool any part of the stator, and that the two streams of air are kept quite separate, thereby obtaining very low even temperature rises all over the machine. The use of filters for the air used for cooling is always recommended, but a decision as to their necessity can only be made upon knowledge of local conditions in each particular case.

Clamping of Stator Windings.—Heavy metal clamps are arranged all round the winding to prevent any movement of the connectors or of the projecting ends of the coils under the strain imposed upon them when the machine is switched in or out of circuit, or whenever a sudden short-circuit occurs in the distributing system. Wood used for clamping is considered conducting, and micanite plates are always inserted to insulate the coils from the wood.

Terminals.—The terminals are usually arranged at the bottom of the shell at the slip-ring end, the cable being brought up to them from the cellar underneath. They are thus in a naturally protected position without necessitating unsightly boxes in the engine-room.

Rotor Construction.—The rotor is of the drum type, the rotor winding being distributed in slots all round the periphery. Whenever possible the rotor body and shaft are one solid forging. This design has been adopted, as a solid forging is the strongest possible mechanical construction and gives the highest possible critical speeds well above the running speeds. The slots are obtained by milling them out of the solid drum. All insulating material used is practically incombustible.

Rotor Winding.—The winding consists of coils embedded in the slots all round the periphery of the rotor. They are wound beforehand on a frame. Strong and ample insulation is provided between the winding and the rotor, as well as between the conductors themselves, particular care being taken of the crushing action due to the centrifugal force.

Ventilation of Rotor.—A fan arranged at the slip-ring end draws air from the ducts at the opposite side through longitudinal channels arranged in the rotor. These are kept as close as possible to the winding where the heat is generated. Both fans are of steel plates of high tensile strength. Their shape is designed with particular regard to the efficient working of the fan, and results have proved that windage losses are much smaller than in any other make, due to the care paid to this important detail.

Clamping of Rotor.—Metal wedges are used to keep the winding in the slots. These are driven in tightly whilst the insulation is bent down by means of hot tools, which avoid any damage due to breakage. At the two ends the connections are kept down by strong steel shrouds of ample strength to withstand with safety the centrifugal stresses at maximum speed. These are put on moderately warm to enable ample amount of insulating material being left between winding and the shrouds. The shrouds are located at one end on a spigot provided in the core, at the other end on strong steel end-plates carried from the shaft. Balancing grooves are provided at both ends of the rotor. The whole rotor obtains in this way an extremely mechanical and solid appearance, the winding being entirely boxed in and protected from injury.

Slip Rings.—The current is brought to the winding by means of two steel slip-rings shrunk on to an iron sleeve with a layer of micanite in between. Any danger of distortion or of getting out of truth under speed is thereby avoided. Particular attention is paid to the leads connecting the rings to the winding. These are protected by being sunk into a groove in the shaft and a key-shaped cover fixed over them.

Bearings.—The bearings are of ample dimensions to run without overheating. They are finished off only after the whole of the rotor is completed to ensure a true surface. Ample oil flirts are left at both sides.

Exciter.—This is fixed on a bracket carried from the bearing at the slip-ring end. It is a standard continuous-current generator, fitted with special devices for keeping it cool at high speeds and for balancing it independently of the turbine. It is usually shunt-wound and fitted with auxiliary poles.

Tests.—Numerous tests are carried out during the process of construction to see that the materials are satisfactory at all stages. Amongst the tests which are carried out at the completion of the work are:—

(*a*) Breakdown test for tubes after inserting them in the core.

(*b*) Test between adjacent conductors in a slot, not less than ten times the working voltage between conductors.

(*c*) Between finished coils and between any coil and earth, twice working voltage, but in any case not less than 2,000 volts.

(*d*) Rotor winding tested to earth, with 2,000 volts before running and with 1,000 volts after balancing test. The same test is applied when all connections are made to the slip-rings.

(*e*) Static balancing on flat rails.

(*f*) Dynamic balancing at half-speed.

(*g*) Balancing test at full speed.

(*h*) Synchronous run at full speed to measure iron, windage and excitation losses. During this test the open-circuit curve and the short-circuit curve are obtained.

(*The General Electric Co. Ltd.*)

Air Coolers and Filters.

'Heenan' Air Filter.

The overload capacity of turbo-alternators and generators is dependent to a considerable extent upon the supply of suitable volumes of cool air for carrying away the heat generated by electrical loss. The usual method is to mount fans on the rotor shaft, arranged to extract air through a supply system in which a combined air filter and cooler is inserted.

The 'Heenan' Air Filter (*Heenan & Froude, Ltd.*) receives ordinary unfiltered air from the neighbourhood of the generating station and brings it into very thorough and intimate contact with wet scrubbing surfaces. The arrangement of these surfaces has undergone a complete transformation since the machine was last described in the ENGINEER'S YEAR-BOOK. The rotary principle has been given up in favour of stationary air screens, the surfaces of which are kept thoroughly wetted by water issuing from jets. After cleansing the scrubbing surfaces the water gravitates to a tank, from which it passes through strainers to a centrifugal circulating pump and thence to the distributing jets. The atomisation of water forming part of certain air-filtering systems is entirely avoided. The air leaves the filter in an entirely natural condition, containing no trace of loose moisture.

The filtering efficiency of this apparatus is extremely high, both heavy and fine dust being eliminated. The cooling effect in hot summer weather in temperate climates is often as high as 20° or 30° F. In tropical climates the latter figure is sometimes exceeded. The consequent reduction in air temperature is of great value in permitting the generating plant to run on heavy overloads without overheating.

ROTARY CONVERTERS.

The G.E.C. Rotary Converter

The following is a specification of a Rotary Converter of standard type :—

Frame.—The frame is constructed of cast iron or steel of high magnetic permeability. It is split horizontally and bolted together by strong steel bolts. The construction permits the top half to be readily removed for inspection or repair.

Main Pole-Pieces.—The main pole-pieces, which are bolted to the frame from the outside are built up of laminations in order to reduce eddy-current losses in the pole faces to a minimum. The design is such as to permit the removal of a field coil without disturbing the armature or yoke. In exceptional cases cast steel poles with laminated shoes may be employed.

Armature.—The armature is built up of best quality stampings of high permeability and low iron loss. They are mounted on a cast-iron spider and held tightly in position by heavy end-plates. The laminations are accurately punched before assembling and are covered with a special insulating compound which is effective in reducing eddy-currents to a minimum. The core is held together between the end-plates by means of bolts which, however, do not pass through the active portion of the core and therefore introduce no local circuit for eddy-currents. Ventilating ducts, adequate in number and ample in dimensions, are provided at frequent intervals. Similar ducts are included at the two ends between the core and end-plates. The general construction of the armature is such as to afford a current of air to the field coils for ventilation and cooling. The armature spider is extended at one end for carrying the commutator so that the latter is driven positively, independently of the shaft. The armature winding is composed of former wound coils, taped, varnished, and baked before assembly. The slots are lined with several layers of non-hygroscopic insulating material. Special care is taken to make the leakage surfaces as large as possible. The aperture at the top of the slot is filled by strong wooden wedges driven in tightly. There are no binding bands on the armature core itself, that part of the winding being retained in position by the wooden wedges. The end windings are so shaped that the surface exposed for cooling is as large as possible. After winding a black insulating compound is sprayed by compressed air on to the armature until it is completely coated. A large number of equalising connections is provided to ensure that out-of-balance currents, if any, shall not pass through the brushes. Prior to assembling in the frame the armature is balanced statically, and, on test, care is taken to assure that this has been done accurately.

Commutator.—The commutator is built up of hard-drawn copper segments, insulated by best mica insulation and held tightly between two V-shaped clamping rings in such a manner that the inevitable expansion of the copper and iron on account of temperature rise, may take place without in any way affecting the commutator surface. During its construction the commutator is subjected to several baking processes, with the result that there can be no possibility of moisture remaining in the mica insulation, and when completed the whole commutator gives a true ring, which indicates that the entire mass has been formed into one rigid body. In addition, the construction is such that 'breathing' is reduced to a minimum and the possibility of moisture permeating the insulation is eliminated. A considerable distance to the iron parts is allowed at the front and back of the commutator in order to secure a high insulation resistance to earth, and to prevent any leakage to the iron. The radial depth of the segments is ample for the size of the commutator, and varies somewhat with the size of the machines. For commutators of over 14 ins. diameter the wearing depth is at least one inch. Before leaving the works, the mica between the segments is grooved to a suitable depth to promote good commutation. To assist in cooling, the commutator lugs which connect the segments to the armature windings are given a considerable width and thus provide a large cooling surface.

Field Coils.—Shunt field coils are wound upon spools composed of a material with high insulating properties, a former larger than the poles being employed in the winding process to ensure that no undue stresses are imposed upon the spool when in position. The wires are insulated with a double cotton covering and after being wound are put into a heated impregnating chamber where they are dried for several hours under vacuum, the vacuum pump drawing off all moisture. After removal from this chamber they are flooded in a duplicate chamber (while still under vacuum) with a heavy insulating compound. They are then subjected to heavy pressure at the same temperature, the insulating compound being forced right through the layers of the coils. Series coils are wound with bare copper strip and painted with an insulating compound. Ample leakage surfaces to the frame are provided. The connections between the coils on adjacent poles, both for shunt and series windings, are of great mechanical strength.

Commutating Poles.—G.E.C. rotary converters are fitted with commutating poles of a design which permits sparkless collection of current at all loads with fixed brush position. The coils are wound with bare copper strip and painted with an insulating compound. The mica spools are wound direct on the poles and ample leakage surfaces are provided.

Damping Winding.—A substantial damping winding is fitted to the field poles. This is instrumental in strongly opposing any tendency to hunt, whether that tendency may arise from changes in load or from any low-frequency oscillations originating in the generating plant. It consists of a pair of heavy copper rings bolted together by copper bolts between the poles and connected up by drawn copper rods passing through the pole faces and fixed at each end of the rings. In order that any pole winding may be removed, the rings are divided up between the poles and jointed in a manner which permits the joint to be readily unmade for the removal of the pole or winding, and at the same time in no way impairs the mechanical strength or the electrical conductivity of the rings. A damping winding of high conductivity and great rigidity is thus obtained which completely damps out all oscillations.

The damping winding is also necessary for improving the starting characteristics of the converter when started from the alternating current side, from transformer tappings.

Booster.—The booster—if provided—takes the form of an alternating current generator, with a stationary field. The booster armature is mounted on the main shaft side by side with the armature of the rotary converter, and is constructed on the same principle as the armature of the rotary. The current passes from the converter slip rings through the booster armature to the armature of the rotary. The booster field-frame is split horizontally into two parts, and mounted on the bedplate by the side of the main frame. The booster field may be excited either by shunt or series windings, or both.

Six-phase and Four-phase Connections.—Rotary converters intended to work on a three-phase supply are usually wound as six-phase machines, drawing a six-phase supply from three-phase transformers in order to take advantage of the greater output and more even heating of a six-phase armature as compared with a three-phase. Similarly converters for operating on a two-phase supply are wound four-phase.

D.C. Brush Gear.—The direct-current brush-holders are fixed to a strong cast-iron arm projecting radially inwards from the brush rocker. The rocker is carried in a spigot in the yoke and can be turned by means of a hand-wheel and screw. The rocker is split across the horizontal diameter, so that the halves can be readily removed for inspection or repair. The rings connecting the brush sets of the same polarity are carried behind the brush rocker on insulating supports; they are well insulated from the rocker and have ample clearances and cooling surfaces. Provision is made for separating the halves of the rings should it be desired to remove one-half of the brush rocker for any reason. Each brush carbon is contained in a separate box-type holder to avoid rubbing, and a helical steel spring exerts radial pressure upon the brushes. This steel spring, which is enclosed in a brass tube and is therefore not exposed to dust, presses down a plunger, the tip of which is insulated and therefore prevents the spring from carrying current. The design of the brush holder is such that each brush mechanism is self-contained; the pressure of the brushes can therefore be adjusted when running, and one brush can be removed without in any

way disturbing the others. The brush gear is of compact design, giving a maximum distance between adjacent brush sets, thereby assisting in the prevention of flashing-over.

A.-C. Brush Gear.—The alternating current brush holders are mounted on semi-circular arms which are carried on, and insulated from, a strong bracket projecting from the pedestals bearing on the slip-ring end of the converter. Each brush is contained in a separate box-type holder of a similar design to those working on the commutator. Each brush can be easily adjusted independently of the rest of the brush-gear. Terminals for the incoming cables are provided and are fixed direct on to the arms.

Slip-rings.—The slip-rings are of phosphor bronze, and so designed as to ensure efficient cooling. Each ring is so cast that the portion between the contact face and the internal diameter takes the form of a fan. The rings are given a large radial wearing depth. A cast-iron sleeve which is securely keyed to the shaft forms the base for the slip-ring structure. This sleeve is insulated throughout its length with compressed mica ground to shape, the slip-rings being shrunk on to this. The connections from the armature to the slip-rings consist of solid copper bars strongly bolted into the slip-rings at one end and supported at the other by a steel ring shrunk on to the sleeve, similarly to the slip-rings. These connecting bars are covered with insulating material and are efficiently protected from breakdown to the other slip-rings through which they have to pass. Ample clearances are provided for cleaning. Wherever possible, each tapping of the armature winding is brought to the rings separately in order to avoid unbalanced current. Thus the slip-rings themselves act as balancing rings.

Shaft.—The shaft is of such strength that it will carry the armature without undue flexure or vibration. It is supported by two main bearings lined with white metal and split in halves.

Bearings.—The bearings are of the self-oiling type, and have rings which dip into oil chambers of large dimensions. The bushes are of cast-iron lined with best quality white metal and are split horizontally. The ratio between the length of the bearing and the diameter of the shaft is as 2·5 to 1. A glass level gauge with draw-off tap is fitted to each bearing. The general design of the bearing is such as to preclude any oil flinging.

Bedplate.—A strong bedplate of box section is provided, having heavy ribs connecting the sides at various points. Its general construction is substantial and ensures complete freedom from vibration. The bedplate is fixed to the foundations by strong bolts and plates supplied with the machine.

Speed-Limiting Device.—All large rotary converters (and small ones if desired) are equipped with a speed limiting device which will shut down the machine if by any chance the normal speed should be exceeded by a predetermined amount. This device works on the centrifugal principle. A weight which tends to move under the action of centrifugal force is mounted on a shaft and revolves with it. Under the action of the centrifugal force it tends to swing outwards against the compressive resistance of a spring. At a predetermined speed the arm, to which the weight is attached, flies out sufficiently to trip a trigger device, which makes contact in a tripping circuit, and thereby opens the direct current circuit breaker or, if desired, cuts out resistance from the converter field circuit. This device is usually fixed at the direct current end of the rotary shaft.

Oscillating Gear.—If desired, an oscillating device can be supplied for moving the armature to and fro longitudinally while it is running, thus preventing grooving of the commutator and slip-rings. As the armature rotates, it is alternately pushed out of the magnetic centre and then released, thus causing a smooth oscillation.

Temperature Rise.—The rotary converter is capable of developing its full rated load continuously with a rise in temperature of 40° C. (72° F.).

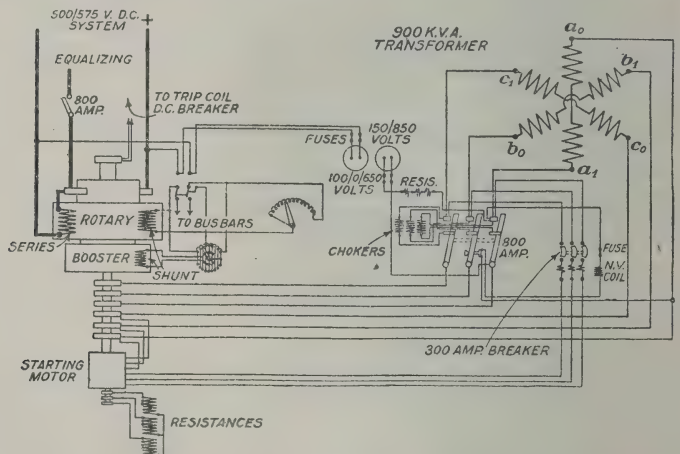
Overload Capacity.—The rotary converter will give an overload of 25 per cent. for two hours, and 50 per cent. for 15 minutes. It will also withstand overloads of 100 per cent. momentarily.

Starting Motor.—If the rotary be supplied with a starting motor, the latter is mounted on an extension of the bedplate. The motor is of large capacity and is adequate in size to run the converter up to speed in a short time. The motor is either of the solid rotor or slip-ring type, as circumstances demand. The starting torque is sufficient to permit rapid acceleration in the first moments of starting, even though the supply voltage is below normal, as may be the case after a shut-down at the main power station.

Tests.—All material is subjected to tests at various stages of its manufacture to ensure that no faults exist in the completed machine. Tests for static and dynamic balance are also carried out before the machine leaves the works. Excellence in this respect is assured. Standard final tests on rotaries for 650 volts direct current or under include a 2,000 volt flash test with alternating current for five minutes, and six hours run on full load to ascertain the efficiency and temperature rise

G.E.C. Methods of starting Self-Synchronising and Controlling Rotary Converters.

It is usually required that rotary converters shall be of the self-synchronising type, as the running of sub-stations is thereby facilitated. This practice can therefore be considered standard. If two rotary converters are run in parallel on both the alternating and continuous-current sides, difficulties are experienced in that the load divides itself unequally between the two machines, depending on slight differences in resistance on the commutators and the like. When an alternator has been required, therefore to feed directly two rotaries in parallel it has commonly been arranged with two separate windings, one for each rotary. This method, however, leads to difficulties in the winding of the alternator. The means adopted by the G.E.C. to meet both these requirements are described and illustrated below.



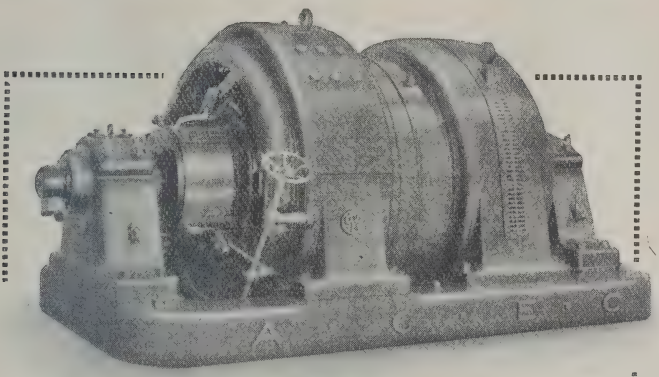


FIG. 17.—Diagram of connections for self-synchronising rotary converter.

The scheme of connections for G.E.C. rotary converters is given in Fig. 17. The essential features are the synchronising switch and the choking coils. The rotary converter is provided with a starting motor, which is started by closing the triple-pole circuit-breaker shown at the right of the figure. This brings the set up to approximately synchronous speed. Meanwhile the switch shown in the figure is closed in its starting position, where the blades make contact on the long synchronising contacts. Under these conditions the slip-rings of the rotary are connected to the source of alternating-current supply through the choking coils, which limit the current taken by the machine. This current, however, is sufficient to pull the set into synchronism. When this has happened, the synchronising switch is pushed right home, so that the blades go into the full-on contacts. Mechanism is provided which prevents the attendant from accidentally closing the synchronising switch straight away in its fully-closed position. On slightly pulling it towards the "off" position a pin releases a slotted bar, which falls under its own weight, allowing the pin to pass along the slot and permitting the synchronising switch to be pushed right home. When this happens, an interlocking contact is operated which opens the no-volt coil of the starting-motor circuit breaker, tripping the latter, so that the converter set is left in synchronism with the starting motor disconnected.

The standard starting motor used is provided with a solid rotor. The stator windings are adjusted once for all when the set is first put into use so as to give the best value of slip to the starting motor and so as to necessitate the minimum value of synchronising current. At the bottom of Fig. 17 a fixed resistance will be seen connected to the slip-rings of the starting motor. This is provided in those cases where it is desired to run the starting motor for prolonged

LA COUR MOTOR CONVERTERS

are provided with our patent automatic starting and self synchronising gear which enables them to be started and synchronised by anyone without the necessity of a skilled operator being in attendance.

They are supplied with either two or three bearings and in the latter case are made with our patented method of interconnections between the rotor and the armature, thus avoiding the inherent weakness of a hollow shaft.

There is no high tension current on any revolving part and the machines automatically balance the two sides of a three wire system within fine limits.

Full particulars will be supplied on request.

periods for grinding the commutator or slip-rings, etc., as a solid rotor on this duty would tend to over heat.

The method adopted by the G.E.C. for the parallel running of rotary converters involves the use of a balancing transformer. This transformer consists of three cores, upon each leg of which two windings are arranged, each winding being in series with the corresponding phase of either rotary. It will be clear from this that when the currents are equal, the windings being reversed with regard to each other, no magnetism is induced in the core of the balancing transformer. Directly the currents become unequal, however, the magnetic balance is upset, and a voltage is induced in the one winding of such a character as to restore the balance. It is found in practice that quite a small balancing transformer is sufficient to balance large machines, and this scheme has been in successful operation in several places.

MOTOR CONVERTERS.

The Motor Converter represents a compromise between the motor generator and the rotary converter, combining the best features of each type of converting plant. It consists of a self-starting a.c. motor, the rotor of which is coupled both electrically and mechanically to the armature of a d.c. generator, about half the power supplied to the motor being transmitted to the generator by way of the shaft, and half by the electrical connections. The motor fulfils the dual functions of a transformer and a motor, while the generator similarly acts both as a rotary converter and a dynamo. The rotating parts—the rotor of the motor and the armature of the generator—run at half the speed corresponding to the frequency of supply. The motor converter is used to supply direct current when fed with alternating current, and *vice versa*, the ratio of the a.c. and d.c. voltages being determined by the design.

Comparing the three methods of conversion, the motor-generator is more expensive, takes up more floor-space, and is much less efficient than its rivals, whilst it possesses no advantages comparable with these drawbacks, except under special circumstances, such as very wide voltage regulation or very low power factor (when working d.c. to a.c.). The chief advantage of the rotary converter is that, including transformer losses, it is slightly more efficient than the motor converter at full load—about 1½ per cent. for 1,000 kilowatts. On the other hand, the motor converter has a high efficiency at half and quarter load, is not easily thrown out of step with the generating plant by a heavy drop in voltage, and is practically immune from liability to flash over on a short circuit occurring, while it can carry heavy overloads without sparking. The motor converter is very easily started up from the a.c. side and synchronised with the supply frequency, without risk of reversal of the d.c. polarity—a drawback to which the rotary converter is very subject; it can equally well be started from the d.c. side, and it works with unity or leading power factor, which varies very little when the d.c. voltage is varied over a wide range The rotor of the motor converter is usually wound for 12 phases, conferring upon it very high synchronising power and stability of running. The generator can be shunt or compound wound, according to requirements, being capable of a variation of d.c. voltage of 40 per cent.; thus it can be used alternatively for supplying a light and power system at, say, 400 volts, or a traction system at 550 volts, and like a rotary converter, it can be arranged for use in connection with a three-wire system, automatically balancing the load. As the motor and generator together have the same total number of poles as the equivalent rotary converter, each machine has fewer poles than the latter, so that a 50-cycle motor converter operates under as favourable conditions as a 25-cycle rotary converter, with corresponding advantages in respect of the wider spacing of poles (entailing less magnetic leakage) and of brushes (with consequent freedom from flash-over). As the slip rings of the motor-converter are only used for starting up, or for balancing a three-wire system, their maintenance is less onerous than that of the six slip-rings and brushes which carry the whole of the a.c load in a rotary converter.

Owing to the stator of the motor being wound for the full supply pressure (up to 10,000 volts), no transformers are necessary, and thus the floor-space occupied is a minimum; the switch-gear also is simple and compact. When exceptionally wide variations of d.c. voltage are required, the motor converter can be provided with a 'booster,' as in the case of a rotary converter, but as the booster carries only half the load, it is much smaller. The starting current is from 25 to 35 per cent. of the normal full-load current.

Whilst the machine is usually required for converting from three-phase or two-phase current, it is also suitable for use on a single-phase supply, and in this case it offers special advantages its synchronising power being practically as good as on a polyphase supply, and its efficiency being but little lower.

Motor converters run perfectly in parallel at either or both ends, and are not subject to hunting. Whilst their good d.c. regulation is highly appreciated on lighting systems, their ability to cope with heavy overloads and violent load fluctuations renders them particularly well suited for supplying d.c. tramway and railway systems.

The Peebles Motor Converters.

The Peebles Motor Converter, fig. 18 (of which *Bruce Peebles & Co. Ltd., Edinburgh*, are the sole manufacturers for Great Britain, its Colonies, and other countries), is designed to convert polyphase alternating current into continuous current or ***vice versa***. This type of machine has met with considerable success in actual practice, and it is claimed by the makers that while escaping the defects of the older types of converting plant—motor generators and rotary converters—the motor converter possesses practically all their advantages, and in addition has several valuable features peculiar to itself but unattainable in any other machine.

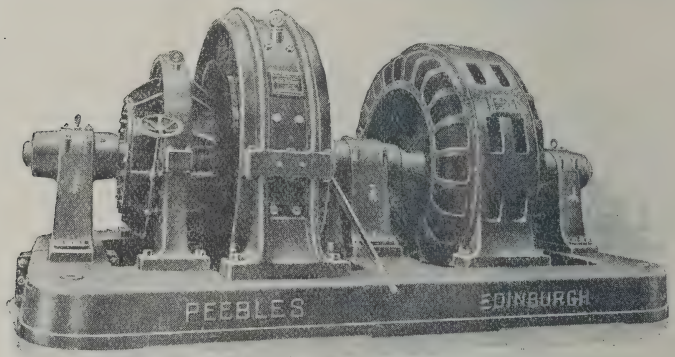

Fig. 18.—2,000 KW. 50-Cycle Peebles-la Cour Motor Converter.

An important feature of the motor converter is that transformers are unnecessary, as the stators of these machines can be wound for high-pressure currents; the rotor, however, always carries low-pressure current only.

The motor converter is self-starting, but runs synchronously when up to speed. Voltage regulation up to 40 per cent. at the continuous-current end can be obtained, an instance being the machines with this voltage variation supplied to Manchester Corporation. The motor converter is particularly suitable for 3-wire supply, as it will automatically take care of unbalanced loads. With these machines there is no possibility of reversal of polarity, and the brush-holder arms being widely spaced, 'flashing over' will not occur even under the extreme conditions of a dead short circuit.

Principle of Motor Converter.

The motor converter consists of an induction motor coupled to a D.C. generator, the rotor winding of the former and the armature winding of the latter being electrically connected. For the sake of simplicity, assume that the induction motor and D.C. generator each have the same number of poles, and—leaving out the question of starting—that the combined rotating element revolves at a speed corresponding to half the synchronous speed of the induction motor, or, in other words, that the 'slip' is 50 per cent. It follows that the rotating field set up in the stator by the supply current rotates relatively to the rotor at a speed corresponding to half the periodicity of the supply circuit, and it thus induces in the A.C. rotor windings a series of E.M.F.'s which will have a periodicity equal to half that of the supply circuit. Now the number of poles of the D.C. generator is assumed to be equal to that of the induction motor, and the D.C. armature being coupled to the induction motor rotor is rotating at a speed corresponding to half the periodicity of the supply circuit; therefore the E.M.F.'s induced in the D.C. armature winding must have the same periodicity as the E.M.F.'s in the A.C. rotor winding. On account of this fact it is possible to connect the rotor and armature windings together (provided each is wound with a suitable number of turns); when such connections are made the speed remains constant, and the two ends of the motor converter thus connected together operate as a single synchronous machine.

Owing to the induction motor rotor revolving at a speed corresponding to half the periodicity of the supply circuit, only half the electrical energy led into the stator is converted into

mechanical energy, and transmitted by means of the shaft to the D.C. generator; the other half of the supplied energy, however, is transferred through the inter-connections between the two halves of the combined rotor to the D.C. armature in the form of electrical energy; thus the induction motor operates half as motor and half as transformer, while the D.C. generator operates half as an ordinary generator and half as a rotary converter.

As the size of the induction motor depends on the speed of the revolving field and not on that of the rotor, the motor of a motor converter is, theoretically, only half as large, at the motor converter speed, as it would require to be if it converted the whole of the electrical energy led into it into mechanical energy. Similarly the D.C. generator of a motor converter runs at a speed corresponding to half the frequency of the supply circuit—which, incidentally, is of considerable advantage from a commutation point of view—and consequently it is smaller than (for the same output, primary frequency and speed) an ordinary D.C. generator or rotary converter would be.

The rotor is generally built with twelve phases, and this accounts for an exceedingly strong synchronising force which makes it almost an impossibility for the motor converter to fall out of step.

Fig. 19 shows a simple diagram of connections of the Peebles Motor Converter.

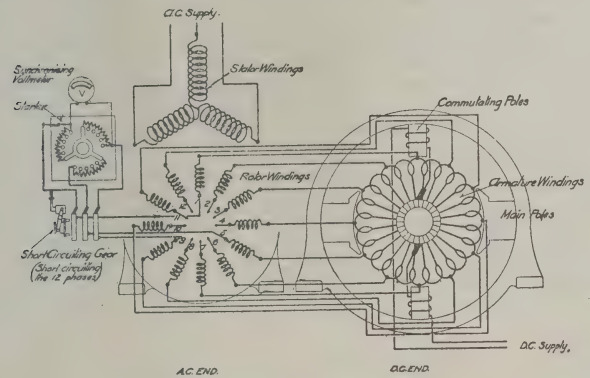

FIG. 19.—Diagram of Connections of Peebles Motor Converter.

The synchronising current taken at no load is only the watt current necessary to cover the no-load losses, the absence of higher harmonics being due to the feature of the polarity of the revolving field, and to the high reactance of the A.C. end. The motor converter can be used for power factor correction at a certain predetermined load and voltage ratio.

Spare or stand-by motor converters may also be used solely as power factor improvers. When a motor converter is to be used for this purpose, it is run up and synchronised as usual on the A.C. side, but the D.C. circuit is left 'open,' and if the D.C. excitation is sufficiently increased by shunt regulation the A.C. side will supply leading wattless current.

General Design and Construction.

Motor converters are generally provided with three bearings, the electrical connections between the rotor and armature being carried by leads through hollow portions of the shafts. The slip-rings are placed close to the rotor windings and are of small dimensions, their function being merely to start the machines, and in 3-wire installations to carry out-of-balance current. All motor converters are fitted with slip-ring short-circuiting gear, which is brought into operation when the machines are synchronised.

Standard motor converters are fitted with commutating poles and will carry 100 per cent over-load for short periods without any injurious sparking at the commutator, and with fixed brush position.

Machines for traction service are arranged to compound automatically from 500 volts at no

load to 550 volts at full load; the power factor is unity at about three-quarter load, while at larger loads the wattless current is leading, this having a favourable effect on the supply system.

A feature of motor converter installations is the simplicity of the control gear, rendering skilled attention unnecessary.

Mercury Vapour Rectifiers.

The necessity of converting alternating to direct current in many cases, and the desirability of dispensing with running machinery in sub-stations, etc., has led to the development of the rectifying properties of the mercury vapour lamp for this purpose. Essentially the rectifier consists of an arc *in vacuo* between iron anodes and a mercury cathode, which allows the current to pass in one direction only, namely, from the anodes to the cathode, as the names imply. In order to enable the rectifier to deal with large amounts of power, the original glass bulb has been replaced by a steel container, the difficulty of making stanch joints having been overcome; and whereas in rectifying single-phase current the resulting unidirectional current pulsates between zero and a maximum value, in the case of three-phase current the pulsations are reduced in amplitude by using three anodes connected to the three phases, or better still, by connecting the transformer to give six-phase current and using six anodes, the fluctuation can be almost wholly eliminated. Rectifiers of this type can now be made for outputs of 250 kw. per cylinder, and being characterised by low first cost, small depreciation and maintenance, and high efficiency, besides requiring very little attention, are rapidly coming into use. They work well in parallel with one another and with a battery, and possess the property of close regulation; the average overall efficiency is about 90 per cent., the power factor on full load about 94 per cent., and the rectifier is practically independent of frequency and wave-form. Installations up to 16,000 amperes at 250 volts are in operation, and as there is a constant drop of 15 to 20 volts through the rectifier, the higher the voltage the higher the efficiency.

The rectifier consists of a steel cylinder, exhausted to at least 0·1 mm. of mercury, with the mercury cathode at the bottom and six iron anodes suspended from the cover, suitably insulated. Auxiliary anodes, one for starting the rectifier (which operation takes only a few seconds) and two for excitation (to keep the rectifier in operation if the load temporarily falls to zero), are provided. The rectifier chamber is water-cooled, as the temperature in the interior must not exceed 70° C., and a cooled chamber on the top of the main cylinder condenses the vaporised mercury, which returns to the cathode by gravitation. A vacuum pump is necessary to maintain the high vacuum, but after a few months' working the residual gases are all removed and the pump need not be used. Choking coils or induction regulators ensure stability of operation and provide means of regulating the D.C. voltage. The transformer used in conjunction with the rectifier is specially wound, and is practically equivalent to an ordinary transformer of a kvd. rating about 40 or 50 per cent. larger than the D.C. output. A 750-kw. rectifier occupies about the same space as a rotary converter of 100 kw., and weighs 4,100 kilograms.

The 'Tungar' rectifier, which is suitable for charging small storage batteries, is more closely allied to the 'valves' used in wireless telegraphy, the cathode being an incandescent filament.

COST OF ELECTRICAL ENERGY.

Electricity is now supplied in all industrial districts and large towns in the United Kingdom at cheap rates, the figures in Table I being typical of average prices in 1919. The cost of producing the Board of Trade unit is widely used as a means of comparing the economy of one station

TABLE I.

South Metropolitan Company	9,800	0·96	1·51	8·19

with another, and the selling price per unit is also commonly used as a measure of the excellence of an electricity supply undertaking, but these values depend so greatly upon local conditions that such comparisons are very misleading unless qualifying factors are introduced to take account of these. The table shows that wide variations exist in the cost of production and the average price received. The figures for power companies are not published, but are generally lower than those given in the table.

The total cost of supplying electricity is made up of :—

Power Station Charges.—Capital charges (interest, reserve, depreciation and sinking funds—say, 10 per cent. on the capital) ; fuel and stores ; wages and salaries ; repairs, rents, rates, etc.

Distribution Charges.—Capital charges ; maintenance, rates, wages, salaries, etc.

The total capital charges usually represent about 50 per cent. of the total cost of supply. The average cost of connecting a consumer, including the service main, meter, and proportion of the distribution main, is about 25*l.* The coal bill represents about 25 per cent. of the cost, and the other charges make up the remaining 25 per cent. If, therefore, by using their supply for longer hours without increasing the maximum demand, consumers double the number of units supplied to them, the cost of the whole supply will only be increased by 25 per cent., and the average cost per unit will be reduced by 37 per cent. As the distribution capital represents about half the total capital, and the cost of transformation, distribution, and maintenance of meters represents some 20 per cent. of the total cost, no decrease in the price of energy supplied in bulk from super-stations can possibly result in a very large reduction in price to the small consumer ; he can make a greater reduction in the price per unit himself by making a better use of the supply. In an ordinary private house, if the units used for lighting are about 300 per annum, the units used for heating and cooking will be about 3,000 per annum. Taking the price for lighting at 6*d.* per unit, and the price for heating and cooking at 1*d.* per unit, the average price per unit will be 1·4*d.*

Table II shows the cost of underground and overhead transmission lines. Under the best conditions, the cost of transmission for distances exceeding 20 miles is a serious item. The increased cost of plant and mains implies that the supersession of existing plant will be delayed.

TABLE II.—SHOWING THE COST OF TRANSMISSION SYSTEMS AT 1919 PRICES FOR LABOUR, TAKING COPPER AND LEAD AT 100*l.* AND 25*l.* PER TON RESPECTIVELY.

Two cables and six overhead wires are included in each line to work with three-phase alternating current. (*J. S. Highfield*, '*Journal of the Society of Arts.*')

Electricity Supply.

The standard pressures of supply laid down by the British Engineering Standards Association (Report No. 77—1921) for new systems and installations are as follows (at consumers' terminals):—

Direct current, 220 and 440 volts; alternating current, 240 volts between neutral and each phase, 416 volts between phases.

Extra high pressures, 3,000, 6,000, 10,000, 30,000, 60,000, 100,000, and 120,000 volts.

In each case the station pressure is assumed to be 10 per cent. higher at full load.

Under present conditions the cost of generating electrical energy in power-stations has increased by more than 100 per cent. compared with pre-war conditions. At the large power-station of the Detroit Edison Company at Connors Creek, U.S.A., the following results have been obtained (cents per kilowatt-hour) :—

	Year ended June 30.	
	1916.	1920.
Operation :—		
Superintendence	0·013	0·010
Wages	0·043	0·062
Fuel	0·158	0·471
Lubricants	0·001	0·001
Station supplies	0·005	0·011
Maintenance :—		
Station buildings	0·006	0·010
Steam equipment	0·019	0·036
Electrical equipment	0·003	0·001
Total	0·248	0·602
Kilowatt-hour output	125,158,800	488,060,600
Maximum demand (30 minutes), kw.	35,000	104,000
Average load, kw.	14,300	55,600
Load factor	0·409	0·534
Coal per kw.-hr., lb.	1·44	1·83
British thermal units per kw.-hr.	19,700	22,800

This station is one of the largest and most up-to-date in the world. It should be observed that the costs given above are production costs only, to which must be added interest and depreciation charges, management, taxes, etc., and the cost of distribution, in order to arrive at the selling price.

Averaging twelve stations in 1920, aggregating 250,000 kw. capacity, the cost of production was 1·35 cents per kw.-hr., the total operating cost 2·625 cents per kw.-hr. sold, the coal consumption 2·4 lb. per kw.-hr. generated, and the load factor from 30 to 40 per cent. The average revenue per kw.-hr. sold was 3·9 c., and the average prices were for lighting 9·1 c., and for power 2·6 c. (*'Electrical World.'*)

An examination of some 120 European installations shows that for large examples of over 10,000 e.h.p. the minimum cost of the hydraulic works is 8·4*l.* per h.p. installed and the maximum 79·6*l.* per h.p. For the majority of the installations the cost lies between 25*l.* and 45*l.* The cost of the electrical plant and transmission lines also varies greatly, ranging from 1·25*l.* to 28·4*l.* per h.p., while the cost of the turbines ranges from 4*l.* to 8*l.* per h.p. The working costs vary between 1·3*l.* and 6·8*l.* per e.h.p. year, with an average of 3*l.* From these figures it appears that on the average, allowing 15 per cent. for interest and depreciation, the cost per e.h.p. per annum is in the neighbourhood of 10·5*l.* In many cases, however, the cost is very much less. The Ontario Power Company, for example, is able to supply power to the Hydro-Electric Commission of Ontario at 1·8*l.* per e.h.p. per annum. It is estimated that many of the large powers in Canada can be developed at a total cost, including all generating machinery and transmission lines, ranging from 12*l.* to 20*l.* per e.h.p., in which case the cost per h.p. per annum should not exceed 2*l.* to 3*l.*

(*Times Engineering Supplement.*)

Diversity Factor.

The 'diversity factor' is the ratio of (the sum of all the individual maxima of the various motors or factories supplied) to (the maximum actually observed at the plant supplying them). Thus in a factory the sum of the maximum outputs of a number of motors over a given period may be 1,000 horse-power, while the highest observed load at the power house at any one time during that period may not exceed 700 horse-power, owing to the fact that the motors are not all working at their greatest load at one time. In this case the diversity factor would be 1·43.

Similarly over a large supply area the sum of the maxima of all the factories, etc., supplied will be greater than the maximum load at the power house. The diversity factor varies in different localities and in different industries. At Sunderland the diversity factor is 1·25, at Leeds 2·40 an average value would be 1·6. The diversity factor is not necessarily the same thing as the ratio of the total kilowatts installed to the maximum load observed, although the two have a certain connection. (*Snell, Journal Inst. E.E.*)

Periods allowed for Repayment of Loans by the Electricity Commissioners.

Purpose of Expenditure.	Maximum Periods., Years.
Land—	
Freehold	60*a*

MOTORS.

DIRECT-CURRENT MOTORS.*

Shunt-wound Motors.

This is by far the most common type of winding, and is generally applied to motors designed for operating at constant speed under constant or varying loads. Nearly all commercial applications, particularly those of large capacity, require this type of motor. When necessary, considerable speed variation can usually be secured by means of a rheostat in the field circuit, increased resistance resulting in an increased speed.

* Abstract from British Westinghouse Instruction Book ; by permission.

It is the practice on many shunt-wound commutating-pole motors to use a stability winding for the purpose of insuring stability under all conditions of operation. This is, in effect, a light series winding which, however, does not change the speed-torque characteristics from those of an ordinary shunt-wound motor.

Series-wound Motors.

These are variable-speed machines particularly adapted to such uses as railway and crane service. The characteristic features of a series-wound motor are its great torque at starting and low running speeds possible.

Compound-wound Motors.

For some special classes of service, in which it is necessary to start under heavy load and later operate at approximately constant speed, a series winding is added to assist the shunt field at the low-speed points. A compound-wound motor combines the characteristics of both shunt and series-wound motors. In most cases, however, the series winding has comparatively little effect except during the starting period.

Starting.

All direct-current shunt and compound-wound motors larger than the very small sizes are started by first giving the shunt field full excitation and then connecting the armature, with a starting resistance in series, to the circuit. The resistance is then cut out in steps as the motor accelerates, the time required to attain full speed varying from about 15 seconds for small, to one minute for large motors. These limits should be used with discretion, since more time is required to start with heavy load than with light load.

After all connections are made according to instructions and all mechanical preparations are complete, see that all the field adjusting resistance (if used) is cut out and that the starting resistance is all in circuit. Close the circuit-breaker (if used), then the line switch, and lastly cut out the starting resistance step by step, allowing enough time for smooth speed acceleration. Too rapid starting results in excessive starting current and possibly flashing at the brushes. The motor should generally start when the armature circuit is first closed through the starting resistance, and failure to start when the second or third step of resistance is cut out is a signal to open the line switch or circuit-breaker at once and find the cause of the failure.

Stopping.

Never move a starter or controller handle to the off position under any circumstances if by doing so the shunt-field circuit of the motor is opened. The high inductance of the motor field may generate voltage enough to puncture the insulation. If it is necessary to open a shunt-field circuit it should be done very slowly, allowing the field current to die out, owing to the resistance of the arc across the switch terminals. If a field circuit must be opened in this manner often, a field switch should be installed, so that a local circuit is closed through the field before the latter is disconnected from the line. Starting rheostats are usually so arranged that the field circuit is always closed through the motor armature. If the starter or controller is provided with a low-voltage release, the line switch or circuit-breaker should always be opened first for stopping; the motor speed will then decrease until the starting resistance is automatically cut into circuit.

Brushholder Adjustments.

The correct position for the brushes in either direction is clearly marked before the machine is shipped, and before starting up the position should be checked. Sparking at the brushes when the machine is operating with load can frequently be entirely removed by shifting the brushes slowly from or towards the neutral point. In any case the correct distance of the brushes from the neutral point is very slight, and the movement should be made with great care, for shifting the brushes too much will cause violent sparking.

Care of Commutator and Brushes.

Carbon brushes are used on all Westinghouse direct-current machines. The chief considerations in caring for such machines are to keep the commutators clean, the brushes properly adjusted, and the contact surface of the brushes good. The last condition, once fulfilled, will usually take care of itself until the brushes are worn out, provided the other conditions are complied with. At intervals depending on the service and the location, the commutator contact surface and end should be thoroughly wiped with clean cloth that is free from lint.

A few drops of oil on the cloth or a piece of paraffin rubbed lightly across the commutator surface will give all the lubrication necessary. Lubricant should be used very sparingly on a commutator, and no grease, oil, or dirt should be allowed to accumulate on the commutator or the brushes.

The ideal appearance of a commutator surface is polished dark brown or chocolate colour. Such a commutator needs no attention other than cleaning when necessary. If the surface has a raw copper colour with gradual roughening, it should be smoothed with sandpaper or, if very rough, with a piece of sandstone; emery paper or cloth should not be used for this purpose. The sandpaper should be held against the commutator by means of a block having the same curvature as the commutator. The sandstone likewise should be curved to fit the commutator. The brushes should be lifted from the commutator surface when using sandpaper or stone, and should not be placed in contact again until the commutator surface is thoroughly cleaned of all gritty particles

Grinding in the Brushes.

When making proper contact with the commutator, the face of the brush is glazed. If the glazed portion does not extend over very nearly all the brush face the brushes should be ground in by wrapping a long strip of fine sandpaper closely around the commutator with the rough side toward the brushes and then rotating the commutator and the sandpaper slowly through perhaps one revolution. Shorter pieces of sandpaper held close to the commutator surface and drawn a few times back and forth under each brush or set of brushes will answer the same purpose. The commutator surface should be wiped clean after the brushes are ground in, and lubricated with a few drops of fresh oil on a clean cloth.

Field Coils.

An open-circuited shunt field coil can be detected by touching the terminals of a voltmeter to the terminals of the individual coils while full voltage is applied to the field circuit. The voltmeter will show no deflection until the defective coil is reached and will then indicate the full voltage.

A short-circuited shunt field can be found by the same test, the voltmeter deflection being least on the defective coil. The short-circuiting of one field coil may easily result in burning out one or more of the others if full voltage is applied to the circuit, unless a resistance equivalent to that of a perfect coil is included in the circuit.

In replacing a field coil make sure that the polarity of the pole differs from that of either adjacent pole. The polarity can be tested with a small bar magnet or a piece of steel wire suspended from its centre by a string. In holding the magnet near the poles successively, it should reverse at each pole, i.e. no two successive poles should attract the same end of the magnet.

Cautions.

Never allow the load to be entirely removed from a series-wound direct-current motor while operating, or to be reduced enough to cause a dangerously high speed. A series motor should not be belted, on account of the possibility of the belt running off, thus permitting the motor to race.

Never open the shunt-field circuit of a motor in operation, otherwise the motor will race, and serious damage will result.

When the shunt-field circuit of a motor or a generator is excited, never open it quickly unless a path for the inductive discharge is provided. The circuit can be opened slowly, if desired, the arc at the opening serving to reduce the field current gradually. *Do not permit any part of the body to bridge this opening*, or a serious shock will be received.

Always follow a fixed regular order in closing and opening switches, unless there are special reasons for departing from this order. A routine method will aid in avoiding mistakes. Keep all switches open when the motors are idle. Close switches carefully, keeping firm hold of the handle until completely closed.

A routine method of making inspections, replenishing lubricants, etc., will also prevent oversights and possible damage.

Speed Regulation of Direct-current Motors.

There are three commercial methods of varying the speed of direct-current shunt-wound motors : (1) by altering the terminal voltage ; (2) by a resistance in series with the machine ; (3) by a resistance in series with the shunt circuit. The first method is not employed as a rule with the ordinary industrial motor, but is only used in connection with self-contained plants such as winding, and certain printing press control equipments. The second method is largely adopted where only a small regulation is required, but it is not efficient by any means, and a fine regulation is difficult to obtain, the power consumption of the motor remaining practically the same throughout the whole range of speed, a large amount of the power being dissipated in the resistance. The method is convenient where it is desired to regulate the speed down to about half for very short periods, such as for crane and haulage work. The third method of control is one which has received a good deal of attention during the last few years, and Messrs. Crompton & Co. have developed a line of motors which are capable of speed regulation by field resistance up to 4 : 1 and in certain cases up to 6 : 1, the torque being maintained constant over the whole range.

APPROXIMATE COMMERCIAL EFFICIENCY OF DIRECT-CURRENT MOTORS PLOTTED AS A FUNCTION OF THE BRAKE H.P.

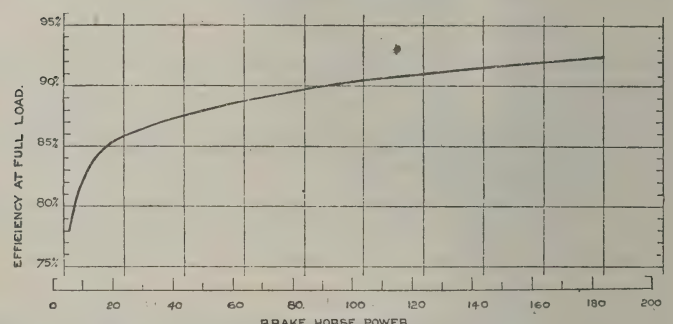

FIG. 20.

Such large variations of speed generally require some special device to compensate for the cross magnetisation of the armature due to armature reaction, and in this series of motors interpoles or auxiliary poles are employed. The poles are placed mid-way between the main field poles and carry either the full armature current or a percentage of it. The interpole flux therefore varies directly as the load and as the armature reaction, and as the tendency of the motor to spark increases as the load, so the compensating flux increases proportionately.

The size of motors with shunt regulation is determined by the minimum speed and the maximum b.h.p., although it may be necessary for the motor to give a much lower output at the minimum speed. This is clear when it is considered that minimum speed requires maximum flux and maximum speed requires minimum flux, that the magnetic circuit must be large enough to carry the full flux, and that the dimensions of the armature are also determined by the number and size of the armature conductors. The only variable, therefore, is the field flux. The efficiency does not largely vary throughout the range of speed at a given load, owing to the fact that at the minimum speed the electrical losses are a maximum, whereas the friction and windage losses are a minimum ; but at the maximum speed the electrical losses are a minimum and the friction and windage losses a maximum. The curve shown in fig. 20, giving the full-load commercial efficiency as a function of the brake horse-power, is typical of constant speed motors running at the normal speeds recommended by the British Engineering Standards Association. Motors with series resistance regulation have their sizes determined by the maximum speed and maximum output, and although the torque can remain constant throughout yet the output or power will be reduced in proportion to the speed.

The Direct-current Series-Wound Motor.

Fig. 21 is a view of a standard direct-current series-wound motor made by the British Westinghouse Electric Company for tramway service. This motor is of 45 b.h.p.; the field frame is of cast steel divided into an upper and lower half, the two parts being hinged together on the side opposite to the axle. The figure shows the lower half hanging open, exposing the armature, the bearings of which are bolted to the upper half of the frame. The pole pieces are built up of annealed soft-steel punchings riveted together between wrought-iron end-plates.

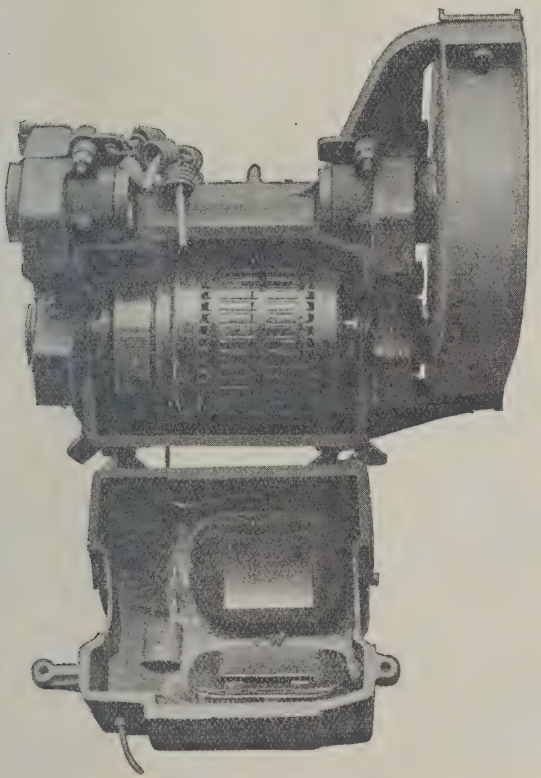

FIG. 21.

The field coils shown in the figure are held in place by a brass support resting on the projecting pole tip. The armature is of the slotted drum type, the core being built up of annealed soft-steel punchings. Ventilation is provided by six axial and one radial air-duct. The armature coils are completely formed before being put in place and are held by steel wire bands sunk in the surface of the armature, so that in the event of the armature bearings being worn the bands do not touch the pole pieces. The winding is of the two-circuit type designed to give a balance of armature circuits should the armature get out of centre owing to wear of bearings. The commutator consists of 117 hard-drawn segments pressed on and keyed to the armature spider. The bearings are of cast iron with special Babbitt metal linings; either oil or grease may be used. The pinion is of forged steel and the gear wheel of cast steel made in two parts bolted

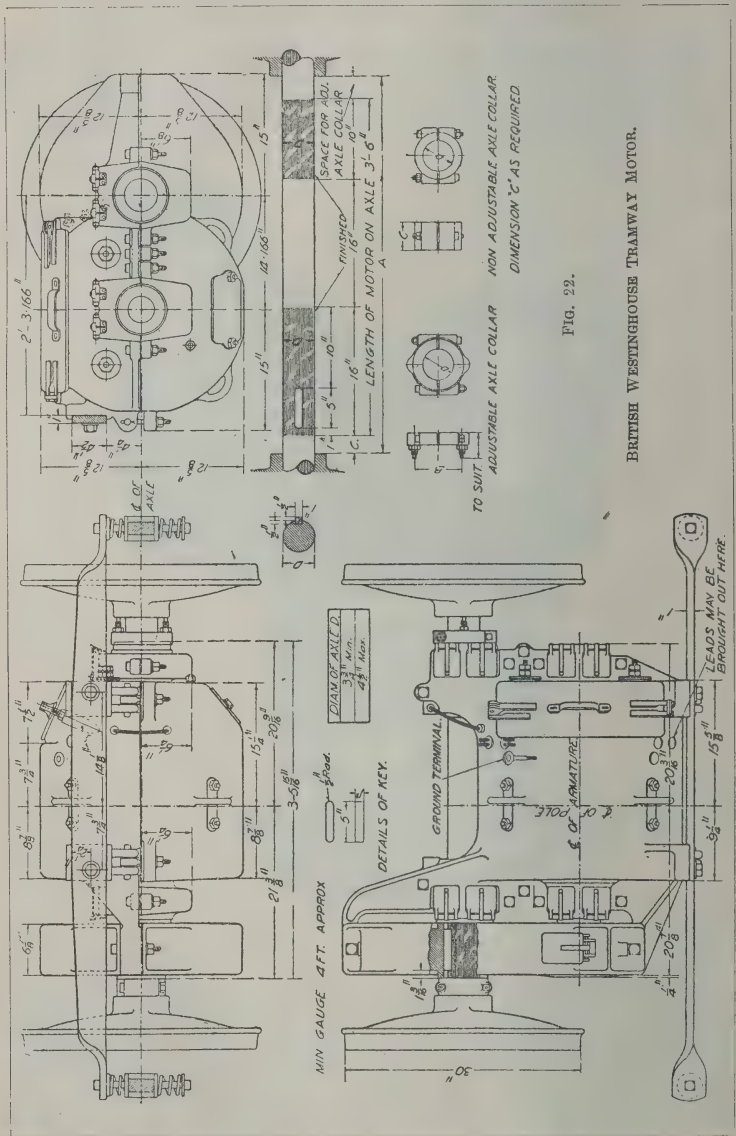

FIG. 22.

BRITISH WESTINGHOUSE TRAMWAY MOTOR.

together. The gears that may be used vary from a 15-tooth pinion and 70-tooth gear to a 22-tooth pinion and 63-tooth gear; the standard gear ratio is 16 to 69.

Fig. 22 illustrates the method of suspension, which in this case is what is known as the cross-bar type. A rectangular suspension-bar is supported on the truck frame, and the motor is bolted to this through machined facings on the upper field-frame. On the other side the motor is supported on the gear-wheel axle in the usual way.

The weights of this motor are as follows. Motor complete with gear-wheel and gear-case, 2,764 lbs. Armature and pinion alone, 540 lbs. Axle gear-wheel and case alone, 340 lbs. The clearance between the top of the rail and the lowest part of the motor with 30 in. wheels is $2\frac{3}{8}$ ins.

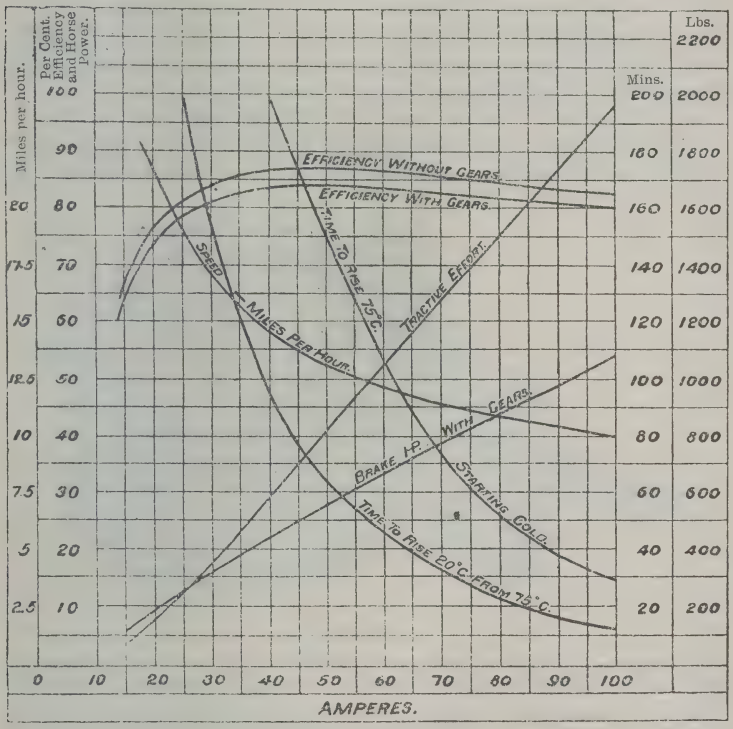

FIG. 23.

Fig. 23 gives the characteristic curves for this motor, from which all necessary information regarding the performance of the motor may be derived. The curves given are those of efficiency, speed, tractive effort, horse-power, and temperature.

The upper temperature curve shows that under the standard conditions under which tramway motors are generally rated, i.e. 75° C. rise in temperature after one hour's continuous run, the corresponding current for this motor would be 75 amperes, which at 500 volts represents an input of 37,500 watts. Following the 75-ampere line to the speed curve, the speed for this current and volts is seen to be 11·1 miles per hour, and continuing the ampere line up to the tractive effort curve the tractive effort is seen to be 1,380 lbs.: this is the useful draw-bar pull with gear and driving wheel used in the test. Using the formula watts $= 2 \times S \times T$ the output in watts is found to be 30,600, or 41 horse-power, giving an efficiency of 82 per cent. as shown on the efficiency curve for 75 amperes. The corresponding efficiency without gears is

given as 85 per cent., representing a draw-bar pull of 1430 lbs., showing a loss of 50 lbs. in the gears. The above rating of 41 horse-power is that for one hour's run; the continuous rating will be considerably less than this, and depends upon the mean terminal voltage. The continuous capacity at 300 volts is given as 38 amperes and is equivalent to a load of about 550 lbs. at the draw-bar. On the other hand the motor will stand large momentary overloads without injury or sparking.

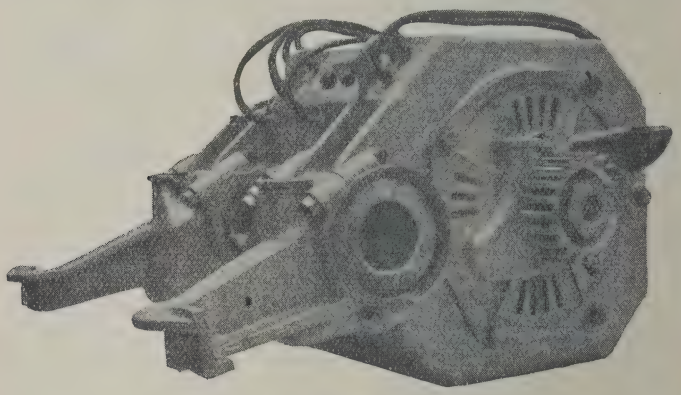
Direct-Current Traction Motors.

(*The English Electric Co., Ltd.*)

The Direct Current series wound traction motor gives in result the effect of the change-speed gear of a motor-car engine, which enables a small-powered motor to exert a big effort when required for acceleration or for climbing gradients. It is capable of working both large and small units both for short distances and main line traffic. The three features of design which have contributed to give the D.C. Motor its present wide range in traction work are:—

(*a*) commutating poles; (*b*) ventilation; (*c*) high-tension design.

(*a*) *Commutating Poles.*—The coils are connected in series with the armature, and their effect is to counterbalance the field set up by armature reaction under the brushes, so that commutation under all conditions of loading is practically sparkless, even with a field shunted, thus giving a range of economical speeds to traction equipments.



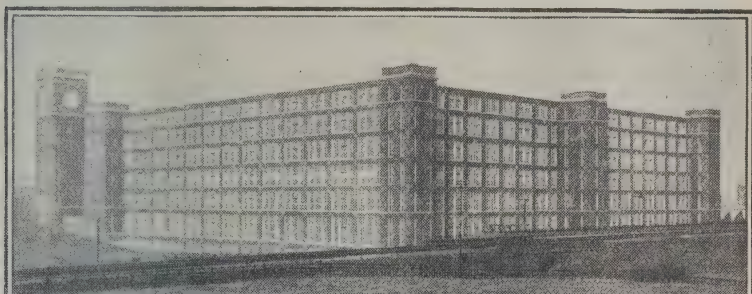


FIG. 24.

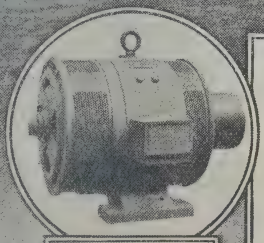
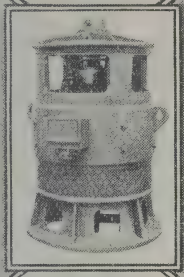
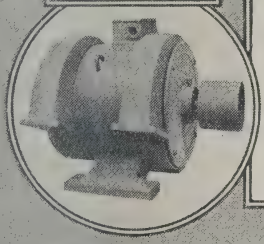


(*b*) *Ventilation.*—Through the introduction of ventilation, it is now possible to transmit up to 400 h.p. on a single axle, on standard gauge, with 48-in. wheels, on the one hour rating of the motor.



All motors manufactured by *The English Electric Co.*, ranging from 30 h.p. to 400 h.p., are fitted with interpoles and are either self or force ventilated. Motors up to 250 h.p. are self-ventilated by means of a fan, which forms part of the armature spider at the pinion end. The air is drawn in through apertures at the commutator end of the motor, and expelled at the pinion end. The fan is provided with two sets of blades, one of which draws the air through ventilating ducts in the armature, and the other over the surface of the armature and round the fields. Motors over 250 h.p. are arranged for forced ventilation in which the air is driven through the motors by means of separately-driven fans.



(*c*) *High-tension D.C. Motors.*—High-tension D.C. motors are successfully in use on the Lancashire and Yorkshire Railway, and on the Newport-Shildon Branch of the North-Eastern Railway, the voltages being 1,200 and 1,500 respectively. Lines up to 3,000 volts direct current are in successful operation abroad, and this voltage has been recommended for use on the South African railways.

The high-tension motors are specially insulated, mica and mica compounds being used throughout for the insulation of armature, field coils, and brushes, so that the di-electric strength of the machines is not affected by high temperatures.

A.C. & D.C. INDUSTRIAL ELECTRIC MOTORS

LONG designing and manufacturing experience coupled with a close study of customers' requirements, enable the English Electric Company to supply reliable electric motors to meet all industrial requirements.

The illustrations show a typical enclosed ventilated motor, a vertical spindle motor and a drip-proof motor, while the background illustrates a large modern factory equipped with English Electric Motors.

Cascade Induction Motors

NOTABLE in the simplicity of their construction, Cascade Induction Motors possess all the advantages of the 'Slipring' type of motors without the use of sliprings or rubbing contacts.

Very high power factor and efficiency are ensured by their special design and mechanical construction.

Cascade Motors are particularly suitable for Mining Machinery. They are also thoroughly efficient for driving all classes of machinery, and have proved successful where Motors of ordinary construction have failed.

On the larger sizes—such as the 350 h.p. motors supplied to the Chemin de Fer du Midi—the motors drive on to the axles through twin gearing, the teeth of the pinions at each end of the armature being staggered to assist in giving uniformity of turning moment.

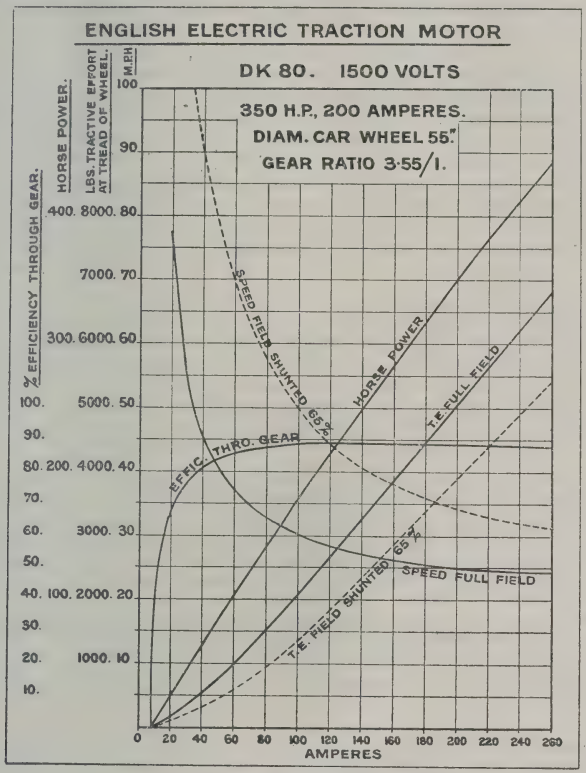

FIG. 25—Alternating-Current Motors,

Fig. 24 shows a typical English Electric 350 h.p., 1,500 volt, traction motor, of which the characteristic curve is shown in fig. 25.

ALTERNATING-CURRENT MOTORS.

Alternating-Current Motors may be divided into the following classes:—Synchronous, Induction, and Commutator Motors.

Synchronous Motors.

An alternating-current generator will, if brought up to speed, excited, and connected to a suitable alternating-current supply, run as a motor at a speed in revolutions per second equal to the frequency divided by the number of pairs of poles. Such motors are called synchronous motors and they will operate only at approximately synchronous speed. They will not start under load, and have to be started by auxiliary means. If overloaded beyond a certain point they will fall out of step with the primary current and come to a standstill. Their sphere of usefulness is limited, and they are most commonly employed as phase regulators on transmission lines, or for driving direct-current generators.

Induction Motors.

Induction motors may be divided into polyphase and single-phase induction motors. The action of a polyphase induction motor may be likened to that of a continuous-current motor in which both the fields and the armature are capable of rotation. Supposing the fields of such a motor to be fully excited, and rotating at full speed with the armature at rest, a current of any desired magnitude may be induced in the armature by simply short-circuiting it, since the generation of a current depends simply on the relative motion of the fields and the armature. The torque produced by the action of the fields on the induced current will tend to turn the armature, and if the fields be kept rotating at a uniform rate, the armature will speed up until the relative motion of the fields and the armature is sufficient to generate a current that exactly balances the load; uniform speed has then been reached. The slip, or the difference between the speed of the armature and the speed of the fields, is generally stated in per cent. of the speed that would be reached if the load were nothing, that is, if the armature were rotating at the same speed as the fields. This speed is spoken of as the speed of synchronism. In a polyphase induction motor the rotation of the field is produced by magnetising the fixed part, or stator, by two or more alternating currents in such a way that the resultant magnetic field rotates at a uniform speed. Generally three alternating currents are used differing in phase by 120°. One advantage of such a motor over the continuous-current motor is found in the absence of a commutator, for the current in the armature, or, as it is called, the rotor, can be induced by short-circuiting its coils, the current from the line being led directly into the stator without any moving contacts.

In the single-phase induction motor there is an inductive action between the field and the armature, similar to that which takes place in a polyphase induction motor: the field, however, is not a simple rotating field but may be regarded as two fields rotating in different directions. The result of this is that at starting the armature is subject to an equal pull in both directions—in other words, the motor will not start by itself. But when once the armature has been started in either direction and brought up nearly to the speed of synchronism of either one of the two fields, it will follow that field as if the other were not present. This type of induction motor therefore needs some special device to enable it to be started. Such a device is used in the Heyland single-phase motor, which will start up on full load torque with about twice the current required for an equal torque at full speed.

In a polyphase system the ratio of the current usefully employed to that generated, as measured by the power factor, depends mainly upon the width of the air-gap between the fixed and moving parts of the motor. Hence it is of great importance to reduce the clearance to the smallest limit consistent with safety. This necessitates very careful construction and special precautions have to be taken to prevent any chance of contact between the rotor and the stator. Some mechanical engineers consider the necessity of such a small clearance to be a fatal objection to the use of polyphase motors on railways, but experience shows that such motors can be constructed to run continuously without accident.

Variation of Speed with Load.—In a polyphase motor the speed is nearly independent of the load. This is in marked contrast to the action of a continuous-current series-wound motor, such as is generally used on electrical railways, in which a reduction of speed of 40 per cent. from no load to full load is not uncommon. The polyphase motor maintains the speed at the expense of a corresponding amount of power, while the continuous-current motor economises power at the expense of speed.

Maximum Load.—As the load increases the speed slightly decreases. As the load still further increases, the speed falls off in a greater ratio, until the maximum load is reached. This is called the breakdown load. If the load be increased beyond this the motor cannot recover itself, and is brought to a standstill. In practice the working load should not exceed 50 to 60 per cent. of the breakdown load.

Speed Regulation.—If a resistance be placed in the circuit of the rotor so as to increase the total resistance, say, to double it, the slip for equal torque will be double what it was with the original resistance. The breakdown load is the same as before, but takes place with twice the slip. Thus with any load any required speed can be obtained by merely altering the rotor resistance.

Starting.—There is a certain rotor resistance corresponding to standstill with maximum torque. If the rotor resistance has this value at the moment when the motor is connected to the line, it will start with its maximum torque. If the resistance is taken out of the circuit as the motor speeds up, the torque can be maintained constant and equal to the maximum starting value up to full speed for that load. In other words, the torque and therefore the acceleration can be maintained constant practically up to full speed.

Windings.—There are two kinds of windings. In the first the rotor winding consists of copper bars, rather longer than the rotor core, which are all connected together at their ends. In the second the rotor has a bar winding arranged in such a manner as to allow of an outside resistance being introduced into the rotor at starting to supplement for the time being the resistance of the bars. The former is shortly described as a 'short-circuited' rotor, the latter as a 'wound' rotor.

Comparison of Motors.—From the above it will be observed that, whereas in the motor with the short-circuited rotor there must be, owing to the low resistance of the bars, a considerable rush of current at starting, in the motor with the wound rotor the current at starting may be kept quite low by means of the supplementary resistance. When giving its full load effort, at starting, a wound rotor with resistance in its circuit will take little more than its normal full load current, but a short-circuited rotor will take several times this. If the latter has only to exert at starting a fraction of its full load effort, the current can be kept down by using a starting transformer. This appliance feeds the motor at reduced pressure until it begins to get up its speed, when by a switch it is put out of action.

On account of the constructional simplicity of short-circuited rotors it is preferable, whenever possible, to use motors having these. Save as regards starting current, the short-circuited rotor is superior in every respect to the wound rotor. The momentary excess of current it takes at starting does no harm to the motor itself, but its effect on the regulation of the supply system may be sometimes objectionable, a point which must be carefully considered.

Effect of Starting Motors.—In choosing motors it is necessary to distinguish between those intended to work on town supply mains where the greater part of the current is used for lighting, and those suitable to a scheme in which the bulk of the current is used for power, the lighting being but incidental. In the former case it is necessary that the working of motors should not interfere with the constancy of pressure on the lighting circuits; in the latter case an occasional jump in the lighting may be of no importance.

The effect of a sudden overdraft of current at a low power factor is disturbance to a greater or less extent of the whole supply system, and fluctuations in pressure such as would cause no inconvenience in the working of a power transmission plant would not be permitted on town lighting circuits. The magnitude of the disturbance depends primarily on the amount of the overdraft relatively to the capacity of the generating plant, and to the margin of current-carrying capacity in the supply network.

Choice of Motors.—It will be evident from the foregoing that the choice of the motor depends upon circumstances, and that neither class can be pronounced the better under all conditions.

Motors with short-circuited rotors take momentarily about three times their full load current, if at starting they have to give their full load effort, or from one to one-and-a-quarter times their full load current giving 25 to 30 per cent. of their full load effort, and using a starting transformer. For connection to town mains it is usual, consequent on the possibility of disturbance to neighbouring lighting circuits which might arise from the starting, to limit this class of motor to 5 h.p. or so, when it has to start at full load effort, or to 10 h.p. when operated with a starting transformer.

In a power transmission scheme where there are no neighbours to consider and the lighting is subsidiary, the short-circuited class of rotor can be employed for large sizes, provided that at starting no individual motor takes a current great enough to prejudicially affect the working of the plant. Thus, in a 500 h.p. transmission, motors of 25 h.p. may be switched right on to the mains without the use of starting transformers, while if the starting effort required is only from 25 to 30 per cent. of the full load effort, motors of 50 h.p. provided with starting transformers are quite permissible.

The conditions under which motors with wound rotors should be used are determined by elimination, that is to say, motors of this class are installed in all cases where it is not advisable to use the other. They have their place on town mains for sizes above 5 or 10 h.p., and in power transmission work, when they have to start at full load effort, and their sizes are comparatively large in proportion to the generating plant. Again, in all cases where motors have to start with overload effort, a wound rotor should be used. Not only do motors of this class give at starting their full load effort with only full load current, but 50 or 100 per cent. over the full load effort can be obtained with a current proportionately increased. This control of the current at starting constitutes the advantage of motors with wound rotors.

The curve in fig. 26 shows the power-factor at full-load of polyphase induction motors, as designed by Messrs. Crompton & Co., plotted as a function of the horse-power per revolution. Other things being equal, the maximum power-factor that can be obtained depends upon the number of poles with a given core diameter. For the same size of machine the larger the number of poles the lower will be the power-factor. It will be noticed from the curves that as the size of the machine increases the curves become very flat, and therefore after a certain point a very large increase in size will only increase the power-factor by a very small amount. For the smaller motors, however, the power-factor increases much more rapidly with the size. The horse-power ratings shown are for a normal temperature rise, and show the maximum power-factor that can be reached in these conditions.

The standard windings of these motors are arranged to work on voltages of 110, 220, 440, and 500. They can, however, be wound for any other periodicity and for any higher voltage. The machines can be supplied for polyphase or single-phase circuits with either wound or short-circuited rotors. They are manufactured in 19 standard sizes and are supplied in the same types, and are of the same substantial design and construction as the continuous-current motors.

The machines are designed to give a high power-factor at all loads, and to withstand heavy overloads before falling out of step. When required to start against a load, it is advisable to use motors with wound rotors and starting resistances. Motors with short-circuited rotors are capable of exerting their full-load torque when starting, but the sudden rush of current may be

CURVE SHOWING THE POWER FACTOR OF POLYPHASE INDUCTION MOTORS PLOTTED AS A FUNCTION OF THE H.P. PER REVOLUTION.

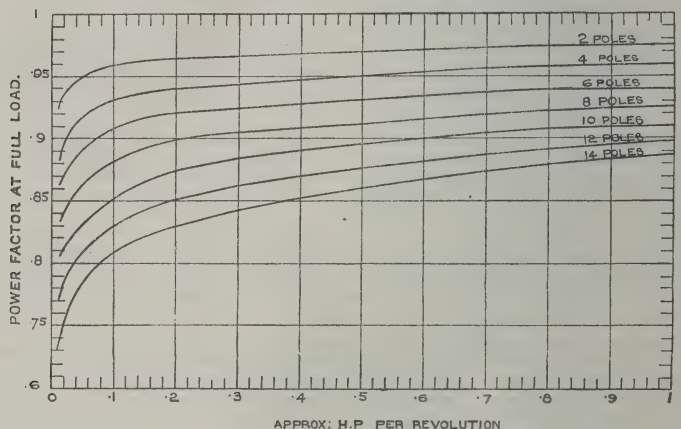

FIG. 26.

as high as four or five times the normal full-load current. Motors of this type may be either switched direct on the line or a special auto-transformer may be used to reduce the line current at starting. Special motors can be designed with permanently short-circuited rotors, and with high resistance winding, capable of starting up against the full-load or even higher torque, but such motors are usually required for special kinds of intermittent working, such as hydro-extractors.

The Cascade Motor.

The 'cascade' principle was originally applied to two motors mechanically coupled with their windings electrically connected in such a way as to make it possible to obtain two speeds. In the case of induction motors, the arrangement adopted was to connect the rotor slip-rings of motor No. 1 to the stator windings of motor No. 2, the torque of the combination being controlled by resistances placed in the circuit of the rotor of No. 2, slip-rings being used. If both machines had an equal number of poles, the 'cascade' connection gave effects equivalent to doubling the number of poles. Or if, for example, one was an eight-pole and one a four-pole motor, the speed for 'cascade' connection was that for a twelve-pole machine. Considerable use has been made of this system, notably on railways, the locomotives on the Valtellina line and for the Simplon tunnel being operated on this principle. The same effect may be secured by connecting the two rotors in series: the starting resistances may then be placed in the stator circuit and the use of slip-rings can be avoided.

In the Hunt 'Cascade' Induction Motor made by Sandycroft, Ltd., this principle has been developed so that the advantages secured hitherto only with two motors can be obtained in a single motor. In an ordinary induction motor, the stator acts on the rotor and there the inductive action stops. Starting torque and speed regulation can only be obtained by inserting resistances in the rotor winding. In the 'Cascade' motor, the rotor, by means of a supplementary magnetic field, reacts inductively upon the stator, to which the starting and speed regulating resistances are connected. The rotor in fact reflects back to the stator part of the energy received from it. This is accomplished by winding the rotor in such a way that it can, under the inductive action of the stator, simultaneously produce two magnetic fields of different numbers of poles; one of these reacts on the stator and generates in its winding induced currents. Each branch of the stator winding is divided into two parallel circuits which are tapped at suitable points. In the case of single-speed motors, or two-speed motors requiring starting or regulation with reduced rheostatic losses below two-thirds speed, these points are connected to resistances by which the torque and speed are controlled.

Owing to the presence of two magnetic fields, one of which is at its maximum when the other is at its minimum, a very even turning movement is obtained at slow speeds, and a perfectly even pull with maximum torque can be obtained at as low as two revolutions per minute. This is a feature of importance with all kinds of winding engines. The slip of an induction motor depends upon the resistance of the windings in which the secondary currents circulate. In the 'Cascade' motor, these windings are in the stator and are of very low resistance, consequently the slip in these motors is very much less than that of ordinary induction motors, and the speed variation between full load and no load is only about 1·2 per cent. For constant speed work the absence of slip-rings is a matter of moment, especially in mining installations. These motors develop full-load starting torque with full-load current, and have a higher power factor than ordinary motors at low speeds where the tendency is for the power factor to become unfavourable.

The question of economical running at two or more speeds is one of great importance. The synchronous motor must run in step with its generator, and the induction motor runs at a speed very nearly that of synchronism. The speed of the former cannot be varied, the speed of the latter can only be varied by inserting resistances in the rotor at great loss of efficiency. A simple modification of the windings of the 'Cascade' motor, described above, enables two speeds to be obtained without rheostatic losses. Slip-rings are connected to a normal rotor winding in star mesh connection. When these rings are open circuited, the portion of the winding connected to the slip-rings is idle, the rotor reacts on the stator, as previously described, and the motor runs at 'Cascade' speed. When the slip-ring circuit is closed, the rotor winding becomes symmetrical, and produces only one number of poles; there is no reflex action on the stator and the motor runs as an ordinary induction motor. Thus, for example, in a twelve-pole 'Cascade' motor, running at 500 r.p.m., there are two fields, one of eight and one of four poles, the latter being the result of rotor reaction. When this is removed by current through the slip-rings, the effective number of poles is eight, and the motor runs at 750 r.p.m. without any resistance. If intermediate speeds are required, they may be obtained by the use of resistances in the usual manner. Other economical speed changes can be obtained in addition by pole-changing, etc. A special application of the two-speed motor, apart from economical running at two speeds, is the avoidance of large starting peaks by two speed starting in connection with winding and similar work, combined with a reduction in starting losses.

A self-synchronising synchronous type of Hunt motor is now on the market and has many unique features. It resembles the Cascade Induction Motor, but has a modified form of stator winding. At synchronous speed the auxiliary field is stationary, and is excited by direct current supplied to the stator windings. These windings are connected to form two parallel-connected star windings, and the exciter is coupled to the neutral points. The direct current produces a field having half as many poles as the main field. The machine is started by resistances connected to the slip-rings, and when so connected the speed can be taken up to synchronous (Cascade) speed or even above it, so that all the usual difficulties of pulling-in are obviated. The motor will start and synchronise with loads of two to three times normal, and with a high starting-power factor and low-current consumption. With motors designed for a leading power factor of 0·7, the starting current for full-load torque is of the order of 10 per cent. to 15 per cent. more than normal full-load current, and the starting-power factor is 88 per cent. to 93 per cent., depending upon the speed for which the machine is built. A remarkable feature possessed by this machine is its entire immunity from 'hunting' or 'phase-swinging.' Extensive tests have been made, but no trace of these troubles has ever been found.

The latest development of the Hunt machine is a self-paralleling generator. This motor closely resembles the synchronous motor, but, as slip-rings are not required, the rotor winding is of the low-voltage short-circuited type as used for the induction motor. These machines possess the same properties as the synchronous motor, and will run in parallel under conditions which would be impossible with generators of the usual type.

AVERAGE EFFICIENCIES OF POLYPHASE INDUCTION MOTORS.

Single-Phase Commutator Motors.

These motors are in most respects similar to ordinary direct-current series motors, with commutator and brushes. The armature is in series with the fields, and hence these motors are sometimes called single-phase series motors. In its simplest form such a motor would have a very low power factor, and would spark badly when run with alternating current. The sparking is largely due to the fact that the armature coils short circuited under the brush form a secondary to the corresponding field winding, a definite transformer action taking place. To overcome these objections special compensating arrangements have to be used. Thus in the Westinghouse motor, used on the Heysham branch of the Midland Railway, neutralising coils are employed to diminish the armature inductance. A further development of the single-phase commutator motor is known as the Repulsion motor, a modification of which has been adopted on the London, Brighton & South Coast Railway.

SMALL MOTORS.

(1)

Specification for Induction Motors, Classes A.G. (Squirrel-cage) and A.G.S. (Slip-ring).

(The English Electric Co.)

The standard machine consists of stator frame with end shields, rotor, terminals, and complete internal connections. Unless otherwise stated in the quotation, the machine is supplied without pulley, coupling, sliding base, foundation bolts, or spanners.

A.G. and A.G.S. Motors are usually supplied in the Protected or in the Enclosed-Ventilated type, but they are also made as Pipe-ventilated or Drip-proof Motors.

The *Protected type* motor is so designed that the internal rotating parts and live parts are protected mechanically from accidental or careless contact, a perforated metal cover being fitted to the cylindrical opening over the rotor fan.

The *Enclosed-ventilated type* is similar to the protected type, but a perforated metal cover is fitted over both cylindrical openings in the frame.

The stator frame is of cast iron. The stator core is built up of insulated stampings bedding directly on the stator frame. The coils are of the 'hair-pin' type in the larger sizes and of the 'dropped-in' type in the smaller sizes, the slots being nearly closed.

The rotor is built up of stampings with nearly closed slots.

In the case of squirrel-cage rotors the end rings are cast on to the rotor bars. The winding is specially designed to give a good starting torque.

In slip-ring rotors the ends of the windings are separated sufficiently to allow a free circulation of cool air.

A cast-iron terminal box is provided on the stator frame, and is fitted with a flange to take screwed conduit. Up to sizes A.G. 6 and A.G.S. 6 inclusive, for all pressures up to 650 volts, six terminals are provided. On sizes larger than these, six terminals are usually provided for all pressures up to 650 volts, but for certain 210-volt motors the standard terminal box will take three terminals only. For pressures above 650 volts three porcelain-insulated terminals are provided.

A trifurcating box can be supplied to fit the above-mentioned terminal box. A trifurcating box can also be supplied for the rotor leads.

End shields are in the form of end plates bolted to facings on the stator frame, and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ample proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use, and is particularly advantageous in the case of induction motors, as there is no appreciable wear of bearings, and consequently no change in the length of air gap after extended use. As the bearings will work equally well in any position, provided the shaft is horizontal, the motor may be fixed to wall or ceiling, without altering the position of bearings or end shields, as is necessary with ring-lubricated machines.

The slip rings are of phosphor bronze, and are arranged outside the end shield on an extension of the motor shaft. There is no earth connection to the slip rings.

The standard design permits of the addition of a short-circuiting and brush-lifting device, by which, through the movement of a hand wheel, the slip rings are short circuited and the brushes lifted out of contact with the rings, thus increasing the efficiency of the motor and reducing wear on both slip rings and brushes. With this device, a cover giving total enclosure to the slip rings is always supplied, and the brush holders are of the lever type.

If the short-circuiting and brush-lifting device is not provided, the slip rings are enclosed in a perforated metal cover and box-type brush holders are used.

The following accessories are supplied as extras, if required :—

Pulley, standard or otherwise, or half-coupling or flexible coupling.

Sliding base, with adjusting screws and four bolts for fixing the motor to the base.

Foundation bolts for fixing the sliding base to the foundations.

Spanners and spanner rack.

(2)

Specification for Direct-current Machines, Class C.B.

(The English Electric Co.)

These machines are of the two end-shield type, and are supplied with standard shaft extension but without pulley, coupling, sliding base or foundation bolts, unless otherwise ordered.

Commutation poles are fitted as standard on all sizes from C.B. 7 upwards.

C.B. machines are usually supplied in the Protected or in the Enclosed-ventilated type, but they are also made as Pipe-ventilated, Drip-proof, or Totally-enclosed machines.

The *Protected type* motor is so designed that the internal rotating parts and live parts are protected mechanically from accidental or careless contact, a perforated metal cover being fitted to the cylindrical opening over the armature fan.

The *Enclosed-ventilated* type is similar to the Protected type, but a perforated metal cover is fitted over both cylindrical openings in the frame.

The frame is circular, of cast steel. The four main poles are bolted to the frame and are laminated except in the smallest sizes, C.B. 5 and C.B. 6, which have solid poles. Commutation poles, when fitted, are of solid wrought iron.

End shields are in the form of end plates bolted to facings on the magnet frame, and form substantial supports for the bearings.

Ball or roller bearings, or in certain cases a combination of both, are used, and are of ample proportions. On the larger machines a ball-thrust bearing is fitted.

The bearings are enclosed in dust-proof housings.

This type of bearing has stood the test of lengthy experience in practical use. It requires practically no attention. As the bearings will work equally well in any position provided the shaft is horizontal, the motor may be fixed to wall or ceiling without rotating the end shields, as is necessary with ring-lubricated bearings.

The field coils of all sizes are former wound, thoroughly impregnated and taped all over. All coils are heavily insulated from the poles and the frame, to safeguard against earthing.

The armature is slotted and drum wound, and is specially designed to give thorough ventilation of the windings, core, and field coils. The core plates are keyed directly to the shaft, and are held in position by two end flanges. The windings are carefully impregnated.

The commutator is built up of segments of hard-drawn copper which are held in position by end flanges fitting into deep V grooves in the segments.

The brush rocker which carries the brush spindles is mounted on a turned seating on the end-shield. The brush holders are substantial castings, and the brushes are easily replaceable.

A terminal box is arranged on the magnet frame, and is provided with a cast-iron cover. A flange is provided on the terminal box to receive screwed conduit.

The standard direction of rotation is counter-clockwise when viewed from the commutator end; if the opposite direction of rotation is required, this must be stated on the order.

The following accessories are supplied as extras, if required:—

Pulley for rope or belt (standard or otherwise) or half-coupling or flexible coupling.

Sliding base with adjusting screws and four bolts for fixing the machine to the base.

Foundation bolts.

British Engineering Standards Association's Standardisation Rules for Electrical Machinery.*

(No. 72—1917.) (*Abstract.*)

Rating of Machines.

Two classes of rating are recognised by these Rules:—

(*a*) Continuous Rating. (*b*) Short-time Rating.

(*a*) The British Standard for continuous rating is the output at which a machine can work for an unlimited period and comply with these rules. This rating includes the equivalent of the over-load allowance formerly made.

(*b*) Two standards for short-time rating are recognised, namely, the output at which a machine can work (i) for one hour, (ii) for one half-hour, and comply with these rules.

Variable-speed machines are to have a definite rating for each of the limiting speeds specified.

The maximum temperature of the cooling air is fixed at 40° C., and the rating is based upon the observable temperature and the temperature rise above this value, varying with the insulating material employed. For cotton, silk, paper, etc. (impregnated), and enamelled wire the final temperature of rotating armatures with commutators must not exceed 90° C.; continuous-current field coils, A.C. windings in slots, and transformer windings, 95° C.; commutators and slip-rings, 90° C. When the insulating material is asbestos, mica, etc., the limit is 20° C. higher in each class. Unimpregnated materials are limited to a temperature 10° C. lower than the same materials when impregnated.

The temperature is to be measured by resistance in some cases, by thermometer where the resistance method is inapplicable. If R_2 = the resistance hot and R_1 = the resistance cold, and t_2 the initial temperature, the final temperature of the winding $= t_2 + (R_2/R_1 - 1)/\text{temp. coefficient}$. The temperature coefficient is calculated from the formula $1/(234{\cdot}5 + t_2)$, and at 15° C. = 0·00401.

* By permission of the British Engineering Standards Association.

Mechanical Tests.

Any machine with continuous rating must be able to withstand on test for 15 seconds a load in amperes 100 per cent. in excess of the British Standard rating; an induction motor must withstand without stalling a torque 75 per cent. in excess of its standard rating. Motors for intermittent service must withstand a torque 100 per cent. in excess of the standard rating, and (except squirrel-cage induction motors) exert a starting torque 100 per cent. in excess of the standard.

Dielectric Tests.

High-pressure tests are to be applied for one minute between the windings and the frame of the machine with the core connected to the frame. The test pressure (R.M.S.) varies from twice rated pressure + 500 volts in machines below 746 watts, and twice rated pressure + 1,000 volts in larger machines, to three times rated pressure in machines over 3,000 kw. and up to 5,000 volts, and ten times rated pressure in the case of rotating field coils. The insulation resistance, in megohms, should not be less than

Rated pressure in volts / (1,000 + Rated output in kva.) with a minimum of one megohm, using a pressure of 500 volts D.C.

Rating Plate.

Full particulars are to be given on the rating plate of the machine, including, in the case of a three-phase transformer, a vector diagram showing the general phase relations; a special system for marking the terminals is also prescribed.

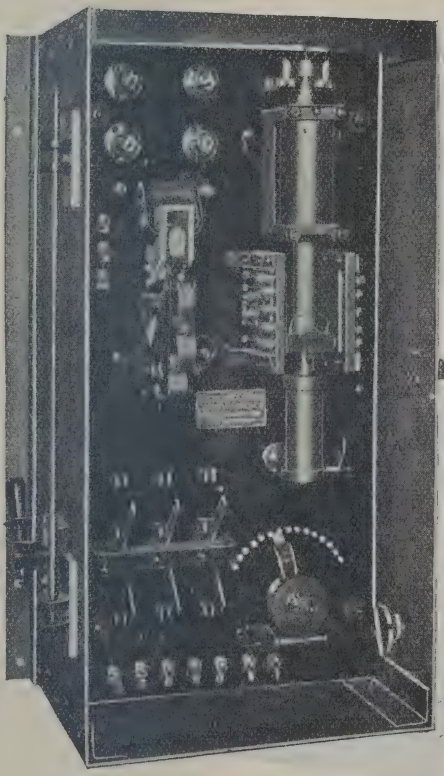
Electrical Pressures, etc.

The pressures in most general use (apart from traction) are for continuous current 110, 220, 440, and 500 volts, and for alternating current 200, 400, 500, 2,000, 3,000, 6,000, and 10,000 volts. Generators are usually standardised according to their destination, motors, for the above-named D.C. voltages, and for 200, 400, and 500 volts A.C. The standard frequency for A.C. machines is 50 cycles per second, and the standard number of phases three, the wave-form to be approximately sinusoidal.

British Standard Switch-gear.

Specifications for air-break switches and circuit breakers for pressures up to 660 volts are given in the *British Engineering Standards Association's Reports* Nos. 109 and 110, 1921. Researches are in progress with regard to the rupturing capacity, etc., and in the meantime the specifications do not apply to switch-gear for use in circuits containing high inductance. Lists of standard current ratings are given, and it is specified that the temperature rise on continuous full load shall not exceed 20° C. for switch-gear rated below 100 amperes, or 30° C. for 100 amperes and upwards.

Marble or slate slabs must be free from metallic veins, and, if of slate, must be treated all over with a damp-proof medium; the slabs are to be insulated from fixing bolts and the supporting framework. The sizes of round copper-back connections and their spacing are tabulated in the Reports. The test pressure to be applied to a switch or circuit breaker is 1,000 volts plus twice the rated pressure, with a minimum of 2,000 volts alternating.



In the case of circuit breakers, the temperature rise of coils is not to exceed 50° C., nor the actual temperature 90° C., unless the insulating material consists of asbestos, mica, or air, in which case the limiting values are 70° and 110° C. respectively. Reverse-current devices must be capable of operating with 15 per cent. or less of the rated current; low-voltage releases must not operate unless the pressure falls to 65 per cent. or less of the rated pressure, but must operate before the pressure falls below 25 per cent. of the normal, at the rated frequency. A reverse-current circuit breaker must not be rendered inoperative if the pressure across the potential coil falls to (Class A) zero, (Class B) 50 per cent. of normal, and a reverse-current device must not operate with a forward current of any magnitude. Magnet-closing circuit breakers must operate between the limits 20 per cent. below and above normal pressure, and pressure-operated tripping coils must operate between the limits 50 per cent. below and 20 per cent. above normal pressure, at 40° C.

When type tests have been made by a recognised authority, a millivolt drop test is to be accepted in lieu of a temperature test.

ELECTRO-MECHANICAL BRAKES.

Electro-mechanical brakes are used in connection with a variety of electrically driven machines, such as lifts, cranes, hoists, elevators, conveyors, rolling mills, paper reeling, slipways, presses, machine tools, etc., where either a quick 'stop' or adjustable gradual 'stop' is desired when the power is cut off either intentionally or unintentionally.

Telephones: Clerkenwell 1924 & 1925. Telegrams: 'Elevanja, Avenue, London.

F. 1917

These brakes consist primarily of an electro magnet which operates the brake blocks through a system of levers or other medium. The magnet is so arranged that, when the current is applied, the magnet is energised and lifts the brake blocks from the drum. If for any reason the current is cut off the magnet is de-energised and the brake blocks are pressed against the drum, the requisite pressure being obtained by springs, weights, or a combination of each.

The brakes are quite automatic in action; thus, in the case of an electrically driven crane, as soon as the driver applies the current to the motor to raise the load the brake is automatically released, and when he switches off the cuerent to stop the brake is immediately applied. Should for any reason the supply current fail, the brake automatically goes on and takes charge of the load.

It is desirable that an electro-mechanical brake should have the following features: compactness of design, robust construction, few and simple working parts, easy adjustment for brake blocks and pressure exerted by same. Coils should be liberally rated, well insulated, and protected from mechanical injury, and so placed that they are not likely to be damaged by oil exuding from the machine. The brake blocks should be readily renewable. If springs are used they should be of the compression pattern.

(*Elliston, Evans & Jackson, Ltd., London.*)

AUTOMATIC CONTROL GEAR.

(*Electric Control Ltd., Empire Works, Glasgow.*)

An automatic controller entirely eliminates the personal judgment of the operator in many cases, which is a distinct advantage where men accustomed to heavy work such as is met with in shipyards, steel mills and the like, are called upon to start up large machines. The controllers are now made suitable for practically any purpose, any horse-power, any supply, and for any particular design of motor requiring special starting apparatus.

The foolproof nature of automatic gear is not the only or the principal argument in its favour as compared with hand-operated controllers under frequent and heavy service.

An automatic controller is one in which the current supply to the motor is regulated by means of one or more switch units, each unit being operated by an electro-magnet; the operation of the magnet is controlled by an auxiliary switch, which therefore only has to deal with very small magnet-currents. This auxiliary switch can be put at any distance from the motor in the most convenient place, whereas the main automatic controller can be installed beside the motor, thus effecting the greatest economy in cable connections.

The original face-plate type of starter, which is still the standard type for moderate size motors starting up only a few times per day, has had to give place to the drum type controller for frequently operated motors as on cranes. This type of controller has been greatly improved in its mechanical and electrical construction, but its design has such inherent limitations when it has to deal with the large currents now employed that excessive wear of the contacts is produced. This necessitates constant attention to the wearing parts, and high maintenance charges. By inherent limitations is meant the fundamental fact that in order to carry larger currents the contact pressures must be increased, and such increase greatly increases the mechanical wear, so that in some cases the contacts may have to be renewed after a few weeks' operation. With an automatic controller of proper design, the wear is very much less, and does not increase with the size of the controller. Contacts operating under severe conditions will only require renewal about once or twice a year.

D.C. motors are controlled by a number of solenoid-operated switches or 'contactors' fitted with powerful magnetic blow-outs and arc shields; they are electrically interlocked so that they can only close in correct sequence, and so arranged that the motor cannot be started up except with all resistance in the armature circuit.

In almost all cases the time intervals between the closing of successive contactors depend upon the acceleration of the motor. This is generally determined by means of series relays fitted to each contactor except the last one. These relays are in the main motor circuit, and are adjusted so as to operate when the motor current drops to the value at which further acceleration is impossible. The operation of the relay closes the control circuit of the next contactor, which therefore closes, thereby cutting out a section of the resistance and speeding up the motor. This is repeated each time until the motor reaches full speed. It is thus evident that the motor current

is kept within safe limits while the motor is accelerated to full speed in the minimum time, which means the minimum loss of power in the starting resistances.

The automatic control of any A.C. motor is now as reliable as with a D.C. motor, for A.C. switches and contactors are manufactured for controlling motors of any horse-power on high or low tension supplies. A standard controller for a slip-ring motor consists of a stator switch or contactor and a number of D.P. rotor contactors complete with relays, the number depending on the h.p.

The stator switch coil is controlled by a small switch, accumulator switch or float switch, pressure regulator or other means, and on being energised closes the stator switch automatically, and the motor is connected to the mains with all the rotor resistance in circuit.

A time element controls the closing of the first D.P. rotor switch, which, on closing automatically, cuts out a section of the resistance in the three phases of the rotor circuit. As with the D.C. set, this is repeated until the motor is up to full speed with the leads to the rings short-circuited.

Pumps are arranged to stop and start according to the rise or fall of water in a tank by means of float gear and an automatic controller. The automatic control of air compressors is being universally adopted on account of the great convenience and economy effected in many cases, irrespective of the benefit of the elimination of skilled attendance.

Each plant requires individual investigation in order to ascertain the most economical method of control. On a D.C. or A.C. supply the compressor can be arranged to stop and start at maximum and minimum pressures only, or to stop and start at maximum and minimum pressures, the speed being reduced or increased between certain definite pressures, unloading at starting, or to run continuously, unloading only at maximum pressure, when the demand for air is great.

Since last year the eddy-current controller for slip-ring motors has been still further developed, and some of the results obtained are noteworthy.

Three solid steel cores of several inches diameter are fixed between solid steel end plates which are fitted with eye-bolts for lifting purposes. Three coils are supported by these cores, and coupled up in either 'star' or 'delta.' The coils are protected by planished steel covers or perforated sheet. The controller has no moving parts whatever.

For steel mill service, especially for live roll gears, these starters have proved eminently satisfactory, and have in fact many advantages over the contactor-type controller. A live roll equipment consists of master switch and mechanically interlocked contactors for the stator, if over 30 h.p., and master switch only if under. In addition to this, the electrical equipment is complete with the addition of the eddy-current starter, which is connected to the slip-rings of the motor without any brakes or braking contactors.

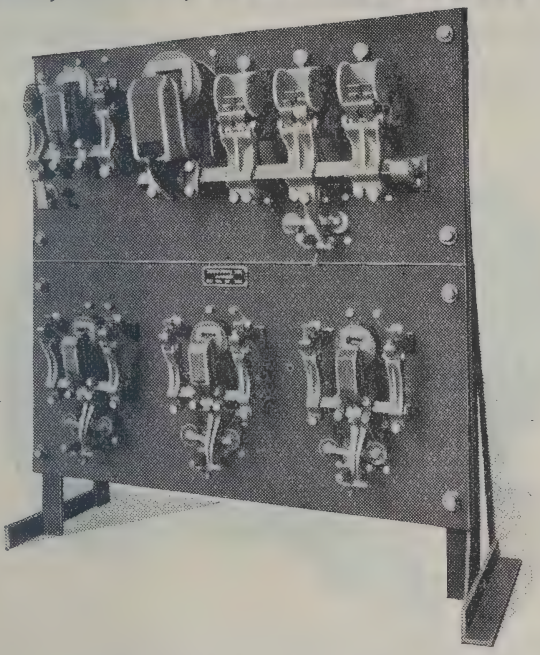
The equipment could not possibly be simpler, and the operation is perfect, for all the usual steel mill requirements can be carried out, and the possibilities of breakdown are made still more remote than they were with contactor gear.

The eddy-current starter limits the starting current, and yet gives the motor ample starting torque, and has proved satisfactory when operating 500 to 800 times an hour. The current at starting on this duty is about 2½ times full load running current, and the plant reaches full speed in about three seconds.

One of the greatest advantages of this type of starter, apart from its simplicity and fool-proof features, is the braking effect produced on quick reversals. Though very powerful, the braking is effected without jarring, and there is in consequence no clashing of gearing.

On reversing the stator switch twice, line frequency and voltage are applied to the starter, which produces a retardation about twice as quick as the initial acceleration. For plate edge planers this point is especially noteworthy, for the slowing down, reversing, and accelerating in the opposite direction is automatic, certain, and done in the shortest possible time, thus increasing output and the range of the machine.

Live rolls can be reversed from full speed in one direction to full speed in the opposite in 2½ seconds, and by manipulation of the master switch 'inching' can be done as with contactor resistance controllers.



One further advantage which commends the gear to many steel works engineers is the fact that there are no adjustments possible or necessary, and in consequence any mechanical defect shows up immediately and can be rectified. With contactor gear, adjustment of relays enables the plant to be speeded up to the detriment frequently of plant and motor.

ELECTRIC CONTROL LIMITED

EMPIRE WORKS, GLASGOW.

When a current flowing in a circuit lags θ degrees behind the impressed e.m.f., the current may be regarded as equivalent to two separate currents at right angles to one another, i.e. one 90° in time behind the other, one of these components being in step with the impressed e.m.f. and the other at right angles to it. If I be the current as actually flowing, then the value of the component in step with the e.m.f. is I cos θ; this is called the power component of the current. The other component is I sin θ, and is called the wattless component. Hence the true power in an alternating circuit is given by the product E × I cos θ, and for this reason cos θ is called the power factor.

Drop in Alternating Current Lines.

Fig. 28 is a vector diagram giving the relations between the e.m.f. of the line, the load, and the generator. E is the e.m.f. of the generator, and e the e.m.f. impressed upon the load; a and b are respectively the ohmic and inductive components of c, the impedance drop of the line; f and g are respectively the ohmic and inductive components of e. The ratio of f to e is the power factor of the load, or the ratio of the true to the apparent watts. The difference between E and e is the drop in the line, or the regulation volts, i.e. the rise in the generator e.m.f. required to maintain the impressed e.m.f. constant. This difference is equal to d, the radial distance between the arc drawn with E as radius and that drawn with e as radius.

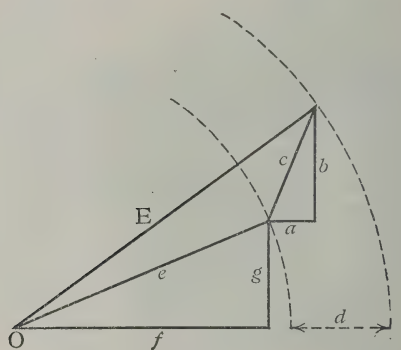

FIG. 28.

The inductive component of c is due to the alternating field set up round the conductor by the current, and the strength of this field depends upon the current, the distance apart of the wires, and the size of the wires. The number of lines of force per ampere per centimetre of length of two parallel wires δ cm. apart and of α cm. radius is given by Maxwell's equation:

$$L = \left(4 \operatorname{Log}_e \frac{\delta}{\alpha} + 1\right) 10^{-6} \text{ millihenries.}$$

The reactance voltage per ampere at N periods per second is then given by the equation

$$e = 2\pi NL10^{-3} \text{ volts.}$$

In the accompanying table are given the reactance volts per ampere as calculated by this formula for various sized wires placed at different distances apart (1) for 1,000 ft. of line of two parallel wires; (2) for one mile of line of two parallel wires. The periodicity assumed in the table is 60~ per second, the reactance volts for any other periodicity will be in proportion to the number of cycles. Values for other distances apart can readily be found by interpolation. From the above equation for L it is seen that the reactance is the same so long as the ratio of the diameter of the wire to the distance apart remains constant.

The following example illustrates the use of the table:—Let it be required to transmit 1,000 kilowatts ten miles, at 10,000 volts, 25 cycles, with a power factor of 80 per cent., using No 0 B. & S. copper conductors spaced 36 inches apart. The apparent power will be $1{,}000 \div 0{\cdot}8 = 1{,}250$ kilovolt-amperes, the current being therefore 125 amperes. From the table, the resistance drop per mile of line is 1·04 volts per ampere, or for 10 miles at 125 amperes $10 \times 125 \times 1{\cdot}04 = 1{,}300$ volts; the reactance drop per mile from the table is 1·37 volts per ampere at 60 cycles, or for 125 amperes 10 miles at 25 cycles the total drop is $10 \times 125 \times 1{\cdot}37 \times 25 \div 60 = 713{\cdot}5$ volts. The impedance drop may be found by measuring the hypotenuse of a right-angled triangle with sides proportional to the resistance and reactance voltages respectively, or by calculation it equals $\sqrt{1{,}300^2 + 713{\cdot}5^2} = 1{,}483$ volts. Hence the generator pressure should be 11,483 volts.

The above calculations assume a single-phase transmission. A simple transposition makes the table serviceable in the case where three-phase currents are used. A three-wire three-phase transmission in which the conductors are symmetrically related may, so far as loss and regulation are concerned, be replaced by two single-phase circuits having no inductive interaction, and identical with the three-phase line as to size of wire and distance between wires. Therefore to calculate a three-phase transmission, calculate a single-phase circuit to carry one-half the load at the same voltage. The three-phase transmission will require three wires of the same size and distance between centres as obtained for the single-phase. If the regulation volts be given, and it is required to find the proper size of the wire, the result must be obtained by trial. Assume a size of wire and calculate the drop. The table will indicate the direction and extent of the change necessary in the size of the wire.

TABLE SHOWING INCREASE IN RESISTANCE OF COPPER WIRES BY INCREASE OF ALTERNATING-CURRENT FREQUENCY.

$n\,d^2$	K	$n\,d^2$	K	$n\,d^2$	K
0	1·0000	720	1·3180	2,880	2·3937
20	1·0000	980	1·4920	5,120	3·0956
80	1·0001	1,280	1·6778	8,000	3·7940
180	1·0258	1,620	1·8628	18,000	5·5732
320	1·0805	2,000	2·0430	22,000	7·3250
500	1·1747	2,420	2·2190		

n = frequency; d = diameter of wire in centimetres; K = increase in resistance.

Size of Mains for Alternating-current Circuits.

In calculating the cross-sectional areas of conductors for the transmission of power by alternating currents, the stress on the insulating material, the loss in the line, the power factor of the load, and the A.C. system employed should be taken into consideration. The simplest plan is first to calculate the size of conductor required to transmit the given power by direct current, using two conductors, and then to ascertain the size of the corresponding A.C. conductor by means of the table given below.

For the same virtual voltage, the stress on the insulation of A.C. mains is 1·4 times as great as in the case of D.C. mains; this must be taken into account when high voltages are concerned, but is usually disregarded when dealing with low voltages. The table therefore gives the multipliers for the same virtual voltage in each case, with the same percentage drop of volts in the line, i.e. the same line efficiency.

System.	Power Factors.				
	1	0·95	0·90	0·85	0·80
D.C. two-wire (unity power factor)	1	1	1	1	1
A.C. Single-phase, two-wire	1	1·052	1·111	1·176	1·250
A.C. Two-phase, four-wire A.C. Three-phase, three-wire	0·5	0·526	0·556	0·588	0·625

If KW = the power transmitted in kilowatts, E the supply pressure in volts, p the percentage drop in the line (referred to the supply pressure), and L the total length of the conductor (twice the distance) in feet, the cross-section of the conductor for D.C. two-wire is given by :—

$$A = 0{\cdot}8\ KW \times L / p\ E^2 \text{ in sq. inches,}$$

for a temperature of 15·5° C. (60° F.)

Having found the D.C. cross-section A, the corresponding cross-section of *each conductor* for any of the other systems can be found by multiplying A by the factor given in cols. 2 to 6 of the above table, in accordance with the power factor of the circuit.

No account is here taken of the capacity of the line, which would be of importance in the case of a long transmission, or of increase of resistance of the line due to a rise of temperature or of 'skin effect.'

TRANSFORMERS.

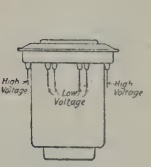
TRANSFORMERS IN PARALLEL.

The simple distributing transformer usually has two high-voltage leads and four low-voltage leads coming out from its windings, as indicated in fig. 1 (p. 1923). It will be seen from fig. 2 that the two centre leads of the low-voltage coils are crossed inside the transformer before they are brought out through the case. This does not make any change in connecting the two sections in series on the outside of the transformer, as this is the same as connecting two batteries in series.

When the coils are connected in parallel, care must be exercised and adjacent leads connected together, as in fig. 4. Looking at the connections from the outside of the transformer, it would appear as though the two sections of the winding were short-circuited, but the diagram shows that the right-hand terminals of each section are connected together, also the left-hand terminals. This is just what is done in connecting batteries or other direct-current elements in parallel—like poles are connected.

Transformers to operate in parallel should be the same voltage, frequency, size, and possess the same characteristics, which means that they should be of the same make. In connecting transformers in parallel, it is only necessary to observe the same rules as used for connecting two or more pieces of direct-current apparatus in parallel; namely, connect like poles to like poles. The question now arises which are like terminals on two or more transformers. This is easily determined in most cases. After the transformers are arranged symmetrically, as in fig. 5, connect the right-hand terminals together and the left-hand terminals together and bring out a lead from each junction point, as indicated.

There is, however, a chance that one of the transformers may have its leads brought out in such a way as to cause a short-circuit when the transformers are connected as shown in the figure.



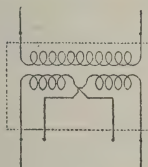


Fig.1

Fig.2

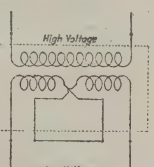

Fig.3

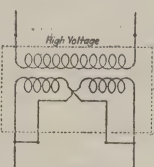

Fig.4

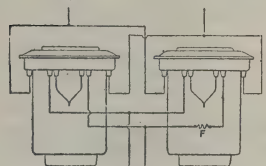

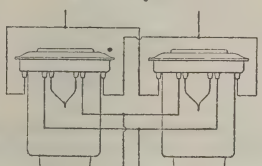

Fig.5

Fig.6

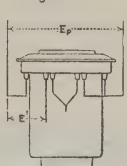

Fig.7

To guard against this a piece of small fuse wire may be connected, as indicated at F. If the connections are correct, the fuse will not blow when the transformers are made alive without load, otherwise the fuse will blow. In case of a wrong connection it may be remedied by crossing either the high or low-voltage leads on one of the transformers, as indicated in fig. 6. A better way would be to test the transformers and find out which has wrong polarity and correct it.

The polarity may be tested as represented in fig. 7. Connect the high-voltage terminals to the line and with one terminal of the low-voltage coil to the high-voltage winding, as indicated in the figure. Measure the electromotive force at E_p and E'. If it is greater at E' than at E_p, the transformer has the correct polarity; if less, the polarity is wrong and either the high or the low-voltage leads must be crossed inside the transformer. The test may be made with 110 or 220-volt current. (*Power.*)

Notes on Transformers.

To seal up holes in transformers or oil-switch cases where wires pass through, a mixture of sulphur and plaster of Paris may be used; if the two are mixed half and half it gives a very hard substance when it has set, and one that is impervious to transformer oil. The sulphur should be melted in a ladle or pot and then an equal quantity of plaster of Paris mixed thoroughly into it. This mixture should be poured into place while hot.

Trouble is often experienced from oil being siphoned out of transformer cases on account of the braided insulation on the lead wires. When this takes place it is usually found that the insulation on the wires dips down into the oil. If the oil level is lowered below the terminal board inside the case and the insulation on the leads scraped off so that where the wire enters the surface of the oil its metallic surface only is exposed to possible contact with the oil, and the leads are properly sealed, there will be little trouble due to siphon action.

Static Balancers.

In three-phase distribution circuits, the voltages commonly used for power purposes are often too high for lighting circuits; accordingly, where lighting is desired, it is necessary to introduce some means of obtaining a reduced voltage. A customary method of providing for this is to take advantage of the fact that by using a star connected generator or transformer having its secondary winding connected in star, it is possible to obtain between any one phase and the neutral point of either generator or transformer a reduced voltage. For example, in a circuit with 400 volts between the phases, it is possible, by taking out a connection from the star point, to obtain a voltage between this point and any one phase of $\frac{400}{\sqrt{3}} = 230$ volts only. To do this, however, the generator or transformer has to be star connected in such a manner that a cable can be brought out from the star point, and this cable must be led to the point where lighting is required. Apart from the cost of this cable, which for any distance is considerable, any out-of-balance lighting would cause unbalanced voltages due to the resistance of this cable and thus would affect the

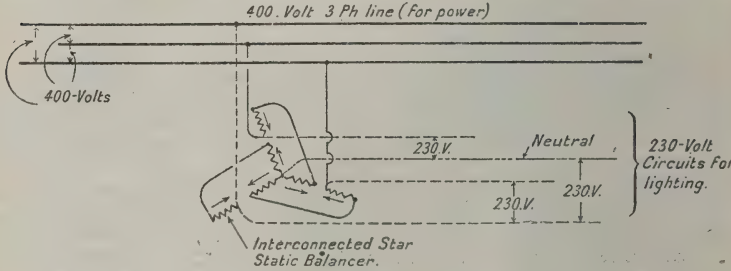

FIG. 29.

lighting detrimentally. Alternatively to the above arrangement, it is possible, by using static balancers, to save the cost of the cable referred to, and also to minimise very largely the out-of-balance effects.

The Westinghouse static balancer, which is shown diagrammatically in fig. 29, consists of a three-phase auto-transformer having a lead brought out from the neutral point of the windings, and the three phases so inter-connected, that current flowing through the neutral passes equally through them.

Static balancers for ordinary industrial conditions are quite small, and of correspondingly low cost. On a 100-k.v.a. circuit, with a maximum out-of-balance current not exceeding 25 per cent. of the full-load current in the outers, a balancer would be similar in size to a 5-k.v.a. transformer, and under these conditions, the out-of-balance of the phase voltage would correspond to one-third the percentage voltage drop of such a 5-k.v.a. transformer. In cases where the voltage required for lighting is not exactly but only approximately the line voltage divided by $\sqrt{3}$ a combined balance and auto-transformer may be used to advantage.

The advantages gained by using static balancers are: (1) The balancer may be placed at any point on the system where lighting is required and the length of neutral wire greatly reduced. (2) The drop in the neutral wire is much reduced, so that better voltage balancing is obtained between the different phases. (3) The current is more equally distributed between the line wires. (4) A standard polyphase wattmeter can be used instead of a special four-wire wattmeter. (5) It is possible to supply a four-wire circuit from a transformer group connected in star-star or star-delta, thereby saving in the cost of the main transformers.

Power Factor Improvement.

With the continual growth of alternating current distribution, the necessity of improving the power factor resulting from an industrial load has become more and more apparent, as a low power factor, by reducing the working capacity of the generating plant and mains and lowering the efficiency of the system, adds to both the fixed and the running charges, besides unfavourably influencing the voltage regulation of the network. In fig. 30 curves are given for commercial induction motors at 500 and 1,000 r.p.m., showing the effect of output and speed on the power factor at various loads.

The power factor can be raised by three methods :—(1) Static condensers ; (2) Rotary condensers ; (3) Phase adjusters.

(1) Static condensers afford the simplest, cheapest, and most efficient solution of the problem, as they require no attendance and involve very little loss of energy. In the *General Electric Review* of August 1918, W. P. Taylor gives a diagram, fig. 31 (page 1926), by means of which the capacity of the static condenser required to neutralise more or less completely

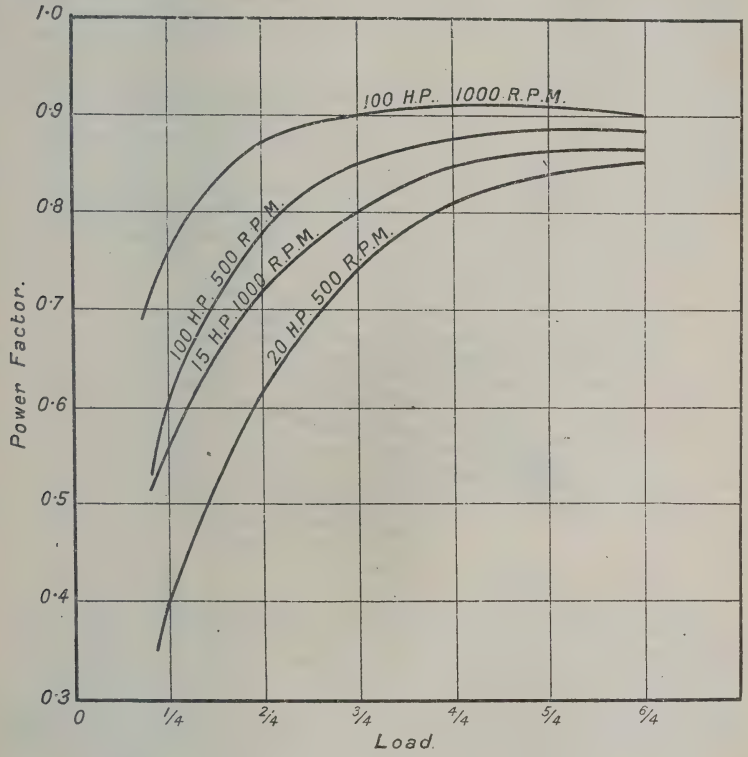

FIG. 30.

the wattless component of the power can be determined. The use of the diagram is best explained by an example. An A.C. feeder carries a current of 500 amperes at 500 volts, and the power factor is 0·6 ; required the capacity necessary to raise the power factor to 0·9. Taking on the 0·6 p.f. line the point corresponding to 250 k.v.a., it will be found that the wattless k.v.a. (ordinate) is 200 and the energy kw. (abscissa) 150. The 150-kw. ordinate cuts the 0·9 p.f. line at a height corresponding to 73 wattless k.v.a. Subtracting 73 from 200 gives 127 k.v.a. as the required condenser capacity. Similarly 88 k.v.a. would raise the power factor to 0·8 and 47 k.v.a. would raise it to 0·7.

The effect of added capacity is greatest when the power factor is lowest ; owing to the relatively large capacity required to bring the power factor up to unity, it is not commercially advisable to attempt to raise it much above 0·9. The condensers should be fixed near the load, in order to improve the power factor in the mains as well as at the generator. The condensers should be disconnected at times of light load, lest the leading current they then take should lower the

power factor, thus bringing about the evil they are meant to remedy. High voltage and high frequency are favourable to the use of static condensers; they are made for pressures up to 750 volts by the *British Insulated and Helsby Cables, Ltd.*, and for higher pressures they are connected in series. In the case of low pressures such as 400 volts, it may be found economical to install transformers to raise the voltage at the terminals of the condensers, thus reducing the capacity required. Another method is to insert a suitable amount of inductance in series with the condensers, whereby the pressure across the latter is increased. To protect the condensers, the control switches should be fitted with overload trips, and to prevent accidents due to the stored-up charge, provision should be made for discharging the condensers through resistances when they are switched off. The efficiency of condensers exceeds 99·5 per cent.

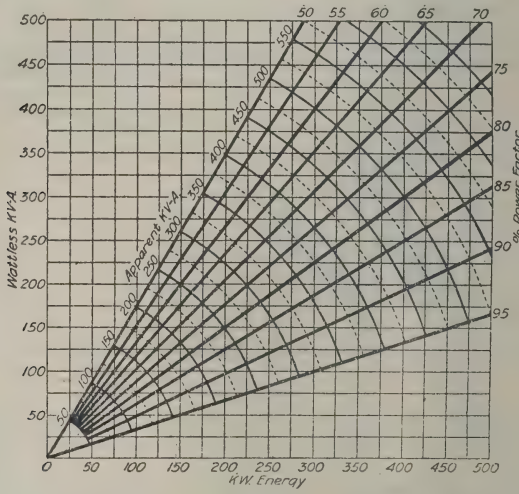

FIG. 31.

(2) Rotary condensers are simply synchronous A.C. motors, over-excited so as to take a leading current, in which condition they act like static condensers. The motor may be run without load, but in this case the method is costly, and it is preferable to use a loaded motor. A rotary converter can be employed for the same purpose. The necessary capacity to produce a given improvement in the power factor of the system is determined in the same way as that of static condensers, using fig. 32; the greater the mechanical load on the motor, the less will be its condenser effect, the rule being that the square of the k.v.a. capacity of the machine is equal to the sum of the squares of the kw. load and of the wattless k.v.a., so that the motor is used to the best advantage when the wattless output = the power output × 0·71 of the k.v.a. rating of the motor. The synchronous motor is usually started up as an induction motor with the aid of an auxiliary squirrel-cage winding embedded in the poles of the field system, or by means of an induction motor coupled to the same shaft, the field being unexcited until full speed is attained; direct-current excitation must be provided, either by a direct-coupled exciter or by an external source.

(3) The phase adjuster is a special machine, resembling a commutator induction motor, which is coupled to the slip-rings of an induction motor whose power factor needs correction, and is mechanically driven, either from the shaft of the main motor or by a small separate motor, the power taken being only that required to overcome friction and windage, and being fully compensated by reduced losses in the main motor. The function of the phase adjuster is to supply the magnetising current for the motor, thus raising the power factor to unity, or even passing that point and supplying current to the system to compensate for low power factor in other machines. An oscillatory type of phase adjuster is also made. A great advantage of this method is that the power factor of the individual motor is improved, so that a smaller motor can be used, with reduced losses. Advantages common to all methods are that the losses in the generators and cables are reduced, and the load factor of the plant is raised so that fewer generators need be run, and considerable economy of fuel as well as of capital outlay can be effected.

Ground Detectors.

Ground Detectors are required in mining work in stations covered by the following extract from the Home Office Rules :—

> ' In every completely insulated circuit, earth or ground detectors shall be kept connected up in every generating and transforming station, to show immediately any defect in the insulating of the system.'

Generally Ground Detectors are either one or other of two kinds, depending upon the pressure of the circuit on which they are used :—

(*a*) For circuits not exceeding 750 volts a milli-ammeter is used. This consists of a voltmeter, the scale of which is calibrated to read milli-amperes. This instrument is used in conjunction with resistances which are so proportioned that in the case of a bad fault giving full line voltage to earth, the needle would indicate the maximum reading marked on the scale.

For three-phase circuits one instrument with resistance is used as shown in fig. 32, illustrating ' Westinghouse Ground Detectors.' One pole of the instrument is connected to earth, the other pole being connected to the centre point of a special three-way key switch. Under normal working conditions the instrument is connected through the three-way key switch and the three resistances shown on the diagram to the three phases, the three keys being locked in the closed position, thus ensuring that the leakage detector is kept in circuit permanently.

If a fault occurs on one of the mains, a deflection is obtained on the milli-ammeter, and to determine upon which phase the fault exists it is only necessary first to release all three keys and

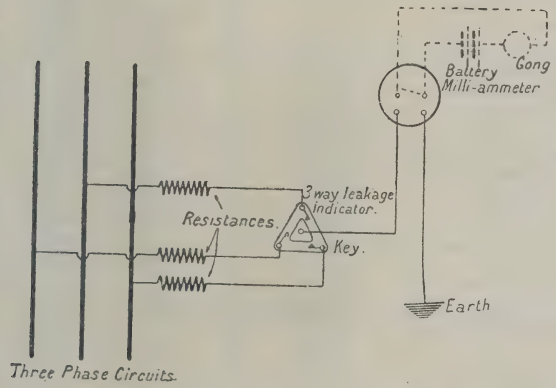

FIG. 32.

then to depress them one at a time. The faulty phase will give the smallest deflection. As indicated in the diagram, a bell and battery can be included and the milli-ammeter can be provided with special contacts so that in the event of a serious fault occurring on the mains the bell would sound an alarm.

(*b*) For circuits having pressures greater than 750 volts, it is customary to use a Static Ground Detector. In this instrument, the indicating pointer carries a large black disc, which under normal conditions appears in the centre of the scale. This disc and pointer are electrically connected to the case of the instrument, which in turn is earthed. The live portion of the instrument consists of two metal plates embedded in the porcelain base of the instrument to the right and left respectively of the central position normally taken up by the black disc on the pointer. When the condition of the system is healthy, the pointer retains the central position, since the pull between the disc and each one of the live pieces of metal is equal. As soon as a fault occurs on one main, however, the attraction between the centre disc and the particular stem to which the faulty main is connected becomes less and the disc is consequently attracted towards the other stem. The scale is calibrated so that the deflection is an approximate measure of the actual conditions. Since the two stems must be connected one to each phase, it is necessary in the case of a three-phase circuit to employ two instruments.

Electrostatic Ground Detectors can only be used on circuits having an insulated neutral. In the case of systems where the neutral is earthed, it is customary for an ammeter to be placed in the earthed connection.

TRANSMISSION SYSTEMS OF THE WORLD OPERATING AT AND ABOVE 70,000 VOLTS.

ALUMINIUM CONDUCTORS.

Conductivity.

The conductivity of aluminium depends upon the purity, and, to a less extent, upon the amount of work put upon the metal in its evolution from billet to the finished wire or bar. The British standard of resistance for hard copper is 2 per cent. higher than that of soft, and this difference also applies to hard and soft aluminium. In comparing the relative conductances of copper and aluminium, therefore, hard should be referred to hard, and soft to soft copper and aluminium, respectively. The conductivity of aluminium usually supplied for electrical purposes is not less than 60 per cent. of Matthiessen's standard for copper, and the accompanying tables are calculated on this basis. An aluminium conductor of the same resistance and length as a given copper conductor will have an effective cross-section in the ratio of 100 to 60=1·666. The effective sectional area of an aluminium conductor is, therefore, 66·6 per cent. greater than that of the equivalent copper conductor, and the diameter will be some 29 per cent. greater.

Weight.

The specific gravity of cast aluminium is about 2·68, but when drawn into wire this is increased to 2·71. As the specific gravity of copper wire is about 8·89, the relative weight of a given volume of each metal is in the ratio of 8·89 to 2·71=3·3. In other words, a copper wire of any given size and length will weigh 3·3 times as much as an aluminium wire of the same size and length. Aluminium, therefore, having a conductivity of 61 per cent. of that of copper, will have a sectional area 1·642 times as great as a copper conductor of the same resistance and length, and the ratio of the weights will be 3·3 to 1·642=2·01 ; that is to say, a copper conductor of any given resistance and length will weigh approximately twice as much as an aluminium conductor of the same resistance and length.

The ratios are therefore as follows :—

	Copper.	Aluminium.
Conductance for equal section	1	0·61
Section for equal conductance	1	1·642
Diameter for equal conductance	1	1·28
Weight for equal bulk	3·3	1
Weight for equal conductance	2·0	1

Tensile Strength.—The tensile strength of aluminium depends largely upon the amount of work that is put upon it during its evolution from the billet or slab to the finished article. It is possible, by employing special rolling and drawing processes, to produce aluminium wire of very high tensile strength, but such wire is hard and 'short,' and is not to be recommended for ordinary purposes, where a certain amount of ductility and 'give' are of advantage.

Durability.—Aluminium has withstood the test of varying and severe climatic conditions. Lines have been in operation for over ten years in exposed positions on the sea coast which show little signs of deterioration. The metal is less affected by sulphurous and sulphuric fumes than copper, and shows less deterioration in the presence of any of the commoner acids. On the other hand, aluminium is somewhat deteriorated by strong alkalies, particularly in a moist atmosphere, and under such circumstances should be protected by a weather-proof covering.

Increase of Resistance with Temperature.—The coefficient of increase of resistance with temperature varies somewhat with the extent and nature of the impurities present, and the temperature range over which it is taken, but is in all cases somewhat lower than for copper. Tests made on different samples of commercially pure aluminium give figures varying between ·32 and ·39 per cent. per degree Cent. between 0 and 50° C. compared with ·38 to ·43 for copper.

Coefficient of Linear Expansion.—The coefficient of linear expansion being somewhat greater with aluminium than with copper, due allowance should be made for this when installing long lines of solid feeders or bars.

Ductility.

Aluminium wires are very ductile and can, without fracturing, be twisted one complete turn in a length equal to their own diameter. This test has been applied to the area of joint of two wires welded in the flame of a blow pipe, for various diameters of wire, and in all cases the joint has stood up and the twist distributed itself evenly over the whole length of wire subjected to the test.

Action of Acids.

Aluminium is not acted upon by any of the common acids in a cold state, with the exception of hydrochloric acid, and withstands the effects of sea-water better than either copper or iron ; but galvanic action is set up between aluminium and any of the common metals in the presence of moisture, and for this reason copper or iron clamps should not be used for outdoor work unless the junction be taped over and thoroughly protected from moisture.

Sulphur has no effect upon aluminium at ordinary temperatures, and consequently aluminium withstands the action of smoke and fog much better than either silver or copper. A thin transparent film of insoluble oxide forms immediately on the surface of aluminium when it is exposed

to the atmosphere, protecting it from further oxidisation or corrosion. This film of oxide is a good insulator and will withstand the application of considerable pressure before breaking down. Advantage is being taken of this feature in the manufacture of magnet windings, etc., which are otherwise uninsulated.

Capacity and Inductance.

Aluminium being a non-magnetic material, the inductance or capacity of the line can only be affected by the increased diameter. This increased diameter will decrease the inductance and increase the capacity by some 5 per cent., but as all transmission lines possess more inductance than capacity, this difference is in favour of aluminium, tending to improve the power factor of the system and to reduce the pressure drop due to inductance.

Heating Effect.

Aluminium, having a larger surface than copper of equal conductance, is more easily able to get rid of its heat, and to transmit a given current with a given I^2R loss aluminium will remain the cooler. This is a considerable advantage when installing electric apparatus in a hot atmosphere, or where current-carrying capacity is of more importance than the permissible pressure drop. In any case aluminium will have a higher overload capacity, from a heating point of view, than copper of equal resistance.

ALUMINIUM CABLE, STEEL-REINFORCED.

After the introduction of aluminium for electrical conductors it became apparent that if a conductor could be obtained, combining the advantages of lightness of aluminium with the strength of high-grade steel now obtainable on the market, the highest efficiency would result. Cables of this character were made up and have now been in service in such a variety of localities and conditions that their efficiency has been thoroughly demonstrated.

The cables consist of a steel core about which the aluminium is stranded. The steel for the smaller size cables consists of a single strand, while for the larger sizes several strands are used. These are composed of 'Extra High Strength' steel having an ultimate strength upwards of 160,000 lbs. per square inch, an elastic limit of 130,000 lbs., and an ultimate elongation of 4 per cent. in 18 ins. These strands are double galvanised, and after the aluminium strands are in place over the steel, around which they fit closely by reason of the stress resulting from the

load on the cable, the steel is to a large extent protected from corrosive action. This protection is due to the almost complete exclusion of moisture from the steel core by the aluminium envelope, and further on account of the insulating oxide film on the aluminium, which tends to prevent the flow of small local electric currents. Another feature which adds to this desirable condition is the fact that zinc and aluminium are closer together in the electro-chemical series than any other two metals in common use.

The following table shows at a glance the superiority in mechanical characteristics of steel-reinforced conductors over all-aluminium, or copper of equivalent conductance.

Size.	—	Aluminium.	Al.-Steel Reinforced.	Copper.
6/0 S.W.G. Cu Equiv. (Stranded)	Weight . . .	1·00	1·89	2·38
	Diameter. . .	1·00	1·17	0·83
	Ultimate strength .	1·00	2·71	1·62
2 S.W.G. Cu Equiv. (Stranded)	Weight . . .	1·00	1·48	2·14
	Diameter. . .	1·00	1·14	0·81
	Ultimate strength .	1·00	1·96	1·17
8 S.W.G. Cu Equiv. (Cu solid, Al Stranded)	Weight . . .	1·00	1·47	2·05
	Diameter. . .	1·00	1·07	0·69
	Ultimate strength .	1·00	1·84	1·36
Average . . .	Weight . . .	1·00	1·61	2·19
	Diameter . . .	1·00	1·13	0·78
	Ultimate strength .	1·00	2·17	1·38

Splicing.

In the matter of splicing the same general rules apply as for all-aluminium conductors, except that for the larger sizes the steel and aluminium are joined separately, the former by means of a steel McIntyre sleeve, and the latter by a two-piece compression joint.

For the smaller sizes the steel and aluminium are joined by the same sleeve. The sleeves are made of aluminium and 2½ times the length used for all-aluminium cables. The middle section is given 1½ turns in the opposite direction to the other parts.

Dead ending.

In order to develop the strength of the cable and to prevent overstraining the aluminium by reason of the slipping of the steel, dead and anchor clamps should grip the aluminium and steel separately.

Copper Equivalent S.W.G.	Total Area. sq. in.	Diameter. ins.	Weight per 1,000 yds.	Elastic limit. lbs.	Ultimate strength in lbs.
8	·0408	·25	187	1240	1770
7	·0471	·28	216	1440	2050
6	·0564	·30	259	1730	2460
5	·0688	·33	315	2100	2990
4	·0823	·36	373	2520	3590
2	·1161	·43	532	3550	5040
0	·1610	·51	737	4920	6990
2/0	·1849	·55	848	5650	8030
4/0	·2590	·65	1270	9300	12880
6/0	·3465	·77	1695	12440	17140

The values given for elastic limit and ultimate strength are taken as the sum of the corresponding values for the individual strands. These values for the individual strands are based upon the following data :—

Elastic Limit, Aluminium . . . . . 14,000 lbs. per square inch.
" " Steel . . . . . 130,000 " " "
Ultimate Strength, Aluminium . . . . 24,000 " " "
" " Steel . . . . . 160,000 " " "

Aluminium cable, steel-reinforced, being a composite material does not have definite values for its coefficient of expansion and modulus of elasticity. Approximate values for these quantities have, however, been derived, and it has been found from experience that deflections calculated by means of them are sufficiently close to the actual to meet all practical requirements.

OVERHEAD TRANSMISSION LINES.

Length of Span.

In England, short spans of from 120 to 150 ft. are commonly adopted. In Norway, Sweden, Switzerland, Italy, Canada, and U.S.A., spans averaging 500 to 550 ft. are becoming standard practice. These lines are designed upon lower factors of safety than those prevailing for the relatively small transmission projects in this country.

Sag.

The formulæ usually employed take no account of elasticity in the conductor, which allows the wire to stretch and thus relieve the strain, so that under actual working conditions the stresses in the wire at temperatures below the temperature of erection will always be lower than that calculated. This in itself constitutes a factor of safety, so much so that the British Post Office ignores wind pressure altogether for small copper wires, as being compensated for by elasticity. It is more or less standard American and Canadian practice to calculate the sag so as to give a theoretical maximum stress on the wire equal to its elastic limit at minimum temperatures. with an actual wind velocity of 65 miles per hour (equal to 10·5 lbs. per sq. ft. effective wind pressure on the projected area of the wire). The maximum temperature range commonly taken is 150° F., and the elastic limit of aluminium wire at 14,000 lbs. per sq. in.—such values having been found ample in practice. Continental official regulations stipulate a factor of safety of three on the breaking load, which latter is usually taken as 30,000 lbs. per sq. in.; this limits the maximum theoretical stress on the wire to 10,000 lbs. per sq. in.

The British Post Office Regulations specify a factor of safety of 4 on the wire, and a maximum wind pressure of 17 lbs. per sq. ft., and for small wires they neglect wind pressure altogether. The British Board of Trade Regulations for lines under their jurisdiction specify a factor of safety of 5 on the breaking load of the wire. Assuming an average tensile strength of 30,000 lbs. per sq. in., this limits the maximum theoretical stress on the wire to 6,000 lbs. per sq. in. Wind pressure is taken as 25 lbs. per sq. ft. on a flat surface, corresponding to 15 lbs. per sq. ft. effective wind pressure on a cylindrical surface.

The following table shows the sags on two typical sizes of aluminium cable on a short and long span, respectively, and brings out very clearly the disadvantage under which lines are erected under the conditions prevailing in Great Britain. These large sags necessitate heavier and more costly poles, increasing the cost of the line, and generally militate against the adoption of long-span long-distance transmission.

SAGS ON ALUMINIUM STRANDED CABLES.

	Tensile Strength	Factor of Safety.	Maximum Stress.	Effective Wind Pressure.	120 ft. span. 0·5 in. diam. Cable. Calculated Sags.		500 ft. span. 1·0 in. diam. Cable. Calculated Sags.	
	Lbs. per Sq. In.		Lbs. per Sq. In.	Lbs. per Sq. Ft.	0° F.	150° F.	0° F.	150° F.
					Ft. Ins.	Ft. Ins.	Ft. Ins.	Ft. Ins.
America & Canada .	—	—	14,000	10·5	0 3	2 6	3 1	13 10
France . . .	31,500	3	10,500	(12·5)	0 6	3 1	4 4	14 1
England . . .	30,000	5	6,000	15	1 3	4 7	8 4	15 10

These data have been calculated from the following formulæ, which are those most commonly employed, but it should be noted that they take no account of elasticity in the conductors, so that the actual stresses at temperatures below that of erection will in practice be lower than those assumed in the calculations, owing to the wire extending and relieving the strain. This provides a further margin of security, which is allowed for in Continental practice by taking lower factors of safety.

$$d = \frac{l^2 w}{8S} \qquad d_1 = \sqrt{(d^2 + \tfrac{3}{8} k T l^2)}; \qquad w = \sqrt{W^2 + P^2}$$

Where

l = length of span in feet; d = sag at minimum temperature; d_1 = sag at maximum temperature; S = stress at minimum temperature in lbs. = breaking load of wire ÷ factor of safety; W = weight of wire in lbs. per foot run (see table, p. 1929); P = ·06 × wind pressure in lbs. per sq. ft. × diameter of wire or strand in inches; T = difference between minimum and maximum temperatures Fahr.; k = coefficient of linear expansion per degree Fahr. (see table, p. 1931).

(*The British Aluminium Company, Ltd.*)

The Pacific Coast companies are giving considerable attention to the use of steel in place of copper for transmission lines. Steel conductors not only effect a saving due to reduced cost per unit of length, but also because of the longer spans permissible. Standard spans of 350 ft. to

450 ft. have been used extensively in the past; with the introduction of steel a 700-ft. span was selected as standard, and many miles of line have been built with spans of this length. The spans necessitate large sags, and the old style triangular construction, with pole-top pin, has been adopted, to give greater clearances between conductors.

Owing to the greater strains, more careful guying is required at corners, and at sharp corners four or six anchors to the pole are occasionally required. The San Diego Co. has installed in main or branch lines, exceeding a mile in length, 201 wire miles of ¼ in., $\frac{5}{16}$ in. or ⅜ in. standard steel; 75 wire miles are under construction, and there are 52 wire miles of ½-in. steel in constant-current series circuits. Most of the constant-pressure circuits are at 11,000 volts, though a few are at 2,300 volts. (*Electrical World.*)

The world's longest span of overhead h.t. transmission wires has recently been built in Norway, by the Stavanger Electric Power Company. It was required to transmit 12,000 h.p. from the power station at Lysefjord across Hoegsfjord to a transforming station at Oltedal, and from this station over 50,000-volt lines to Stavanger. The three wires of the transmission line are supported from three steel towers 7 m. high on each side of the fjord. The total free span is 1,384 m., the sag is 80 m., and the distance to the water surface 40 m. at the centre of the fjord and 80 m. at one side. The biggest span previously built was 1,350 m. across the Strait of Carquinez, in America. The steel cable has 19 strands and a diameter of 16 mm., the breaking strength being 15 kg. per sq. mm. When no wind is blowing the total stress in the cables is 4 tons, but with maximum wind pressure the stress is 7 tons. (*Electrical Times.*)

Ministry of Transport Regulations.

Every application for the consent of the Electricity Commissioners to the placing of electric lines above ground should be accompanied by the following particulars:—

1. Where the undertakers are a company, or a local authority supplying outside their own area, evidence of consent of the local authority for the district.

2. A statement showing commercial or other considerations why underground cables should not be used.

3. A brief description of the proposed system, whether by continuous or by alternating current; the working voltage; the kind of wire, whether copper or aluminium; whether solid or stranded; the total sectional area; tensile strength and elongation; average and maximum length of span; minimum height of wires from the ground; name or description of automatic protective device, if any.

4. A statement whether the supply is to form (1) an extension of an existing system of underground cables, or (2) of an existing traction system, or (3) an independent system.

5. An ordnance map on a scale of 6 ins. to the mile, showing the proposed route of the overhead lines and any existing overhead lines. The sheets of these maps must be fastened together.

6. In the case of high and extra-high pressure, plans of construction of poles, etc., on a scale of about 1 in. to the ft., or a reference to previously deposited plans where these are identical with the proposed work.

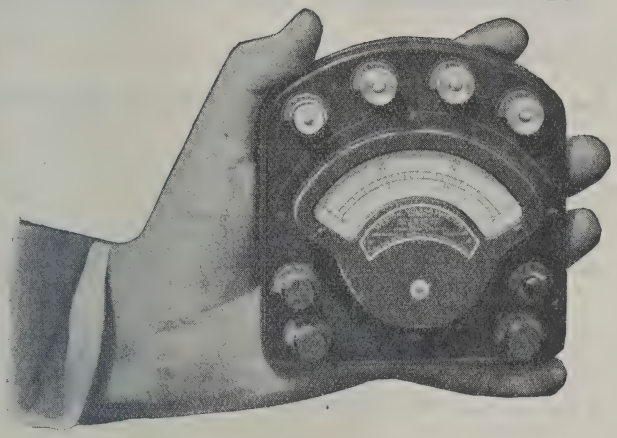
Codes of regulations have been made (1) for overhead lines for low-pressure and medium-pressure continuous-current supply, and for low-pressure alternating-current supply, and (2) for pressures exceeding low- or medium-pressure continuous current and low-pressure alternating current. Regulations will be made for each case separately, following these codes unless special alterations are sanctioned.

Attention is called to the necessity for obtaining the approval by the Postmaster-General of plans and works under Sec. 14 of the Schedule to the Electric Lighting (Clauses) Act, 1899.

The official Regulations for high-pressure overhead conductors assume the maximum conditions of loading to be a wind of 25 lbs. per sq. ft. at a temperature of 22° F. without snow or ice on the conductors, and a factor of safety of 5 is required on the conductors (breaking strength) under these conditions. Wooden poles must have a factor of safety of 10.

The larger the conductor, the longer is the economical span. The higher the tension of stringing, the longer is the economical span, and the less is the cost of the line. The most economical span length is never likely to be less than 250 ft. Span lengths in this country range from 150 to 300 ft. with wooden poles, and up to 350 ft. with steel poles; abroad, 500 ft. is usual. (G. V. Twiss in the *Journal I.E.E.*)

The relative costs of underground cable and overhead lines of the same carrying capacity, using three conductors of 0·1 sq. in. in each case, and carrying out the work on the very best lines, are stated by B. Welbourn (*Journal I.E.E.*) to be as follows:—



Voltage	Cable laid underground	Overhead line
6,000	£1,400	£900
11,000	1,550	950
20,000	2,100	950

Overhead conductors should be spaced apart, up to 6,000 volts, 2 ft.; up to 11,000 volts 2½ ft.; up to 20,000 volts, 3 ft. The minimum size of wire suitable for overhead lines is No. 11½ S.W.G. Earth plates should be of cast iron, 1½ ft. sq. and ¼ in. thick.

The whole subject is under investigation with a view to the drastic amendment of the Regulations by the Electricity Commissioners.

WESTON

ELECTRICAL INSTRUMENT CO. LTD.

Model 280 Portable Type.

MINIATURE PRECISION D.C. INSTRUMENTS.

Moving Coil Type Ammeters, Voltmeters,
Mil-Ammeters, Milli-Voltmeters and Volt-Ammeters.
About 300 Standard Ranges.
Accurate, Dead beat and Reliable.
May be carried conveniently in the pocket.
Weight ranges from 11 oz. to 1 lb.

Write for List D 3.

AUDREY HOUSE, ELY PLACE, HOLBORN, E.C.1.

Telephone No.: 2029 Holborn. Telegrams: 'Pivoted, Smith, London.'

(See also next page.)

WESTON

Instruments for Research.

For Research Work the following Portable Instruments are recommended:

	Accuracy.	Scale Length.
Model 1, Standard Portable D.C. Ammeters, Mil-ammeters, Voltmeters and Milli-voltmeters	$\frac{1}{5}\%$ ...	$5\frac{1}{4}''$
Model 5, Laboratory Standard D.C. Ammeters, Mil-ammeters, Voltmeters and Milli-voltmeters	$\frac{1}{10}\%$ ...	$11\frac{1}{8}''$
Model 310, Standard Portable Single-phase A.C. and D.C. Wattmeters, including Special Low-power Factor Instruments	$\frac{1}{4}\%$ ...	$5\frac{1}{4}''$
Model 329, Standard Portable Polyphase Wattmeters	$\frac{1}{2}\%$ ...	$5\frac{1}{4}''$
Model 322, Standard Portable Micro-ammeters...	$\frac{1}{4}\%$ ...	$5\frac{1}{4}''$
Model 341, Standard Portable A.C. and D.C. Voltmeters	$\frac{1}{4}\%$ ...	$5\frac{1}{4}''$
Model 370, Standard Portable A.C. and D.C. Ammeters and Mil-ammeters	$\frac{1}{4}\%$ ...	$5\frac{1}{4}''$
Model 326, Electrodynamometer Laboratory Standard A.C. and D.C. Ammeters Voltmeters and Wattmeters	$\frac{1}{10}\%$ ...	$12''$

WESTON Transformers of high accuracy are supplied to operate in conjunction with the above A.C. Instruments.

Full particulars will be sent upon application.

ELECTRIC MEASURING INSTRUMENTS.

Weston Standard Ammeters and Voltmeters.

Direct Current.

In these instruments, although the scales are remarkably uniform, no particular 'law' of deflections is assumed, as must be done when printed or engraved scales are used. A skeleton of each scale is laid out by actual comparison with an accurate standard, and the lines afterwards are inked in. Finally, the work is checked by comparison with the same standard. No multiplying constant is necessary (except with high-range voltmeters), as simple inspection of the position of the pointer on the scale gives the value in amperes or volts. Time in making readings is therefore saved, and errors of calculation are avoided. The scales of all direct-current instruments have practically uniform divisions from zero to the top mark. The range is thus greater than is common, while the uniform size of the scale divisions permits of their visual subdivision with uniform accuracy. The pointer comes to rest at once, although absolutely no friction can be detected, thus reducing the time required for readings, and preventing unnecessary wear of the moving parts.

There is no 'magnetic lag,' giving rise to different deflections with the same current or potential, as in instruments having iron in the moving parts. The 'temperature correction' is negligible, being for all voltmeters having a range above 15 volts, not greater than ¼ per cent. for a range of 35° F. above, or 35° below, 70°, and for the ammeter, less than 1 per cent. for the same range of temperature. The instruments of the 'Direct Current' type may be kept in circuit any length of time, as the heating effect, except in the higher ranges, is so small as to be inappreciable. In the voltmeters provided with a 'calibrating' coil, changes in scale-value resulting from accidental injury are easily checked; this is a very valuable feature, as all instruments are subject to occasional accidents and to rough usage, which may prove injurious. The user of these instruments can at any time roughly check their scale-values by applying a single cell of some constant form to the terminals of the calibrating coil.

Alternating and Direct Current.

These instruments can be used in measuring the current or voltage of both alternating and direct-current circuits with equal accuracy, being of the electrodynamometer type. Owing to the principle of operation, they cannot be made with a uniform scale throughout, but the upper two-thirds of the scale is practically uniform. To prevent errors from parallax, mirror scale-plates and knife-edge pointers are provided. The entire movable and field coil system is mounted in a double closed iron shield, which effectually protects it from external magnetic fields and electrostatic influences. Damping is accomplished by means of an air damper, which is very effective.

In voltmeters it is necessary for great accuracy to have the current taken by the instrument as small as practicable; the Weston Model 341 voltmeter is designed with this object in view and the current required is much less than is usual in this type of instrument. For ordinary measurements no corrections are necessary for temperature or for frequencies up to 133 cycles per second, nor is it necessary to take reverse readings on direct-current circuits. When great accuracy is required, however, such corrections can be made. The instruments may be left in circuit continuously. In general, they are guaranteed to have an accuracy of ¼ of one per cent. of full-scale value on the working portion of the scale.

Similar characteristics are found in the portable wattmeters made by the company.

All ammeters are really milli-voltmeters, as they merely measure the drop of potential across a constant resistance. This constant resistance is termed a shunt. The potential drop is directly proportional to the current passing through the shunt, if the shunt is correctly designed, and the instrument can therefore be graduated in amperes. The resistance of these shunts is very low: for a Weston switchboard ammeter of 100 amperes the resistance of the shunt is approximately ·0005 ohm. The shunt must not be strained when fixing to the bus bars or the resistance may be altered, which would alter the reading of the instrument. For this reason shunts are usually securely fastened to a base of hard wood. Low-range ammeters up to about 200 amperes can have the shunt contained within the instrument case. The resistance of the instruments does not exceed about 2 ohms, and about 25 to 30 milli-amperes is required for full-scale deflection.

Voltmeters which are placed directly across the circuit must be high-resistance instruments, and only require about 10 or 15 milli-amperes for full-scale deflection. For special testing work Weston voltmeters can be obtained which have a resistance of 2,500 ohms per volt, and only require ·0004 ampere for full-scale deflection. It is important to have a high-resistance voltmeter for testing the E.M.F. of dry batteries, etc.

Owing to the temperature coefficient of copper being high, all copper in the instrument should be reduced as much as possible to eliminate temperature errors. The moving system should be as light as possible to reduce the wear upon the pivots, which should work in good

jewels. The air gap must be small to insure the permanence of the magnet, which must be specially aged and carefully made. In Weston instruments the air gap is approximately ·04 in. Any number of different range shunts may be used with moving coil ammeters, so that accurate readings may be taken over a wide range.

More current is required to operate moving iron instruments than is necessary for moving coil instruments. For this reason moving iron voltmeters are not suitable for testing dry cells. The resistance per volt of moving iron instruments is about 12 to 20 ohms, against 60 to 100 or higher for moving coil instruments. The pointers of moving iron instruments always move in one direction, irrespective of the direction of flow of the current, and cannot therefore be made with centre zero. They will not have such uniform scales as moving coil instruments, the scale being contracted at one end, and in some instruments at both ends. Moving iron ammeters cannot be supplied with shunts to obtain a wide range of readings.

In reading instruments, the eye, the pointer, and the mark on the scale should be in a line at right angles to the plane in which the pointer moves, in order to avoid errors due to parallax. In edgewise instruments this line of vision must pass through the centre of the arc swept out by the pointer; one eye must be closed. In multi-range instruments each range should be a simple multiple of the other ranges; and the figures upon the scale of the instrument should preferably

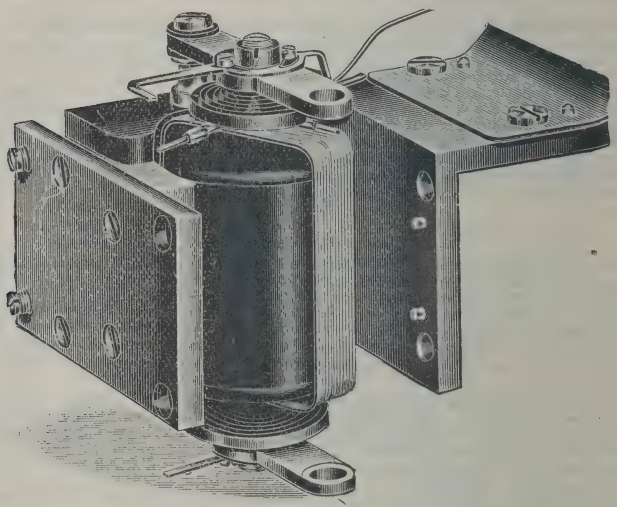

FIG. 33.

indicate the number of scale divisions. An instrument having a range of 150 or multiples thereof should be calibrated to have 150 divisions, figured 0–150. There is less liability of error in reading direct in scale divisions, and afterwards multiplying by a correct constant, than in mentally calculating the value of a fraction of a scale division, especially if there is a rapidly fluctuating load.

The accuracy of an instrument is best expressed as a percentage of the maximum load the instrument is intended to measure. For instance, an instrument having a range of 500 volts with an accuracy of $\frac{1}{10}$ per cent. should be correct at every point upon the scale to within half a volt. If the instrument has 100 scale divisions, this corresponds to $\frac{1}{20}$ of a scale division, which could be accurately read upon a portable instrument with a knife-edge pointer working over a mirror to eliminate errors due to parallax. If, however, the accuracy is taken as a percentage of the actual reading, when reading this instrument at 100 volts the error would not have to exceed ·1 volt, which would correspond to $\frac{1}{10}$ of a scale division, and would not be readable by the naked eye. If the instrument is supplied with an additional range to read 0–100, an accuracy of $\frac{1}{10}$ per cent. upon this range would represent ·1 volt, and would correspond to $\frac{1}{10}$ of a scale division.

Fig. 33 shows the moving coil of a Weston D.C. milli-voltmeter in position, for which purpose the magnet and one pole piece have been removed. The moving coil is a light rectangular aluminium frame, upon which are wound a few turns of silk-insulated copper wire; this frame is pivoted to

work in hard and highly-polished sapphire jewels. The pivots are small, specially hardened, and very finely ground and polished, so that no friction can be detected when they work in the jewel centres. The moving coil rotates in the narrow air gap formed between the pole pieces, only one of which is shown, and a soft iron core. As this air gap is only ·04 in. it is essential for the moving coil to be very accurately pivoted, so as to move freely in this narrow angular space. With such a narrow air gap it is also necessary for the sides of the rectangular frame to be formed to a radius slightly greater than the radius of the core. The motion of this coil is controlled by two flat spiral springs, which are made from a special Weston alloy ; they are arranged to work in opposition to each other, so that one uncoils and the other coils up when the moving coil rotates. The inside end of each spring is fastened to one end of the winding upon the coil, and the outside end fastened to an adjustable arm. One of the binding posts is connected directly to one of the arms, and the other binding post is connected to the other arm through a suitable resistance. The magnet, which is very carefully aged, is accurately ground to fit over the pole pieces, to which it is securely fastened.

THE SYNCHROSCOPE.

Apart from special methods only applicable to polyphase machines, two devices are in general use for synchronising alternators, (*a*) the synchronising lamp or voltmeter, and (*b*) the rotating field synchroscope. The former is more simple, but suffers from the defect of being insensitive as regards the exact moment of switching in, which should be when the machines are in exact coincidence of phase. Machines may be as much as 16 degrees out of phase before the synchronising voltmeter shows 1 per cent. of variation from its maximum reading, so that a little error of judgment may result in a considerable shock on switching in. A further objection is that although the rapidity of fluctuation of the lamp or voltmeter reading indicates the difference between the frequencies of the machines, there is nothing to show which of the two machines is the faster, and considerable time may thus be wasted. In order to make the lamp method of real service, therefore, it is necessary to combine it with some device for indicating exact coincidence of phase and also whether the incoming machine is fast or slow ; and this is what has been done in the Weston Synchroscope.

If an ordinary dynamometer wattmeter has both its fixed and moving coils wound with fine wire, and two alternating voltages are applied to the terminals of these coils, it will show very accurately when these two voltages are in exact *quadrature*, as the wattmeter will indicate zero in this case, and deflect to right or left if the phase difference is greater or less than 90. By connecting a condenser in series with one of the coils, and introducing a small amount of inductance into the other, it is easy to arrange that the wattmeter indicates zero when the two voltages are in phase instead of in quadrature, and this can be checked by connecting the two circuits to the same supply. Under these circumstances, if one circuit is connected to the bus bars and the other to the incoming machine it is only necessary to see that the synchronising lamp is bright and the watt meter pointer at zero to be able to throw in without any shock.

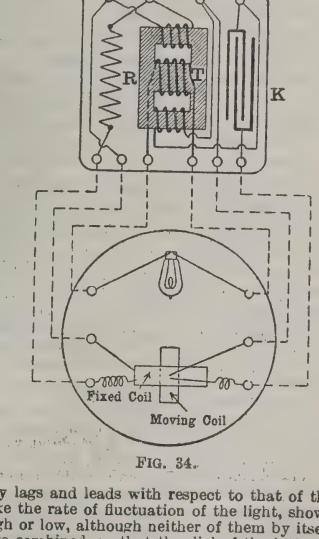

FIG. 34.

But this only indicates when the machines are in exact synchronism, and not whether the incoming machine is too slow or too fast. If the speed of the incoming machine is low or high, the lamp will flicker in the ordinary manner and the wattmeter will also deflect to right and left alternately as the voltage of the machine alternately lags and leads with respect to that of the bus bars. The rate of oscillation of the pointer, like the rate of fluctuation of the light, shows the amount by which the speed of the machine is high or low, although neither of them by itself indicates which. But if the lamp and wattmeter are combined, so that the dial of the latter is illuminated by the former, the difficulty is at once solved. For if the machine is fast the wattmeter pointer swings over from left to right while the lamp is bright, while when it swings back the lamp is dark. In consequence the back swing is not seen, and instead of the pointer appearing to oscillate it appears to rise with the dawn of light at the left-hand side of the scale, to swing across in full light and to disappear on the right of the dial with the extinction of the light, almost exactly like the rising and setting of the sun, and as if it were steadily revolving in one direction.

When the machine is slow, the lamp is bright as the pointer swings from right to left, and the direction of rotation is therefore apparently reversed. As far as its practical application is concerned, the instrument resembles in every way the rotating field synchroscopes (except that the fluctuation of the light is visible), and the arrangement is extremely simple, and free from any loose contacts.

The actual indicating instrument is almost identical in construction with the switch-board wattmeter, the only differences being that the dial carries a bold central mark with two arrows indicating ' Fast ' and ' Slow,' and that the synchronising lamp is inserted behind it. This lamp can be easily withdrawn and replaced. An auxiliary box contains an ordinary synchronising transformer, T, for the lamp, and a non-inductive resistance, R, and a condenser, K, for connecting in series with the two wattmeter coils respectively. A small inductive coil for adjusting the exact quadrature is included in the instrument case. Fig. 34 is a diagram of the connections of the instrument and box, which will be readily understood from the principle of the instrument.

METERS.

In all commercial motor meters there is necessarily a certain amount of friction, which as time goes on tends to increase more or less according to the design, and to cause the meter to slow down.

This defect manifests itself particularly at low loads, and is the more serious as the majority of meters are worked at points very low down on their load curves. For long periods the working point is frequently at or below one-tenth full load capacity, and in many instances, particularly where metal filament lamps are used, the working load is liable to be between one-twentieth and one-fiftieth the full load capacity of the meter for many consecutive hours daily.

Pointer type clocks should have light machine cut gears, and should run with an exceedingly small amount of friction, which, being constant, is easily compensated for. This fact constitutes an important advantage in favour of clocks of this type.

Roller cyclometer clocks have more friction than the pointer type, and moreover possess the defect that as the friction is a varying quantity it cannot be compensated for. A meter may have to move round one counter only, or again it may have to move up to five counters at one time.

Jumping figure cyclometer clocks are a modification of the roller type, having the friction load more evenly distributed through the use of a falling weight device. This weight is wound up slowly by the meter. It is released at the proper time, and in falling carries round the additional counters which it is necessary to move.

This partial equalisation of friction makes cyclometer clocks which have springing figures better than the roller type, although not so good as the pointer type clocks, where the friction is a constant quantity. An important feature of springing figures in comparison with roller type counters is that with the former no halving of figures takes place.

In all meters, the friction tends to increase more or less according to the design, etc., of the meter, and to cause the speed to slow down correspondingly, and it is essential to obtain the highest possible accuracy initially.

Manufacturers are generally willing to guarantee the accuracy of their meters, so that a.c. meters can be obtained which are capable of easy adjustment within plus or minus 2 per cent. from 50 per cent. overload down to one-fiftieth of full load.

The voltage drop in the main coils should be as low as possible. The drop varies with the size of the meter, being greatest in the smaller sizes and diminishing as the ampere capacity increases, due to the fact that in meters of large capacity fewer turns are required to create a similar torque. The loss in the shunt circuit should also be small, but should not be reduced at the expense of the torque, as in meters where the torque is reduced in consequence of the current in the shunt circuit being very low, the retarding effect of friction becomes great, affecting the accuracy of the meter under low load conditions. Moreover, with low torque more compensation will be required to balance the friction, and under such conditions trouble from ' creeping ' through vibration, due to street traffic or other external causes, will be much more liable to occur.

A record should be kept of the life of every meter on the system of any supply undertaking. As meters are received from the makers they should be checked against a standard which should be certified from time to time by some recognised authority such as the National Physical Laboratory. This check should be made at various loads, say 125 per cent., $\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{10}$, $\frac{1}{20}$ and $\frac{1}{50}$ full load, at unity power factor, and at half load 50 per cent. power factor, and the results obtained should be plotted on a card; a note of any subsequent attention required by the meter should be added to its record, and at the end of recognised intervals—say every two or three years—each meter should be brought in for overhaul and tested carefully before breaking any seals. The result obtained should be added to the record, thus affording a means of continuously studying the behaviour of every meter.

The following tests, arranged in order of their relative importance, are easily made :—

(1) Accuracy at varying currents from 2 per cent. to 150 per cent. load with voltage, frequency, and power factor constant.

(2) Accuracy at varying voltage with constant current and frequency.

(3) Accuracy at varying power factor with voltage, frequency, and current constant.

(4) Accuracy at varying frequency with constant load and voltage.

BRITISH STANDARD SPECIFICATION FOR ELECTRICITY METERS.

(*No.* 37—1919.) (*Abstract.*)

16. The construction of the meter shall be mechanically sound and suitable for its purpose and shall be such as to give reasonable assurance of permanence in all mechanical electrical and magnetic adjustments and shall not be seriously affected by external magnetic fields.

17. The parts of the meter within the case shall be carried on a substantial stiff framework forming, if desired, part of the case. The framework shall not be liable to distortion by changes of temperature, presence of moisture, or other cause. They shall be completely enclosed in a substantial dust-tight metal case, the front and sides of which may be glazed. The case shall be of sufficient strength to afford adequate protection to the working parts against mechanical injury with reasonable usage, and capable of being sealed in such a manner that access to the working parts and the electric or magnetic adjustments of the meter can only be obtained by breaking the seals. Care shall be taken to ensure that the mechanism as well as the interior of the case is free from dust or other extraneous matter immediately prior to sealing.

18. One or more substantially glazed dust-tight windows shall be provided in the front of the case in such a manner as to give a clear view of the register, and also of those working parts the observation of which is necessary for rapid testing of the meter. It shall be impossible to remove the glass without breaking the seals of the case or breaking the glass itself.

20. The terminals of the meter itself, unless of the switchboard type, shall be enclosed by a separate cover suitable for sealing, or contained in an external compartment of the case.

21. All meters of sizes above 100 amperes shall be provided with soldering sockets, except where provision is made for coupling with strip or bar connections.

22. The pressure circuit shall be connected to the supply side of the main circuit, and a disconnecting device shall be provided in the terminal compartment, to enable the pressure circuit to be entirely disconnected from the main circuit, in order that it may be supplied with current from a separate source for purposes of testing. The disconnecting device is not necessary where separate terminals are provided for the pressure circuit.

23. The meter, unless of the switchboard type having external connections, shall be provided with separate facilities enabling the purchaser to seal independently the terminal compartment and the meter case. Facilities may also be provided for independent sealing by the manufacturer.

24. Every meter, the accuracy of which is affected by small changes in level, shall be provided with means of ascertaining, without breaking the seals, that it is correctly levelled.

25. A diagram of connections to be attached to the meter.

26. The circuits of the meter shall be capable of carrying full load continuously without injury to any part of the meter, without any permanent change in its accuracy, and without the temperature of any accessible part of the case exceeding 10° C. above the temperature of the surrounding air, except when a shunt is employed in a separate compartment forming an integral part of the meter, when the temperature of any accessible part of the case of such compartment shall not exceed 30° C. above the temperature of the surrounding air.

27. Every external resistance shall be completely enclosed in a strong metal case.

Every external resistance shall be so constructed that when the marked pressure is applied to the meter and resistance combined and is maintained continuously, no injury shall be done to any part of the resistance, and the temperature of any accessible part of the case shall not exceed that of the surrounding atmosphere by more than 30° C.

28. The insulation resistance between all the electric circuits of the meter coupled together, and the containing case, or other metal not intended to be insulated when the meter is in use, shall be not less than 5 megohms.

The insulation resistance between the main circuit and the pressure circuit (if any) shall be not less than 2 megohms.

The insulating material between all the electric circuits and the containing case, or other metal not intended to be insulated when the meter is in use, shall withstand, for one minute, an alternating pressure equal to twice the pressure of the circuit for which the meter is intended, with a minimum of 1,000 volts. All the electric circuits shall be coupled together before applying the high pressure.

The insulation resistance shall be measured with a pressure of not less than 200 volts nor more than 500 volts (direct), applied for a sufficient time for the reading of the insulation indicator to become practically steady.

---

* By permission of the British Engineering Standards Association.

29. The rate of loss of energy in the pressure circuit at marked pressure shall not exceed the values given in the following table:—

Meter.	Marked Pressures up to 250 volts.	Marked Pressures above 250 volts.
Direct current	5 watts	2 watts per 100 volts
Alternating current	2 watts	1 watt per 100 volts

The rate of loss of energy in the meter current circuit for all meters having a marked current not exceeding 50 amperes shall not exceed 10 watts; with the further restriction that the pressure drop shall not exceed 2 volts.

When the meter has more than one element the above requirements shall apply to each element independently.

30. The forward direction of rotation of the rotor, if any, shall be clearly indicated.

32. The following shall be the standard sizes of meters:—2·5, 5, 10, 20, 40, 50, 100, 150 200, 300, 400, 500, 600, 800, 1,000, 1,500, 2,000, 3,000, 4,000, and 5,000 amperes.

34. When a current equal to one-hundredth of the marked current of the meter (or when this is less than one-twentieth of an ampere, then one-twentieth of an ampere) traverses its main circuit, the rotor shall start and continue running steadily, the pressure circuit, if any, being energised at the marked pressure in phase with the current in the main circuit.

35. The error of the meter at the standard or marked temperature, pressure, frequency, and at unity power factor shall not exceed the following values:—

PERMISSIBLE LIMIT OF ERROR.

Load.	Meters without external shunts or transformers.	Meters with external shunts or transformers.
	Per cent. from true reading.	Per cent. from true reading.
Full load to one-fifth full load (inclusive)	+ or − 2	+ or − 2·5
From one-fifth to one-tenth full load	2·5	2·5
At one-twentieth full load	4·5	5·0

36. If the meter has a pressure circuit, a variation of 5 per cent. above or below the marked pressure at any load from full to one-tenth shall not cause a change in the rate of registration in respect of such variation of more than one per cent.

39. The meter shall not be injured, and its accuracy shall not be permanently impaired, by a current 25 per cent. in excess of its marked current maintained for a period of one hour, or by the passage of a current in the main circuit not exceeding 30 times the marked current of the meter for a period not exceeding half a second, the rotor, if any, being free to rotate, and the pressure circuit being energised at marked pressure.

40. The meter shall not be injured, and its accuracy shall not be permanently impaired, by the application of a pressure 15 per cent. above the marked pressure for a period of one hour.

41. Every meter having a pressure circuit shall not register with its main circuit open when the pressure circuit alone is acting, either when marked pressure is applied or when this pressure is increased to 10 per cent. above the marked pressure.

THE EVERSHED MEASURING INSTRUMENTS.

Evershed & Vignoles.)

These instruments are very largely used for the measurement of the resistance of insulators and conductors; they embrace ranges from 1 microhm up to 10,000 megohms. All are direct reading in the strictest sense, and the ruling feature of each is to provide a means of measurement which shall be so simple that it can be used by any unskilled person, so rapid to use that a test shall occupy but a few seconds and so portable that the instrument can be taken anywhere to do the work required.

THE 'MEGGER' TESTING SET consists of a moving-coils type ohmmeter combined in one box with a high-pressure generator driven by a folding crank handle. The general principles of the construction and the electrical connections of the set are shown in the following diagram.

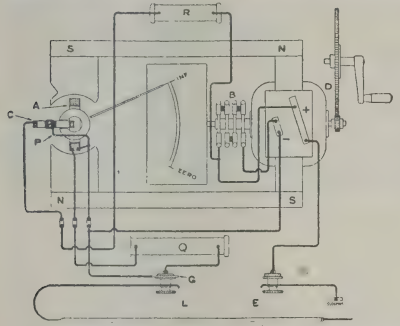

FIG. 35.—Megger Testing Set.
Diagram of Connections.

A=current coil; P=pressure coil; C=compensating coil; N, S=magnets; Q, R=resistances; B=brush gear; D=driving gear; + − =generator terminals; G=guard plate; L=external 'line' terminal; E=external 'earth' terminal.

In external appearance the 'Megger' testing set is similar to the 'Bridge Megger' testing instrument shown by fig. 36, but without the terminals at the end of the case. To carry out an insulation test on a system, connect the 'line' terminal to the circuit and the 'earth' terminal to a good earth. If testing between two wires, connect one wire to each terminal.

When the handle of the generator is turned at about 100 r.p.m. the rated voltage will be developed, and the value of the insulation resistance under test will be indicated directly by the pointer over the scale. The instruments are fitted with either variable or constant-pressure generators; the constant-pressure type should always be used when testing the insulation of circuits having considerable electrostatic capacity, such as large house-wiring installations, supply and feeder cables, etc. The constant-pressure device consists of a centrifugal friction-clutch, which secures that when the handle is turned above the slipping speed, the speed of the generator, and consequently the terminal E.M.F., remains constant. All 'Megger' and 'Bridge Megger' testing sets are provided with a system of guarded insulation to ensure that no internal or surface leakage can affect the readings. Any error in tests of high insulation due to leakage across the surface of the material under test can be eliminated by the use of a guard wire connected to the 'guard' terminal, which is provided on all high-range instruments.

THE BRIDGE-MEGGER TESTING SET, fig. 36, is a combined ohmmeter and generator of the usual 'Megger' type for insulation testing, but also arranged so that the ohmmeter can be converted into a Bridge Galvanometer by means of the change-over switch fitted. The current for the Bridge tests is provided by the generator (constant-pressure type), and a direct-reading resistance box of special and convenient design is supplied as a standard of comparison. The whole combination forms the most rapid known means of measuring that range of resistances for

FIG. 36.—Bridge-Megger Testing Set in Use.

which the Bridge method is adapted, and the value of the resistance is given plainly in a row of figures, which prevents errors. The series of ranges covers Bridge measurements from 0·01 ohm upwards, and insulation measurements up to 1,000 megohms. In addition to the measurement of insulation and conductor resistances, the set may be used for the localisation of faults on telephone and telegraph cables, or on electric light cables if their resistance falls within the limits of Bridge methods.

THE 'DUCTER' POTENTIAL OHMMETER TESTING SET provides for the measurement of resistances from 1 microhm up to 100 ohms by the direct deflection method. The current for this set is supplied by a separate battery, and a pair of duplex handspikes are used for making contact on the resistance under test. With these instruments the resistances of switch and fuse contacts, armature windings, rheostat coils, rail-bonds, sheathing and earth circuits in collieries, joints and the like, are easily and rapidly determined.

LAMPS.

Metal Filament Lamps.

Tungsten has a specific gravity of about 20. Its melting point is over 3,000° C., which is higher than that of any other known metal. The proportion of its total radiations which is in the visible spectrum is greater than that of other substances which are considered normal.

While the melting point of tungsten is very high it oxidises at a very low temperature—(about 300° C.). It also softens at a very low temperature, and filaments which are easily broken when cold can be bent permanently into any desired shape at a temperature below the oxidising point. This characteristic is taken advantage of in making many filaments of special form, especially in making low voltage lamps ; many filaments of spiral or helical form are made by winding straight pieces of filament on hot mandrels. Similar forms of filaments when made of carbon must be made in the desired form before carbonisation. The specific resistance cold of carbon is 800 times that of tungsten and at normal working temperature it is 33 times that of

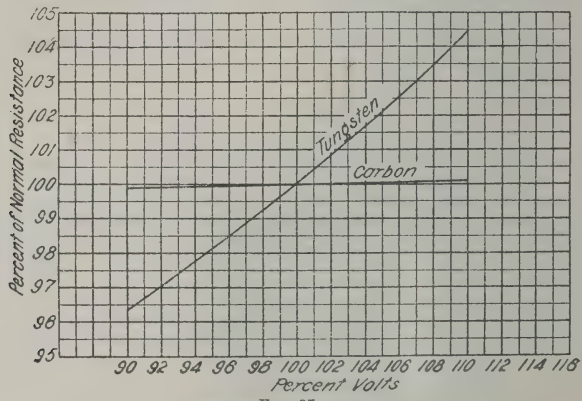

FIG. 37.

tungsten. The low specific resistance of tungsten is a disadvantage in making high voltage lamps, making it necessary to use very long thin filaments for these lamps. The length of filaments for 120-volt lamps ranges from 450 mm. for 20-watt lamps to 1,400 mm. for 500-watt lamps. Lamps of standard voltage are now made ranging from 20 watts and 16 c.-p. to 500 watts and 400 c.-p., all of which are well designed and of good quality.

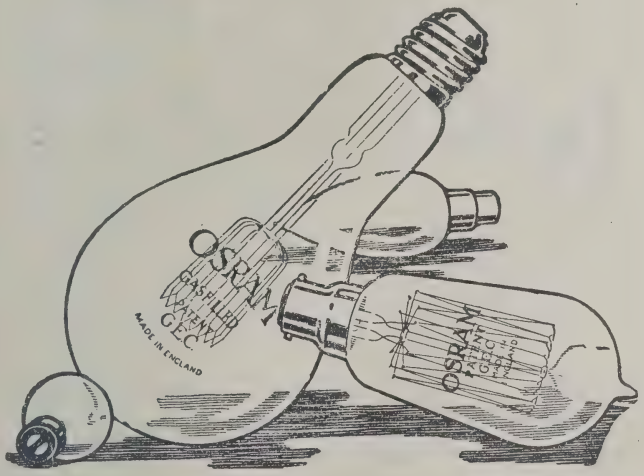

Fig. 37 shows that in a tungsten filament an increase in voltage is met and partly counteracted by an increase in resistance, while in a carbon filament the resistance remains practically constant ; consequently any increase in voltage produces less increase in watts, less increase in candle-power, and less decrease in life in a tungsten filament than in a carbon filament. The curve (fig. 38) shows that an increase of 3·7 per cent. in voltage will halve the life of a carbon lamp, while it requires an increase of 5·2 per cent. to halve the life of a tungsten lamp. The cold resistance of a tungsten filament is only one-twelfth the resistance at normal operating temperature, consequently when first connected to the circuit the current is for an instant much greater than the normal current. This excessive current is of sufficient duration to cause an instantaneous rise (overshooting) in candle-power, which is higher than the normal candle-power. The best filaments are more fragile than are carbon filaments. Tungsten filaments when burning are quite soft and plastic and must be supported at points sufficiently near together to prevent the filaments sagging and touching each other or the glass. Spring supports are used in many lamps designed to prevent sagging, and they do in fact keep the filaments nearly straight under all circumstances. These supports prevent the filaments being attracted over against the glass and being broken by static electricity, which is a frequent cause of trouble with carbon lamps. The variation of light from a filament due to the variation in current caused by the successive impulses of an alternating current depends upon the heat capacity of the filament, the heat-radiating characteristic and the resistance characteristic. Tungsten has a specific gravity about 10 times that of carbon and a specific heat one-fifth as great, so that the heat capacity of a tungsten filament is about twice that of a carbon filament of the same dimensions. The heat radiating characteristic of tungsten is better than that of carbon because at a given temperature it radiates heat less rapidly than does carbon. The

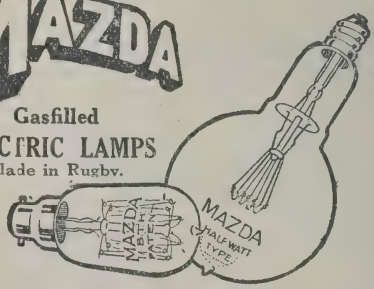
Supreme Economy

THE high efficiency, brilliance and extraordinary physical strength of Mazda lamps are essential to any lighting scheme which shall ensure larger output and lower costs.

Science, by developing the Mazda Gasfilled lamp, has reduced the original cost of electric lighting and enormously extended its field of application. With Mazda lamps, suitably equipped and arranged, you can have artificial illumination which is as good in quality and intensity as daylight, and is less costly and far less troublesome than the relatively ineffective illuminants hitherto in vogue.



Mazda Gasfilled lamps will provide all the light you want. Our Illuminating Engineers will, if you wish, show you how to employ this light to the best advantage—to get the utmost results therefrom in the form of effective and appropriate illumination. This expert advice entails no obligation on your part—it is just part of the unrivalled Mazda service.

resistance characteristic of tungsten is also more favourable than that of carbon for the retention of energy and heat as the current wave recedes. All these physical characteristics of tungsten are therefore better than those of carbon in respect of the retention of heat, and they all tend to make the flicker of tungsten lamps less than of carbon lamps of the same size filament. The actual diameters of tungsten filaments, however, are much smaller than those of carbon filaments of the same candle-power lamps and this more than offsets the advantages of the other characteristics, for the flickering of tungsten lamps is greater than that of carbon lamps of the same candle power while it is much less for lamps with the same size filaments. The flicker of a 25-watt tungsten lamp on a 60-cycle circuit may be observed by standing with your back to the lamp and moving a pencil rapidly backwards and forwards. The flicker of a 40-watt tungsten lamp on a 60-cycle circuit is scarcely perceptible on a moving pencil.

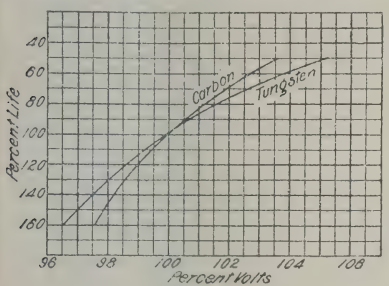

FIG. 38.

(J. W. Howell, Am. Inst. E. E. Proc.)

The British Engineering Standards Association has issued a standard specification for 'normal type vacuum tungsten-filament electric lamps' (Report No. 133, 1921), in which limiting values are given for the dimensions of the bulbs and bayonet caps, and the conditions of test are laid down. The limits of variation in initial watts and in initial watts per average candle. (mean spherical candle-power) at rated voltage are given in the following table; the initial candle-power must not differ from the candle-power computed from the rated watts and nominal initial watts per average candle (cols. 2 and 3) by more than plus or minus 15 per cent. at rated voltage. The mean of the values of the candle-power measured after 1,000 hours' burning is not to be less than 80 per cent. of the mean value at the commencement of the test.

DRAWN-WIRE MAZDA LAMPS.

This is a tungsten filament lamp (*The British Thomson-Houston Co. Ltd.*), in which drawn wire has replaced the pressed filament formerly used, the drawn wire being many times stronger than the old pressed filament at any time during its entire life.

Siemens 'Britannia' Lamps.

These lamps are sold by *Messrs. English Electric & Siemens Supplies, Ltd.*, and are manufactured in England at Dalston and Preston. They have drawn tungsten wire filaments, and the Standard Vacuum type operate at an efficiency of, approximately, 1·2 watts per c.p. The 'gasfilled' type represents the latest development in metal filament lamp manufacture, and the larger sizes attain an efficiency of, approximately, 0·5 watts per c.p. Both types of lamps are made in an extensive range of voltages and candle-powers. The following are descriptions of the various types available.

Siemens Britannia Standard Type Lamps.—These are made in voltages from 20 to 260, and in wattages from 5 to 100, and cover the lamps in general demand for ordinary electric lighting schemes of average intensity.

Siemens Britannia Traction Type Lamps.—This type of lamp has been introduced to meet the requirements experienced in situations where lamps are subjected to severe shock and vibration, and is now largely used on the leading tramway systems and tube railways. A totally new arrangement of the filament is employed, which ensures maximum strength and adequate support. The complete length of filament is spiralised and carried in a series of loops on a special spider in the usual Siemens manner. The distance between the top and bottom supports is considerably reduced, which ensures maximum strength, while neighbouring lengths of filament are more widely separated, thus obviating short-circuiting of adjacent lengths of filament, which sometimes occurs in the ordinary type of lamp subjected to severe vibration. The filament has no sharp bends, and will not 'sag,' so that the lamp may be used in any position. The spherical candle-power of the lamp is increased, and the light emitted is uniform in all directions other than towards the cap end. It is claimed for this design that these additional advantages have been obtained without appreciable loss of efficiency in operation.

Siemens Britannia Gasfilled Lamps.—The gasfilled type lamp was originally introduced in high candle-power types only, but the range has been increased, with the result that these lamps are now obtainable for standard lighting voltages from, approximately, 30 to 1,500 watts. Owing to their high efficiency, these lamps became known to the public as 'Half Watt' type lamps. It is, however, an essential condition to their production that they should be gasfilled in order to obtain a satisfactory life at the efficiency mentioned. The leading manufacturers are therefore stamping the word 'gasfilled' on the bulbs of these lamps, so that the consumer may be protected should he be offered lamps which, though resembling genuine high-efficiency lamps, are not gasfilled.

The range of Siemens Britannia gasfilled lamps now includes Automobile head-light lamps, from 4 to 14 volts from 8 to 48 watts; Siemens Britannia gasfilled lamps for Railway Lighting, 25 volts, can be obtained from 15 to 100 watts. The 50- to 60-volt gasfilled lamps are supplied from 30 to 500 watts; 100- to 130-volt from 40 to 1,500 watts; and the high voltage gasfilled lamps, 200- to 260 volts, from 60 to 1500 watts. These high candle-power lamps are being employed in large numbers for general lighting in stores, workshops, factories, offices, shops, etc., and for street lighting. They produce illumination without flicker, and require no attention after installation, save occasional cleaning.

Siemens Britannia Automobile and Battery Type Lamps.—In addition to the range of gasfilled automobile head-light lamps mentioned above, Siemens Britannia Battery Lamps are made for automobile lighting, sign lighting, omnibus and yacht lighting; while there is also a variety of types suitable for use in miners' hand and rescue lamps. The voltages of these vary from 2 to 14, and the wattages from, approximately, 1 to 36 watts.

Osram (G.E.C.) Lamps.

The filament of the Osram (G.E.C.) lamp (*The General Electric Co. Ltd.*) consists of pure drawn tungsten wire.

In addition to the low c.p. sizes of Osram lamps, a new tungsten lamp has been introduced in which a gas-filled bulb is used in place of vacuum; the efficiency of these lamps approximates to ½ watt per candle, as compared with vacuum lamps which consume about 1 watt per candle. The Osram gas-filled lamp is known as the 'Atmos' type lamp, and is made from 30 to 3,000 candle-power. The high candle-power lamps are largely used in the place of arc lamps.

The Osram standard or 1-watt lamp is made in sizes from 4 to 400 c.p., and, in addition, standard types have been supplemented by special types for different purposes, such as with concentrated filaments for projection and focusing work; with 'Axial' type filaments for downward illumination, such as over desks, etc.; and for use from low voltage batteries, such as miners' and general portable hand-lamps and automobiles (including motor-bases). The Osram (G.E.C.) lamp 'Atmos' type is also made for automobile headlights.

Notes on Incandescent Lamps.

Efficiency.—Rated according to their mean horizontal candle power, the English parliamentary candle being used as a unit, the highest commercial efficiency of carbon lamps of 8 c.p. and over is 3·1 w.p.c. with a useful life approximately of 450 hours; of a gem lamp, 2·5 w.p.c. with equal useful life; of a tantalum lamp, 2 w.p.c. with a useful life of 800 hours on d.c., uncertain on a.c.; of a tungsten lamp, 1·25 w.p.c. with a life of 1,000 hours.

Although the operating temperature of the tungsten filament is higher than that of any of the other illuminants mentioned herein, the lamp itself, while in service, is much cooler than the carbon, gem, or tantalum lamp.

Intrinsic Brilliancy of Lamp Filaments.—The candle power per square inch of the filament of carbon 3·1 w.p.c., gem 2·5 w.p.c., tantalum 2 w.p.c., and tungsten 1·25 w.p.c. lamps is 480, 625, 750, and 1,000 respectively.

Quality of Light.—The light of tungsten lamps more closely approaches daylight than that of other illuminants. It naturally follows that tungsten lamps cause colours to retain more nearly their true values than any other artificial light source.

The Tungsten Lamp Association has formally endorsed the standards advocated by the British Electrical and Allied Manufacturers Association and the British Engineering Standards Association. These pressures are 100, 110, and 115 for low voltages, and 200, 220, and 230 for high voltages. At the moment, the Association does not propose to go so far as these figures indicate, but to adopt a wider range, as follows :—25, 50 and 55 volts for under 100 volts ; 100, 105, 110, 115, 120 and 125 volts for low voltages ; and 200, 210, 220, 230, 240, and 250 volts for high voltages. It is felt that the change can be made more easily by a gradual transition. Eventually the standards of the B.E.A.M.A. and of the British Engineering Standards Association will be made applicable to lamps manufactured by members of the Association.

Having given the number, candle-power, watts per candle, and voltage of electric lamps, the current consumed is given by the formula :

$$A = \text{No. of lamps} \times \text{c.p.} \times \text{watts per candle} \div \text{voltage}.$$

Thus 20 tungsten lamps of 25 c.p., taking 1·2 watts per candle on a 200-volt circuit consume

$$20 \times 25 \times 1{\cdot}2 \div 200 = 3 \text{ amperes}.$$

ARC LAMPS.

In a D.C. arc lamp the top or positive carbon burns about $1\frac{1}{2}$ inches per hour, and twice as fast as the bottom or negative carbon of the same diameter. A 1,000-candle-power lamp requires carbons about $\frac{9}{16}$ inch in diameter and consumes about 1,000 watts.

ANGOLD MAGAZINE FLAME ARC LAMP.

(The General Electric Co. Ltd.)

The Angold Magazine Flame Arc Lamp is arranged to burn carbons of comparatively short length (maximum 15 ins.) without copper coating or metal core ; twelve pairs of these carbons can be filled in the magazine at one time, and thereby, according to the type of lamp, 120 to 150 hours be obtained.

The carbons are so arranged that as soon as one pair is consumed the next pair comes into operation. The magazines can be filled up if only part of the trim has been consumed, so that at any time the full burning hours obtainable with a full magazine can be assured. The positive carbons cannot be put into the negative magazine, and when the last carbons are consumed, the feeding gear is automatically put out of action. Partly burnt carbons need not be removed. The interval of time during which the light is extinguished does not exceed two seconds.

The direct current lamp is manufactured for 8 or 10 amperes and can be supplied with self-contained equivalent resistance and automatic cut-out, or it can be supplied without these accessories. In the latter case, however, the lamps can only be used singly, on suitable voltage, or two in series on 100–120 volts. For longer series (or even for two lamps on higher voltage) equivalent resistances and automatic cut-outs have to be provided. If it is inconvenient to have these accessories self-contained they can be supplied in the suspension type, or if it is necessary to lower the lamp from contact gear a box-type is recommended.

Both 8-ampere and 10-ampere lamps are designed for 9 mm. positive and 8 mm. negative carbons, 15 ins. long. Each trim of carbons consists of 12 pairs.

An alternating-current lamp of this make will burn in parallel singly on any voltage between 100 and 250 volts—25 cycles to 100 cycles. Each lamp is fitted with a self-contained transformer choker so that it can be connected directly to the mains.

(For 'Illumination' see Section XXXV., Part III., page 2137.)

Fuses.

FUSE TABLE. (APPROXIMATE S.W.G.)

Approximate Fusing Current in amperes.	Tin.	Lead.	Copper.	Approximate Fusing Current in amperes.	Tin.	Lead.	Copper.
1	37	35	47	60	12	12	21
2	31	30	43	70	10	9·5	20

(*P. W. Harley.*)

FUSING CURRENTS FOR COPPER WIRE.

The following table has been found to be closely correct for average conditions:—

Size of wire B.S. gauge	30	28	26	25	24	22	21	20	19
Fusing current in amperes	10	15	20	25	30	40	50	60	70
Size of wire B.S. gauge	18	17	16	15	14	13	12	11	10
Fusing current in amperes	80	100	120	140	160	200	240	280	330

To restore a service temporarily it is useful to know the above if no regular alloy fuse wire is to hand, when motor or other circuits have blown their protective links.

THE ELECTRICAL EQUIPMENT OF SHIPS.

REGULATIONS ISSUED BY THE INSTITUTION OF ELECTRICAL ENGINEERS (SEPTEMBER 1919).

(*Abbreviated.*)

General.—These regulations apply to all sea-going ships except ships of war. They relate to the use of electrical energy for all purposes except the propulsion of ships, and comprise the main requirements for ensuring satisfactory results.

Nature of Supply.—Standard systems of distribution are two-wire D.C. or A.C., three-wire D.C., three-phase three- or four-wire. Standard pressures are 110 volts and 220 volts D.C., 110 volts single-phase A.C. Standard pressures have not been fixed for polyphase currents, but must not exceed 150 volts for lighting and 250 volts for power and heating. The standard frequency is 50 cycles per second.

Generating Plant.—Generators shall conform to the British Standardisation Rules, except that they shall be capable of sustaining an overload of 25 per cent. for two hours in temperate climates and cool situations on board ship. Generators shall be over-compounded 5 per cent.; they shall be placed where they do not affect the compasses, with their axes fore and aft, and the frames shall be efficiently earthed.

Switchboards.—If marble or slate be used, all conducting parts connected to one pole shall be insulated with mica or micanite, and the slab shall be similarly insulated from the frame, which must be earthed. All circuits and apparatus shall be labelled. Voltmeters and lamps shall be protected with fuses on each insulated pole, and switches shall be so connected that their moving parts are not alive in the off position. Switches shall be connected between the fuses and the omnibus bars. A distinctive system of colouring shall be employed on switchboard omnibus bars and conductors. Where generators are run in parallel, each shall be protected with a circuit-breaker with overload and reverse-current trips; if compound-wound generators are used, an equaliser switch shall be interlocked with the circuit-breaker. On three-wire systems no fuse or switch shall be inserted in the neutral conductor. In three-phase three-wire systems each generator must have a triple-pole circuit-breaker with overload trips on at least two phases; if four wires are used, the circuit-breaker must have an overload trip on each phase. Unless one pole is permanently earthed, the main switchboard must be provided with means for testing

the insulation of the system. Conductors and switches must be so proportioned that their temperature shall not rise more than 54° F. above the temperature of the surrounding air, when carrying the normal working current. Up to 10 amperes, the fusing current of fuses shall be three times the normal working current of the circuit; above 10 amperes, twice the normal current. Fuses shall comply with the British Standard Specification No. 88, and shall not be placed in switches, ceiling roses, or wall plugs or sockets.

Conductors.—All conductors shall be of annealed copper conforming to British Standard Specification No. 7. No cable shall have a less cross section than 0·0015 sq. in., except for ornamental fittings, for which the cross section may be 0·001 sq. in. All conductors over 0·0033 sq. in. shall be stranded. The size of conductors shall be such that the fall of pressure between the main switchboard and any point on the installation under the maximum probable load shall not exceed 2 volts plus 3 per cent. of the omnibus-bar pressure for lighting, and 2 volts plus 5 per cent. for power and heating. Standard sizes for ship installations are given in the table on page 1864.

Cables, whether single or twin, must be either vulcanised-rubber insulated (braided or lead-covered, with or without armour) or paper insulated and lead-covered, with or without armour. For particulars see tables on pages 1861 and 1862 for single cables, 250 volts, rubber insulated, and on page 1859 for paper insulated cables.

The insulated conductors must be able to withstand a test-pressure of 1,000 volts for half an hour, alternating at a frequency between 25 and 100 cycles per second, after twenty-four hours' immersion in water and whilst still immersed. Cables must be made with a distinctive coloured braiding. Flexible cords shall be vulcanised-rubber insulated in accordance with the table on page 1861, and shall withstand a test of 1,000 volts alternating for fifteen minutes, after twenty-four hours' immersion. The ends of all cables of 0·007 sq. in. and over shall be provided with soldering sockets. Cables may be run in wood casing in dry situations; otherwise, armoured and lead-covered cables shall be secured with metal clips and the resistance of the metal sheathing between any two points of a completed installation shall not exceed 2 ohms. Metal staples must not be used. If exposed to damage, cables shall be protected with sheet-iron plating or heavy-gauge screwed conduit, electrically and mechanically continuous, earthed and drained. Cables in machinery spaces or exposed to sea-water shall be lead-covered. Cables in refrigerating chambers shall be in full view from end to end, and shall be lead-covered and supported by non-metallic clips. Conductors of opposite polarity carrying direct current may be, and if carrying alternating current they shall be, bunched when in conduit. Lead-covered and armoured cables may, in all cases, be bunched, whatever their polarity. All connections between rubber-insulated cables shall be made by means of joint boxes; between cables and flexibles by clamped connections in suitable receptacles. Connections between lead-covered paper-insulated cables shall be made by the same means as for rubber-insulated cables, or preferably, instead of joint boxes, lead sleeves wiped on to the cable coverings may be used, filled with insulating compound. Cables passing through decks or watertight bulkheads shall be provided with deck tubes or watertight glands; unarmoured cables passing through beams and non-watertight partitions shall have the holes bushed with lead or other soft non-ferrous metal.

Distribution.—Final sub-circuits for lighting, etc., shall carry not more than 600 watts, with a maximum of ten points, and shall be connected to a sub-distribution board. Every sub-distribution board, and every consuming device taking more than 600 watts, shall be connected to a section or main distribution board, and the latter to a separate way on a larger board or the main switchboard. Each two-wire circuit on a distribution board shall be protected by a fuse on each insulated pole, and, except in the case of a sub-distribution board, by a switch on one insulated pole. No fuse or switch shall be connected to an earthed pole. The neutral of a three-wire system, or of a three-phase four-wire system, shall never be interrupted by a fuse or switch. Every three-phase circuit shall be controlled by a triple-pole circuit-breaker with overload trips on at least two phases, or by a triple-pole linked switch and a fuse on each pole. No fuse rated at less than 3 amperes need be employed on any final sub-circuit.

Earth Connections.—Only steel ships shall be wired on the single-conductor system. Earthing connections carrying current shall be of the same size as the corresponding insulated conductor. Earthing connections not normally carrying current shall be of copper of the same size as the working conductor (but not less than 0·003 sq. in.) up to 0·007 sq. in., and above that size not less than 0·007 sq. in. for every 50 amperes of working current or part thereof. Earth connections shall be secured by screws not less than $\frac{3}{8}$ in. in diameter.

Interference with Compasses.—Dynamos, batteries, and all apparatus producing an external magnetic field shall be fixed at such a distance from the compass that the magnetic field produced thereat has a negligible value. No single-conductor cable carrying continuous current shall be fitted within 30 ft. of standard and steering compasses. Conductors in the vicinity of the compass shall be twin, or as close together as possible. Incandescent lamps used for lighting the compass shall not consume more than 0·6 ampere, and no live part shall be less than 7 ins. from any part of the magnetic system.

Navigation Lamps.—Each navigation lamp is to be separately wired and controlled by a separate switch and fuses, and to have an automatic indicator in circuit to give warning of the failure of the light.

Storage Batteries.—The cells shall be so constructed that the electrolyte cannot be spilled with strong containers (not celluloid). They should be in a single tier and mounted on oil insulators. The deck must be lined with lead or other acid-resisting material, and all exposed metal protected with acid-resisting paint. The battery compartment must be well ventilated. Switches and fuses must be fixed outside the battery room. All connections in the battery room are to be of bare metal or lead-covered cables.

Fittings.—Fittings are to be so designed and fixed that dust and moisture cannot accumulate within them, and are not to be mounted on surfaces liable to become damp. In exposed positions they are to be weatherproof and waterproof; open type fittings must not be used near inflammable goods or where inflammable dust or gases can occur. Switches, etc., must not be installed in bunkers or where inflammable gases may be present. Weatherproof portable lamp fittings with metal frames must have all metal parts connected to earth by a third conductor in the flexible cord, and must be provided with hooks to hang them up with. Lampholders in weatherproof portable fittings must be earthed, and in open type fittings they must be insulated and protected with insulating shields. Plugs and sockets must be so constructed that they cannot be readily short-circuited or earthed or allow an arc to be maintained. Plugs must be provided with hand-shields or interlocked with switches in the sockets. Weatherproof plugs and sockets must be employed in exposed positions.

Lamps.—Arc lamps must have the whole of their live parts insulated from the frame, and must be provided with wired globes or other protection; they must not be fitted near combustible goods or where gases can accumulate, and each circuit must be controlled by a switch and fuse on each insulated pole.

Motors.—Motors over $\frac{1}{8}$ b.h.p. are to conform with the British Standardisation Rules, with carbon brushes, suitable terminals, and automatic lubrication. If fitted in compartments where inflammable goods or gases may be present, they must be of the flameproof type; where the temperature is liable to exceed 120° F., they are to be either pipe-ventilated or of the forced-draught type. Motors over 3 b.h.p. must have starters with no-volt release, or controllers.

Control Gear.—Regulators and controllers are to be of incombustible materials and guarded or enclosed in incombustible cases; contacts shall be renewable, and all live parts enclosed by metal covers, and so designed that they cannot be touched by the operator. Resistances shall not rise to an excessive temperature, and no accessible part of the apparatus may rise above 130° F. Internal connections shall not be soldered. Control gear shall not be placed where inflammable gases can accumulate, unless it is flameproof; in exposed situations it shall be totally enclosed. Resistances shall be placed in well-ventilated compartments and away from combustible material.

Heating and Cooking Apparatus.—Appliances shall be so constructed that parts which are handled cannot exceed a temperature of 130° F. The elements shall be readily replaceable; live and highly-heated parts shall be guarded. Connections between the elements and switches or external leads shall be made without solder, and their temperature shall not exceed 200° F. All appliances for pressures exceeding 150 volts shall be efficiently earthed. Whether portable or fixed, appliances shall be controlled by fixed switches; portable appliances shall have at least one section of the elements controlled only on the live side of the wall plug or other connection with the fixed portion of the circuit. Non-luminous appliances shall be provided with visual indicators showing when current is passing No appliance taking over 1,000 watts shall be portable.

Internal Communications.—Transforming apparatus and batteries shall conform with the rules for lighting and power plant. If the working pressure exceeds 25 volts, all parts of the apparatus shall be made and fitted in accordance with the rules for lighting and power circuits. Cables shall be made and fixed in accordance with the rules for light and power cables. Fuses need not be fitted in branch circuits for pressures not exceeding 25 volts, or in circuits supplied from primary batteries.

Lightning Conductors.—Conductors shall be fitted to all vessels having wooden masts, of copper tape or rope having not less than 0·15 sq. in. sectional area. When in dry dock, ships' lightning conductors shall be connected to an efficient earth on shore.

Oil Ships.—On oil ships the pressure shall not exceed 110 volts; no part of the system shall be earthed, and double-pole linked switches shall be used on every circuit or sub-circuit. All cables shall be lead-covered, with or without armour. Distribution shall be on the two-wire two-conductor system. No wiring shall be taken into oil-holds or coffer-dams, which must be lighted by lamps entirely outside the space and separated from it by an airtight glass bowl. Lamps in dangerous spaces shall be in gas-tight fittings, and the switches shall be outside the spaces; no portable lamps other than self-contained battery-fed lamps (mining type) may be used in dangerous spaces.

Trials.—The insulation of the whole system, with all lamps and fuses in place, is to be tested before putting into service with direct current at twice the working pressure between the system of conductors and earth, and shall not be less in megohms than 10 divided by the number of lamps (on lighting circuits), but the insulation resistance of any final lighting sub-circuit need not exceed one megohm. The insulation resistance of every piece of apparatus, with switch or control gear, etc., shall be not less than half a megohm. The installation shall be run for six hours and all the apparatus operated, not necessarily simultaneously.

General Rules of the Institution of Electrical Engineers.

(Revised 1916.)

(*Abbreviated.*)

LOW PRESSURE, NOT EXCEEDING 250 VOLTS.

General Arrangement.

Every system not being an earthed concentric system must be protected by main linked switches or main linked fuse-switches under the control of the consumer, and these must be easily accessible and placed as near the generator or the point of entry of the supply as circumstances permit.

Where the supply is given from the three wires of a three-wire system, the neutral conductor, whether earthed or not, must never be interrupted unless the outer conductors are simultaneously interrupted; hence no fuse or unlinked switch may be included in the main neutral conductor.

When the pressure between the outer conductors of a three-wire system exceeds 250 volts and the three wires of the system or two pairs of wires are brought into premises, the supply must be given from two pairs of terminals arranged so as to minimise the danger of shock, and the wiring from these terminals, including that behind distribution boards, must be kept distinct throughout in separated circuits which must not be bunched.

Where energy is taken from all the conductors of a two-phase or three-phase system, the conductors must be protected on each pole by an automatic circuit-breaker, or by a fuse in conjunction with a linked switch, or by a fuse-switch.

Conductors must radiate from distributing centres, and in large systems feeders will be necessary between centres and sub-centres. For lighting purposes in any sub-circuit which supplies more than a single point, the current must not exceed 6 amperes up to 125 volts, nor the power 600 watts, from 125 to 250 volts, and the maximum number of points on any sub-circuit must not exceed 10. Every sub-circuit must be protected on each pole by a fuse.

When protected from mechanical injury by metal conduits, or by a covering of tough rubber compound, conductors of opposite polarity may be bunched, and when carrying small currents for incandescent lighting, from sub-centres, conductors of the same polarity, if without joints, may be bunched when the protecting tubing or casing is non-metallic. If the supply is alternating and the protection iron or steel, the lead and return conductors must be bunched.

There must be no contact between conductors (or their insulating material, metallic sheathing or tubing) and gas pipes. Non-conducting distance pieces must be used where necessary.

Earthing conductors must be of copper and of a sectional area not less than that of No. 14 s.w.g.

Gas pipes must never be used to obtain an earth connection.

In places where inflammable or explosive dust, gases, or vapours are liable to be present, dynamos, arc lamps, mercury-vapour lamps, and wall plugs and sockets must not be used. In such situations, glow lamps must, with their holders, be enclosed in air-tight fittings of thick glass; switches, fuses, and resistances must be enclosed in flame-tight incombustible cases; and motors, with their live parts, starters, terminals, and connections, must also similarly be enclosed.

Conductors—Size and Conductivity.

Excepting for wiring fittings, the cross-sectional area of any copper conductor must not be less than that of No. 18 s.w.g. The cross-sectional area of fittings wires must not be less than that of a No. 20 s.w.g.

The size of conductors on lighting circuits within a building will be determined by the permissible drop in volts, which should not exceed 2 per cent., plus a constant allowance of 1 volt.

Insulated copper conductors must be of annealed copper, and must have a conductivity not less than that of the E.S.C. standard; where sulphur compounds are present in any part of the insulating material the copper in contact with the insulating material must be protected therefrom by tinning or otherwise.

All insulated copper conductors having a greater area than that of a No. 16 s.w.g. wire must be stranded.

Conductors—Insulation.

Conductors must be specially insulated with material which does not rapidly deteriorate at the highest temperature to which it will be subjected; for instance, rubber must not be allowed to exceed 130° F., and paper or fibre 176° F

The insulating material on any conductor other than a flexible must be throughout either—

(*a*) A non-hygroscopic dielectric, such as vulcanised rubber of the best quality, which only needs mechanical protection; or

(*b*) A hygroscopic dielectric, such a impregnated paper or fibre, which must be encased in a waterproof sheath, generally of soft metal, such as lead, drawn closely over the dielectric.

The dielectric must not soften sufficiently to allow decentralisation under working conditions.

The dielectric must be such that when the insulated conductor has been immersed in water for twenty-four hours it will, while still immersed, withstand a pressure test of 1,000 volts for half

an hour in the case of 250 volt cables, and one of 2,500 volts for half an hour in the case of 650 volt cables, with an alternator capable of giving an output of not less than 5 kilowatts.

Concentric conductors should in all respects conform to the requirements laid down for single conductors.

Conductors—Flexible.

Flexibles must be of a sectional area not less than that equivalent to No. 22 s.w.g., and they must be made up of wires twisted together on a short lay, the sectional area of each wire being not less than that of No. 36 s.w.g. The insulating material used as the dielectric must be pure rubber equal to washed Para rubber of the best quality or vulcanised rubber of the best quality. Pure rubber must be laid on in two layers, care being taken that each layer overlaps, and the radial thickness of the dielectric must not be less than 20 mils. Each coil of pure rubber flexible must be tested for 15 minutes with a pressure of 1,500 volts alternating between the conductors at a frequency of 50–100. Vulcanised rubber flexible must be insulated with one layer of pure rubber and two layers of vulcanised rubber. In the case of flexibles having a conductor cross-sectional area less than ·0009 sq. in., the radial thickness must not be less than 33 mils for low pressures and not less than 62 mils for medium pressures. When sulphur is present, the insulating material must not be in direct contact with the copper wires.

Conductors—Bare.

Conductors without any insulating covering may be used indoors—

As collector wires for travelling cranes and similar appliances, but they must be so supported upon insulators as to prevent contact between the conductors themselves, or between the conductors and the walls or the structural or other metal work, should a collector wire be displaced from any insulator. The insulation at each straining point must consist of double insulation with proper straining gear. The current must be under complete control by means of a switch and a fuse, or a fuse-switch, in each supply conductor. Lightning arresters must be fitted if the bare wiring extends to a position exposed to lightning.

As trolley wires for locomotives, cranes, and similar appliances, but they must be insulated by means of double insulation with proper straining gear between each wire and earth at their points of support. Wall rosettes or brackets used as supports for span wires should not be fixed within 1 ft. of any gas pipe. Controlling switches and fuses, or fuse-switches, and lightning arresters must be provided.

As battery connections, but such conductors must be well spaced from each other and from all structural or other metal work, and be rigidly supported on insulators.

For other purposes, under special circumstances and in positions inaccessible to unauthorised persons, but permission for such use should be previously obtained from the Fire Offices insuring the risk.

Conductors—Protection.

Insulated conductors (except flexibles) may be cased in steel conduits in accordance with the British Standard Specification, which must be earthed throughout; or they may be cased in wood, in dry places. Insulated conductors protected with tough rubber compound 50 mils thick and capable of resisting abrasion, acids, oils, and alkalis, may be used without conduits or wood casing.

Joints and Connections.

Joints, when unavoidable, must be accessible, and they must be mechanically and electrically perfect to prevent heat being generated. All joints must be soldered, except where flexibles are connected to hard wires. Soldering fluids containing acid, or other corrosive substances, must not be used.

When junction-boxes are used they must be so constructed that—

(*a*) the conductors cannot be readily short-circuited;
(*b*) the insulation between opposite poles is rigid and durable;
(*c*) the connections do not heat;
(*d*) if used in damp places, moisture is excluded by suitable means.

Conductors of larger sectional area than that of 7/18 s.w.g. must be soldered into proper cable thimbles for connection to terminals. Where there is any possibility of stress on the thimbles the conductors must be secured, in addition to the soldering, by some mechanical device, such as one or more set screws.

Switch and Distribution Boards.

Main and distribution switch and fuse boards must be fixed in dry situations, and be so arranged that a fire thereon cannot spread, whether occurring at the front or back. Their bases must be of incombustible and insulating material, with moisture-proof bushes fitted at the points of support if the material is hygroscopic. The possibility of a permanent arc must be prevented either by sufficient spacing of all live parts, or by the use of separating partitions.

Connections at the back of main boards must be accessible, symmetrically placed, and spaced apart, and so arranged as to prevent the access of acid fumes from batteries to the board.

No open-type fuses may be placed at the back of switchboards.

The cases of instruments, if metallic, must be insulated from the circuits.

Every voltmeter or pilot lamp with its connecting wires should be protected by a fuse on each pole.

Combination switch and fuse boxes must be so arranged that it is possible to operate a switch without uncovering the fuses, if these are of the open type.

When fuses are of the open type and grouped together, the case of the distribution board will be a sufficient protection from the fused metal provided the distance from cover to fuse exceeds 1 in. with glass-fronted cases. If made of wood, the case must be protected with fire-resisting material, and a clearance of 1½ in. should be provided.

Switches.

Switches, whether fixed separately or combined with lampholders or fittings, must comply with the following requirements :—

(*a*) Overheating must not take place at the point of contact or elsewhere, when the full current flows continuously.

(*b*) They must be so constructed or arranged that the contacts cannot accidentally close when left open.

(*c*) They must be incapable of forming a permanent arc when breaking circuit, and they must be tested with pressures and currents 50 per cent. in excess of those which will be used on the circuits for which they are intended.

(*d*) The bases must be of incombustible non-conducting and moisture-proof material.

(*e*) Circuit-breakers must be so arranged and placed that no combustible material is endangered by their action.

(*f*) Unless placed in an engine-room or in a compartment specially arranged for the purpose, switches must have their live parts covered. The covers must be of incombustible material, and must be either non-conducting, or of rigid metal, and clear of all internal mechanism.

(*g*) Switches in positions where they are liable to injury, or contact with goods, should be further protected by an open-fronted box or other suitable guard.

(*h*) Handles must be insulated and so arranged that the hand cannot touch live metal, or be injured through an adjacent fuse blowing.

(*i*) Switches having a handle projecting through an open slot in the cover must not be used.

Fuses.

Fuses must comply with the following requirements :—

(*a*) No overheating of any part must take place when the full current flows continuously.

(*b*) They shall effectually interrupt the current when a short-circuit occurs, and when the working current through them does not exceed 10 amperes the fuses must interrupt the current before it exceeds three times the working current.

(*c*) The terminals must be so spaced apart or screwed that an arc cannot be maintained when the fuse is blown.

(*d*) The bases must be of incombustible, non-conducting, and moisture-proof material.

(*e*) Unless placed in an engine-room or in a compartment specially arranged for the purpose, fuses must have incombustible covers to retain the fused metal.

(*f*) Fuses must not be placed in ceiling roses, lampholders, or wall sockets.

Branch fuses must be grouped together in accessible positions in sight, and should be symmetrically placed and labelled for each circuit.

Wall Plugs and Sockets.

Wall plugs and sockets must be capable of withstanding a test with pressure and current 50 per cent. in excess of those for which they are intended. They must have incombustible bases, and in damp places they must be watertight.

Wall plugs and sockets must be constructed so that they cannot be readily short-circuited. Clearances should be such that an arc cannot be started if the connector is pulled out while the current is flowing.

Flexibles for portable fittings must end in a wall plug and socket fitted with a suitable cord-grip.

Every wall plug and socket must be independently controlled by a fixed switch on the live side. To avoid leaving the flexibles alive, it is preferable that the portable fittings themselves should not be provided with switches.

Ceiling Roses.

Ceiling roses must comply with the following requirements :—

(*a*) The bases must be of incombustible, non-conducting and moisture-proof material ;

(*b*) The covers must be of incombustible material, and must be either non-conducting, or of rigid metal clear of all live parts ;

(*c*) The terminals must be relieved of the direct pull of the attached conductor and fitting, and be so arranged that no short circuit can take place ;

(*d*) They must not be used for attachment to more than two pairs of flexibles, unless specially designed for multiple pendants.

Fittings for Supporting Lamps.

Wherever brackets, electroliers, or standards require to have the conductors threaded through tubes or channels formed in the metal work, these must be of ample size and have no sharp angles or projecting edges, which would be liable to damage the insulating material, and the open ends should, where possible, be bushed.

Where possible, the conductors should be carried without joints through the fittings to the lamps, but where connections at the fitting are unavoidable special care must be taken to make the joints equal in conductivity and insulation to the rest of the work.

Lampholders.

Lampholders must—

(1) be incombustible ;

(2) not be hung from flexibles exposed to the weather ;

(3) not contain a switch if for pressures above 250 volts.

Switch lampholders must be controlled, preferably in groups of not more than ten, by a wall switch.

Arc Lamps.

Arc lamps must—

(*a*) be guarded by lanterns or globes arranged to intercept falling particles of carbon ;

Note.—Lanterns or globes may be dispensed with where an open arc is essential, as in photography, and where no combustible material is present, as in a foundry ; but the flooring immediately under the lamp, if of a combustible nature, must be protected from falling particles of carbon. Open inverted arc lamps, in the presence of combustible matter, must have metal reflectors rigidly attached beneath the arc, which at all times must be below the level of the upper edge of the reflector. The reflector must project at least 15 ins., measured horizontally beyond the arc on all sides.

(*b*) be insulated from their support ;

(*c*) be fixed so that their cases cannot come into contact with any metallic object ;

(*d*) be controlled by linked switches and protected by a fuse on each pole.

Glow Lamps.

Glow lamps must—

(*a*) Not be placed in close proximity to combustible materials unless specially protected ; shades made of combustible materials must be kept free from contact with the lamps and their holders by suitable guards or supports ; celluloid or similar material for shades and candle tubes is strictly prohibited ;

(*b*) be fitted with guards if placed in positions where goods are liable to be stacked in contact with them ;

(*c*) with their holders, be enclosed in air-tight fittings of thick glass, if placed in positions where they are exposed to inflammable vapour or gas, or to excessive dust or flyings, as in dust-rooms and in raising-rooms.

Heaters.

Heaters must be—

(*a*) so constructed and mounted that their supports and connections cannot become overheated, precautions being taken with regard to their surroundings as in the case of non-electrical heating appliances. They must not be placed in close proximity to combustible materials, unless suitably protected ;

(*b*) controlled by double-pole switches if consuming over 1,000 watts.

Heating circuits must be protected by a fuse on each pole and by a wall switch in each room.

Resistances, Choking Coils, and Alternating-Current Transformers.

The live parts of the above must be—

(*a*) carried on frames or supports and enclosed in cases. These frames, supports, and cases must be of incombustible material efficiently insulated from the conductors ;

(*b*) amply ventilated. Where there is danger of inflammable dust or flyings entering, apertures in the cases must be protected by fine-mesh wire gauze or by finely-perforated sheet metal ;

(*c*) so proportioned that their cases cannot attain a temperature exceeding 176° F.

(*d*) so fixed that no unprotected combustible material is within 6 ins. of the frames or cases containing them, or within 24 ins. measured vertically above them.

Motors.

Motors rated at more than one-third of a horse-power must comply with the following requirements :—

(*a*) They must be protected from damp, dust, and mechanical injury.

(*b*) They must be so placed that no unprotected woodwork or combustible material is within

a distance of 12 ins. from them measured horizontally, or within 4 ft. measured vertically above them, unless they are of a totally enclosed type.

(*c*) When mounted upon wood flooring, unless of the totally enclosed or ventilated type, they must have a sheet of metal inserted between them and such flooring.

(*d*) In positions exposed to inflammable dust or flyings, or where combustible materials are manipulated or stored, they must be either of the totally enclosed or of the ventilated type, provided that any ventilating openings in the cases of continuous-current machines are protected by fine-mesh wire gauze or by finely perforated sheet metal, and that all slip-rings, commutators, and brushes are totally enclosed. Inspection openings fitted with plate glass or fine-mesh wire gauze are allowed. Induction motors may have unprotected ventilating holes in their metal cases, but slip-rings or brushes or any sliding contacts must be completely enclosed in metal cases.

(*e*) They must be controlled by a double-pole switch and protected by a fuse or circuit-breaker on each pole, except with earthed concentric wiring.

(*f*) The starting gear of a continuous-current motor must consist of a starting switch with a no-volt release, and a series starting resistance.

(*g*) The shunt circuit of any motor must be so connected that the field is excited before the armature circuit is completed.

(*h*) Every alternating-current motor must be provided with a suitable starting device.

Dynamos.

Dynamos must comply with the following requirements:—

(*a*) They must not be placed in positions exposed to inflammable dust or flyings, nor where combustible materials are manipulated or stored.

(*b*) They must be protected from damp, dust, and mechanical injury.

(*c*) They must be so placed that no unprotected woodwork, or other combustible material, is within a distance of 12 ins. from them measured horizontally, or within 4 ft. measured vertically above them.

(*d*) When mounted upon or above wood flooring, they must have a sheet of metal inserted between them and such flooring.

(*e*) They must be controlled by a double-pole switch and protected by a fuse, or by a circuit-breaker, on each pole, except with earthed concentric wiring.

Accumulators and other Batteries.

The room in which accumulators or primary batteries are placed must be well ventilated.

The case of each cell must stand on insulators.

Bare conductors are preferable for end and regulating cell connections; and each regulating cell should be protected by a fuse. Each independent circuit from the battery must be suitably fused.

Testing.

The insulation resistance between conductors and between conductors and earth of the whole or any part of the wiring must not be less in megohms than 30 divided by the number of points under test.

In the case of lighting circuits, the whole of the lamps having been connected to the conductors and all switches and fuses being on, the insulation resistance of the whole or any part of the installation must not be less in megohms than 25 divided by the number of lamps.

The value of systematically inspecting and testing apparatus and circuits cannot be too strongly urged. Records should be kept of all tests, so that any gradual deterioration of the system may be detected. Cleanliness of all parts of the apparatus and fittings is essential.

Before making any repairs or alterations, the circuits which are being attended to must be entirely disconnected from the supply.

ELECTRIC CLOCKS AND TIME SERVICE.

The Pulsynetic System.

The Pulsynetic system, designed by *Messrs. Gent & Co., Ltd., Leicester*, is arranged to operate any number of impulse clocks, workmen's time recorders, turret clocks, etc., installed in any large building or institution and connected electrically in series. The hands of such dials are all caused to advance simultaneously at half-minute intervals by means of step by step impulse propulsion movements (fig. 39), which, taking the place of the ordinary spring, or weight, and train of wheels, are operated by electric currents sent out periodically by a MASTER PENDULUM or TRANSMITTER. The latter (fig. 40A) consists of a pendulum, which, by means of a pawl, causes a ratchet count wheel to revolve tooth by tooth—one tooth at every vibration. One of the teeth on the wheel is cut deeper than the others, so that a prolongation of the pawl is enabled to engage with and move aside a spring detent, which it misses during the passage of the other teeth. The detent, when moved aside, allows a weighted gravity lever to descend, and this, through the medium of a friction roller carried thereon and an inclined plane fixed on the side of the pendulum, gives an impulse to the latter, imparting energy sufficient to enable the pendulum to swing during another revolution of the wheel—that is, for a period of half a minute. This gravity

impulse is, of course, constant and invariable, so that other factors, such as temperature variation, etc., being suitably provided for, the time-keeping qualities of the pendulum are exceptionally good. The descent of the gravity lever is caused to close an electrical circuit, which fulfils a dual function : (*a*) energising an electro-magnet, which causes the restoration of the gravity lever to its potential position and (*b*) sending an electrical impulse through the external circuit to

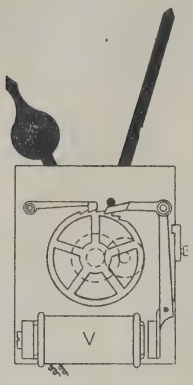

FIG. 39.

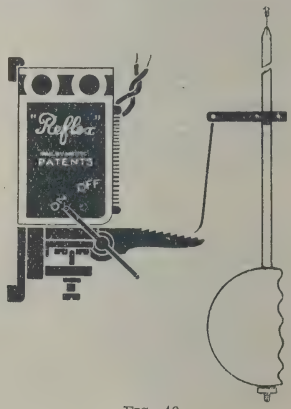

FIG. 40.

operate the impulse movements. The duration of this contact is about ·05 second ; but, depending upon the total self-induction of the circuit, its duration is self-regulating, in that the contact is not broken until the self-induction has been overcome and all the dials operated.

The system includes in series with the transmitter and the clocks a weak battery warning-bell which rings automatically every half minute should the battery run down and so endanger the safe working of the system. This warning is given before the actual breakdown point is reached, affording a safe margin of time in which to recharge or renew the battery. With the latest form of impulse movement one cell only is required in the battery for every three 12-in. clocks in circuit.

The system lends itself conveniently to the automatic operation of sound signals for the starting and ceasing of work, and also to the convenient operation of output and idle machine recorders. This class of recorder has proved itself useful in connection with textile machines and machines which should not be idle during working hours.

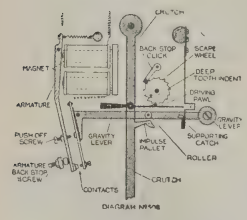

FIG. 40A.

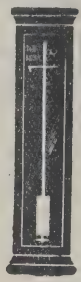


Workmen's Time Recorders are now controlled from the half minute impulses of the system by means of the 'Pulsynetic Reflex' Pendulum Control (fig. 40). With this control the recorders remain independent units, and no mechanical alterations are made, but with the 'Reflex' fitting, as shown in fig. 40, attached to their pendulums, all recorders are compelled to keep in step with the transmitter.

Even if the electrical connections be removed the recorders continue to work under their own power as before, but uncontrolled. This 'Reflex' control is also applicable to the pendulums of large public clocks, and its introduction is a marked advance in the science of the Unification of Time.

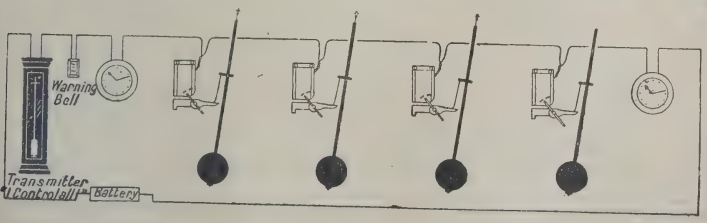
For large turret clocks, the accuracy of whose performance is subject to interference from variation in wind pressure or from accumulations of snow and ice on the hands, a special WAITING TRAIN movement is used, in which the hands are driven continuously by a special type of electric movement sufficiently powerful to overcome any such resistance ordinarily to be expected. The hands are caused to travel at a slightly faster rate than usual, to gain in fact about two seconds per half minute. Every half minute, however, the driving train disconnects

The

OUTSTANDING FEATURES *of* GENTS' Pulsynetic System of Electric Clocks:

¶ The operation of 'Start and Cease Work' Sound Signals.

¶ The regulation of existing Workmen's Registers.



¶ The control of Works, Office & Yard Clocks.

LIGHTNING CONDUCTORS

MANUFACTURED, SUPPLIED, AND SCIENTIFICALLY INSTALLED BY

R. C. CUTTING & CO.,

of Vulcan House, 56 Ludgate Hill,

LONDON, E.C. 4.

Contractors to: The Lords of the Admiralty; H.M. Government; Office of Works; War Department; Home Office; The Principal Railways, Corporations, Colleges, Cathedrals, Titled and Landed Gentry throughout the World.

Established 1879.

Telegrams: ADJUNCTOR, PHONE, LONDON.

Telephone: 8495 CENTRAL.

Architects' Plans inspected and free schemes and quotations submitted

Steel Structures a Speciality.

Expert advice given on existing installations. Competent mechanics sent to all parts. Detailed instructions for fixing supplied with all exported goods.

Contractors also for erecting, razing, heightening, or restoring, with inexpensive scaffolding, STEEL, BRICK, or CONCRETE Chimney SHAFTS, Church SPIRES, Tall TOWERS, and other lofty and dangerous structures.

itself from the hands, which then wait until the driving power is reconnected by means of the usual half-minute electric impulse current sent out by the transmitter driving the other impulse clocks in the building. The waiting period is practically unnoticeable—so that in very large turret clocks immunity from the usual weather interruptions is achieved, together with a greater degree of accuracy in timekeeping than in clocks operated in the usual manner. Efficient electric striking, or striking and chiming apparatus, can be supplied for bells of any size.

This WAITING TRAIN movement has been chosen for driving the hands of the largest electric clock in the world, in the towers of the offices of the Royal Liver Friendly Society at Liverpool. This has four 25 ft. dials, and the weight of a pair of hands is 5 cwt. The minute hands are 14 ft. long, 2 ft. 6 ins. wide at the greatest width, and 9 ins. thick where attached to the spindle. The combined weight of each pair of hands, spindles, and internal counter-weights, is a trifle over half a ton. The area of the hands exposed to snow and wind is very great, nevertheless the type of mechanism employed has shown itself able to withstand the disturbing effect of several severe storms since its erection in 1911.

For ship use special clocks are provided, the Impulse Transmitter being fitted with an automatic arrangement, which enables the whole of the ship's clocks to be automatically advanced or automatically retarded, while sailing east or west. These Pulsynetic marine clocks are installed in a large number of liners and ocean-going steamers.

LIGHTNING CONDUCTORS.

CODE OF RULES FOR THE ERECTION OF LIGHTNING CONDUCTORS.

(*Lightning Rod Conference*, 1882, *and Lightning Research Committee, Royal Institute of British Architects*, 1905.)

Two main lightning rods, one on each side, should be provided, extending from the top of each tower, spire, or high chimney stack by the most direct course to earth. Horizontal conductors should connect all the vertical rods (*a*) along the ridge, or any other suitable position on the roof; (*b*) at or near the ground line. The uppermost conductor should be fitted with aigrettes or points at intervals of 20 or 30 feet. Short vertical rods should be erected along minor pinnacles and connected with the uppermost horizontal conductor. All roof metals, such as finials, ridging rain-water and ventilating pipes, metal cowls, lead flashing, gutters, etc., should be connected to the horizontal conductors. All large masses of metal in the building should be connected to earth, either directly or by means of the lower horizontal conductor. Where roofs are partially or wholly metal lined they should be connected to earth by means of vertical rods at several points. Gas pipes should be kept as far away as possible from the positions occupied by lightning conductors, and as an additional protection the service mains to the gas meter should be metallically connected with house services leading from the meter.

Material for Rod.—Copper, weighing not less than 6 oz. per foot run, either in the form of tape or rope of stout wires, no individual wire being less than No. 12 S.W.G. Iron may be used but should not weigh less than 36 oz. per foot run. Subsidiary conductors for connecting metal ridging, etc., to earth may with advantage be of iron and of a smaller gauge, such as No. 4 S.W.G. galvanised iron.

Points.—The point of the terminal should not be sharper than a cone of which the height is equal to the radius of its base: but a foot lower down a copper ring should be screwed and soldered on to the upper terminal, in which ring should be fixed three or four sharp copper points, each about 6 ins. long. The number of conductors or points to be specified depends upon the size of the building, the material of which it is constructed, and the comparative heights of the several parts; no general rules can be given, but even ordinary chimney stacks, when exposed, should be protected by short terminals connected to the nearest rod, as accidents often occur owing to the good conducting power of the heated air and soot in a chimney.

Fixing.—Rods should preferably be taken down the side of the building which is most exposed to rain. They should be held firmly by holdfasts of the same metal as the conductors (not by insulators), but not so tightly as to prevent free expansion and contraction due to changes of temperature. They should not be bent abruptly round sharp corners; the vertical rods should be carried at a certain distance from the wall to prevent dirt accumulating, and to avoid the necessity of running them round projecting masonry or brickwork. In some cases it may be necessary to carry a rod through a string-course or other projecting stonework to avoid curvature, in which case the hole should be large enough to give ample clearance to the conductor, but it is better to run outside, keeping the rod away from the structure by means of holdfasts as mentioned above.

Joints.—Joints in series of conductors should be as few as possible. As a rule they should only be necessary where the vertical and horizontal conductors are connected, and the main conductors themselves should always be continuous, without artificial joints. Connections between vertical and horizontal conductors should always be in places readily accessible for inspection. Every joint, besides being well cleaned, screwed, scarfed, or riveted, should be thoroughly soldered, and should be protected from the action of the air, especially in cities.

Painting.—Iron rods, whether galvanised or not, should be painted; copper rods may be painted or not, according to architectural requirements.

Protection.—Copper rods to the height of 10 ft. above the ground should be protected from injury and theft by being enclosed in an iron pipe reaching some distance into the ground.

Earth Connections.—It is essential that the lower extremity of the conductor be buried in permanently damp soil; hence proximity to rain-water pipes and to drains is desirable. It is a very good plan to make the conductor bifurcate close below the surface of the ground, and adopt two of the following methods for securing the escape of the lightning to earth: a strip of copper tape may be led from the bottom of the rod to the nearest gas or water *main*—not merely to a lead pipe—and be soldered to it; or a tape may be soldered to a sheet of copper 3 ft. sq. and $\frac{1}{16}$ in. thick, buried in permanently wet earth, and surrounded by coke, charcoal, or pulverised arc-lamp carbons (coke, however, is likely to set up corrosive action on the earth-plate), or many yards of the tape may be laid in a trench filled with coke, well rammed. Where iron is used for the rod, a galvanised iron earth-plate should be employed. A tubular earth connection driven into moist ground makes an effective earth, especially if it is connected to a rain-water pipe. (See also 'Earth Connections,' *below*.)

Masses of Metal.—As far as practicable the conductor should be connected to all extensive masses of metal, such as ornamental ironwork, hot-water pipes, etc., both external and internal; but it should be kept away from all soft metal pipes, and from internal gas-pipes of every kind. Church bells and turret clocks should be connected with the conductor. In the case of a long line of metal ridging, each end of the ridging should be directly connected to earth by a rod. Where the ridge is non-metallic, a horizontal conductor should be run at a short distance above the ridge and be connected to earth.

Factory Chimneys.—These should have a copper band round the top, and stout sharp copper points, each about 1 ft. long, at intervals of one or two feet all round the circumference. The rods should be connected with all bands and metallic masses in or near the chimney. As an alternative, the rods above the band may be curved into an arch provided with three or four points. Two lightning rods should be carried down from the band to earth.

Colleries.—Undoubted evidence exists of the explosion of firedamp in coal mines through sparks from atmospheric electricity being led in to the mine by the wire ropes of the shaft and the iron rails in the galleries; hence the head-gear of all shafts should be protected by proper lightning conductors.

Inspection.—Before giving his final certificate the architect should have the conductor carefully examined and tested by a qualified person, as injury to it often occurs up to the latest period of the works from accidental causes, and often from the carelessness of the workmen.

Earth Connections.

In making earth connections for electrical circuits, lightning rods, etc., it is desirable to provide several paths to earth, as far apart as possible. Connection should be made with the stratum of permanently moist earth nearest the surface of the ground, rather than to deeper layers or even to the water in a deep well. The best earth connection is a water pipe. For most purposes galvanised iron pipes, about 1 in. in diameter, give satisfactory results; in a series of experiments such pipes, driven into stony clay soil, gave the following average results per pipe:—

1 ft. deep .	149 ohms	4 ft. deep .	50 ohms.
2 ft. „ .	88 „	6 ft. „ .	36 „
3 ft. „ .	64 „	8 ft. „ .	29 „

Generally, if moist earth is reached, pipes need not be driven deeper than 10 ft. The resistance of two earth-pipes in series, driven 10 ft. deep, becomes practically constant at any distance apart from 10 ft. upwards. Earth-pipes connected in parallel should be at least one foot apart. They need not be larger than 2 ins. in diameter.

If earth-pipes are used it is better to bury two small plates 20 ft. apart, connected by a stout wire, than one large plate. They should be on edge, with the soil well rammed on both sides. In shallow soil over rock, long narrow strips of metal buried in trenches should be used. Patented devices offer no special advantages. Two plates in parallel, each 2 ft. by 4 ft., 6 ft. deep, 5 ft. apart in stony clay soil had a joint resistance of 16 ohms. A strip of galvanised iron 1·5 ins. wide and 20 ft. long, in a trench 12 ins. deep, had a resistance of 17·7 ohms. The resistance of a water pipe is usually less than 1 ohm, averaging $\frac{1}{4}$ ohm. The addition of salt to the soil round the earth connection greatly reduces the resistance; so does the packing of coke or charcoal round the plate, but both these devices hasten the corrosion of the plate. As a high potential gradient may exist on the surface near the earth connection, unless it is of the buried type, the earth-pipe and connecting lead should be guarded to prevent accidental contact with them. The joint between the lead and the earth-pipe or plate should be embedded in concrete for protection, and the earth-wire should be covered throughout its length. All earth connections should be inspected and tested at least once a year.

Phœnix Office Rules for Lightning Conductors.

The Phœnix Fire Office, in their rules for lightning conductors, point out that the only way to obtain absolute security against lightning is to enclose the building in a metal framework constituting the 'bird-cage' system of conductors. This can be accomplished generally by utilising the rain-water pipes and gutters as part of the system. The ordinary conductors must be fixed in addition, and the whole system effectively earthed. The material of the conductor should

be of copper tape, measuring at least 1 inch by $\frac{1}{8}$ inch, or, if copper cable be adopted, it should not consist of less than seven strands, each $\frac{1}{4}$ inch diameter. Soft iron must be used in place of copper, and, except for chemical reasons and for permanence, the sectional area need not be greater than in the case of copper. Conductors should be kept a certain distance away from walls so as to prevent the accumulation of dirt, but they must not be insulated. If a copper plate is used for the earth connection it should not be less than 3 square feet in area and $\frac{1}{8}$ inch in thickness, and should be adopted only where it will always be in water or moist earth; otherwise connection should be made to the water mains, or the 'tubular' system should be employed. The number of connections depends on the ground area of the building, but there are few structures where less than two are necessary. The elevation rod of factory chimneys should be a circular band placed round the top of the shaft, with points fixed at an angle of 45°, and extending outwards, or an arch of metal, provided with points, may be fixed across the mouth of the chimney.

ELECTRIC HEATING AND COOKING.

A Swiss Commission reporting on the experience of 38,000 consumers using electrically heated apparatus states that the average lives of the heaters are: boilers, 2–10 years; frying-pans, 2–4 years; hot-plates, 1–2 years; flatirons, 2–8 years. Pure mica is the most satisfactory insulating material; clay insulators are also effective. For the plug connections, porcelain or steatite is recommended. The contact plug should be more than 4 mm. in diameter. Hot-plates are preferred to boilers. The average consumption is 0·88 kw. hr. per head per day, exclusive of heating water for washing; including water-heating, 1·04 kw. hr. Each connection for a family of average size (4½ persons) requires a supply of 250 watts for lighting, and 2,500 watts for cooking, or 0·55 kw. per person. There are in winter three peaks due to the cooking load—morning 20 per cent., mid-day 45 per cent., and evening 25 per cent. of the capacity connected. In the case of a network laid out for lighting and power (excluding large factories), if one-fifth of the families cooked solely by electricity, the mains would have to be increased in capacity by 50 per cent. In the case of a large town with 15,000 lighting connections, if one-fifth of the families cooked by electricity the maximum load would be increased by 9 per cent. and the energy sold by 12 per cent.

The time required to boil a given quantity of water with a heater of known wattage is approximately given by the formula :—

$$\text{Time in minutes} = 3{,}700 \times \text{pints} \div \text{watts}.$$

More generally, to heat any liquid to any temperature not exceeding its boiling point is given by the following formula (*Simplex Co.*) :—

$$\text{Time in minutes} = n.g.s.\,(t - t_1) \times 2{,}180 - (\mathrm{W} \times e),$$

where n = no. of pints, g = specific gravity of liquid, s = specific heat of liquid, t and t_1 = initial and final temperatures Fah., W = watts, e = thermal efficiency, per cent. (from 90 to 95 per cent.).

The following are average data for domestic cooking apparatus, etc. :—

Ovens of 1½ to 2 cub. ft., 1½ to 2½ kw. on full heat.
Hot-plates, 6 ins. diameter, 300 watts.
" 18 ins. × 12 ins., 1,800 watts on full heat.
Toasters, 500 to 600 watts.
Egg-boilers, 3 eggs, 300 watts; 6 eggs, 400 watts.
Saucepans, fish-kettles, etc., 1 pint, 400 watts; 12 pints, 1,500 watts.
Frying-pans, 8 in. diameter, 400 watts; 12 in., 650 watts.
Irons, 0·3 lb., 200 watts; 15 lb., 500 watts.
Sterilisers, 400 to 1,600 watts.
Glue-pots, 250 watts upwards.
Soldering-irons, 130 watts upwards. (*Mears.*)

For large kitchens in restaurants, works canteens, etc., various sizes of apparatus are made and combinations. The following data are taken from actual installations.

Class of Kitchen.	Total kilowatts.	Annual Consumption units.	No. of Meals per week.
Restaurant	247·6	146,500	9,518
Staff feeding	130·9	97·140	2,944
" "	40·5	21·141	991
" "	32·8	20,690	640

In the United Kingdom there were in January, 1918, over 400 installations of this class, having a total capacity of about 22,000 kw., and preparing nearly 130,000 meals per day. (*W. A. Gillott.*)

Electricity at one penny or even three-halfpence per unit compares favourably with gas at 2*s.* 3*d.* to 3*s.* per thousand cubic feet for all oven work. (*C. Scott.*)

ELECTRICAL PRECIPITATION OF SMOKE AND DUST.

In recent years the Lodge system of precipitating dust particles or fumes in gases, such as the flue gases from metallurgical works, cement mills or boiler furnaces, has been greatly developed by the Research Corporation, U.S.A., under Cottrell's patents. The apparatus consists of iron pipes through which the gases are led, preferably downwards, with a steel or nichrome wire suspended in the axis of each tube; the wires are charged to a pressure of 30,000 to 100,000 volts and the pipes are earthed. The electric charge is derived from A.C. transformers with mechanical rectifiers driven in synchronism with the alternating pressure so that the polarity of the wires is always negative. The process can be carried on without cooling the gases and requires little power, from 5 to 50 kilowatts being usually sufficient. Resistance should be inserted in the low-pressure circuit to limit the short-circuit current and to provide means of regulation, and reactance in the high-pressure circuit to prevent surging of the electric charge. From 80 to 98 per cent. of the dust can be deposited; in some cases the introduction of steam is necessary. In the case of blast furnace and cement mill gases, large quantities of potash can be recovered, particularly if salt is added to the charges of the blast furnace. Particulars of some successful installations are given below :—

Nature of Process.	Number of Pipes.	Length and Diameter of Pipes.	Pressure volts.	Rate of Flow of Gases.	Remarks.
Copper converter	608	10 ft. × 5 in.	30,000	10 ft. per sec.	97·25 per cent. recovered.
Silver furnace .	Chamber 8 ft. × 6 ft. × 16 ft.		50,000	—	Electrodes 6 in. lead strip.
Cement mills .	800	15·5 ft. × 12 in.	70,000	3·5 ft. per sec.	Temp. 900° F. 20 tons per day
Copper and lead smelting works	384	15 ft. × 12¼ in.	60,000	10,000 cub. ft. per day	Plant increased to 1,312 pipes.
Detarring coal gas	—	—	40,000 to 80,000	30,000 cub. ft. per hour	Unrectified alternating current.

Careful tests should be made before deciding on the dimensions, etc., of the apparatus to be installed. Corrosive substances can be dealt with satisfactorily. At a certain cement factory the potash recovered is worth more than the cement. The kenotron is an efficient rectifier up to 250,000 volts. A similar process is used for separating oil from water.

ELECTRICITY IN AGRICULTURE.

The principal use of electricity in agriculture is to drive machines, in addition to lighting the farm buildings; it is also experimentally used for stimulating the growth of plants. The average power required on a British farm of not more than 100 acres is about 3 h.p.; more than 10 h.p. is rarely needed. In Wales, 270 installations on farms were carried out by one firm in ten years. Motors are used either to drive stationary machines indoors from counter-shafting, or, being mounted on wheeled trucks or stretchers, to drive portable machines out of doors, through belting. A farm load has an excellent diversity factor, and as it does not come on during the evening peak load it is very acceptable to a public supply system. At Hereford the average revenue from farms is about 20*l.* each per annum. With an electric milker one person can milk six cows at once, using 20 watt-hours per cow. To churn 80 lb. of butter requires 1 kw.-hour. Cutting 1 ton of ensilage consumes 1·38 kw.-hours. Threshing corn requires 70 watt-hours per bushel of oats, 100 watt-hours per bushel of barley, 160 watt-hours per bushel of wheat. Grinding a bushel of oats takes 420 watt-hours. Elevating 1 ton of hay, 200 watt-hours. The most suitable type of machine is the three-phase induction motor, on account of its simplicity and safety from fire; fire risk is a most important consideration in connection with farm work.

Electric ploughing is a special application of electricity under exceptional conditions; it is usually effected with hauling gear mounted on trucks, which travel along the sides of the field, hauling the plough (with three to five shares) to and fro across the land. The tractive effort required for ploughing in light soil is 740–820 lb. per sq. ft. of section ploughed; in heavy soil 1,100–1,250 lb. For ploughing a furrow or furrows w ft. wide and d ft. deep, at v ft. per second, the horse-power required = $kwdv/550$, k being a constant as above, depending upon the soil. The speed v should not exceed 5 or 6 ft. per second. The motor should be capable of hauling double the normal load at times. Furrows up to 650 yds. long can be ploughed in this way. On a large farm the capital charges amount to 12*s.* per acre, wages to 2*s.*, energy at 1*d.* per unit to 2*s.* 6*d.* per acre for deep ploughing (12–14 ins. deep), total 16*s.* 6*d.* per acre. For ordinary ploughing the cost is 11*s.* 4*d.* per acre. The hauling gear can be used also for harrowing and rolling the land, and for driving other machinery. The motor for ploughing should be of 25–30 h.p.

(*Delamarre.*)

For stimulating plant growth, the silent discharge from fine bare wires suspended above the crops at a pressure of 50,000 volts or more, D.C., has been much used for experimental purposes. The Agricultural Discharge Co. suspends the wires 13 yds. apart, at a height of 18 ft., using 40 to 50 poles per acre. The Board of Agriculture reports that in 1916 there was an average increase of 30 per cent. in the yield of the crops electrically treated. Experiments are also in progress to determine the effect of passing an electric current through seed in a chemical solution, but official tests gave discouraging results.

TELEPHONY.

Telephonic Transmission.

When an electrical impulse is started in a conductor, the effect of resistance, or of uniformly distributed low insulation, results in a definite attenuation which increases with the length of the circuit, and the effect of capacity is to cause the wave to spread out, this "tailing," as it is termed, not only increasing the attenuation by lowering the amplitude, but causing distortion of the wave itself. This distortion eliminates the higher notes and harmonies, and in extreme cases causes the voice to lose its characteristic tone, and ultimately to become inarticulate. It is found that with long circuits free from external disturbance, such as underground wires, the practical limiting distance of speech is fixed by the loss of amplitude of the waves ; in other words by the diminution of volume rather than by the loss of articulation, although when these limits are approached it is found that articulation begins to suffer, and when the line is still further lengthened, the tones become low and hoarse, and speech ceases to be practicable. This points to the fact that in practical work attenuation due partly to resistance, and partly to electrostatic capacity, is the dominant factor, and this attenuation when combined with disturbance from neighbouring electrical conductors actually determines the limit of speech.

The simple K R law applies with some degree of accuracy to telephonic cables in cases in which wires of approximately the same gauge are concerned, but it fails in cases in which the electrical constants K, R and L vary materially, and it is quite inapplicable as part of a general law to open lines where self-induction is a marked factor or where the conductivity of the wires varies materially. Observations made by the Bell Companies in America show that the K R law fails owing to no account being taken of the important factor L. We are now fairly well acquainted with the various factors that govern and limit the range of possible speech, and the methods by which these limits can, under favourable conditions, be extended ; such, for example, as the partial neutralisation of the effects of static capacity by the addition of self-induction.

For the purpose of determining the limits of speech, and ascertaining the degree of volume and articulation, or in other words the audibility, which may be accepted as satisfactory, and further to establish standard circuits with well-known constants of R, L and K to which all lines may be reduced, one of the types of ordinary lead-covered paper insulated cables, in which the above constants are measurable, has been selected, both in America and in England, and the dimensions of the English standard cable, which agree closely with American figures, are as follows :—

Gauge S.W.G.	Weight per Mile.	Diameter.	R (loop).	K Wire to wire.	L.	Insulation.
	Lbs.	Mils.	Ohms.	Mfd.	Henries.	Ohms.
20	20	36	88	0·056	0·001	200

It is necessary to take into account the variable conditions under which long-distance speech is frequently held. The insulation of long overhead wires may drop in extreme cases to a figure as low as the metallic resistance of the conductors themselves : slight inductive noises are never really absent. The human element largely affects the result. Indistinct speech, disregard of regulations, all tend to limit long-distance speech, and to render the application of very accurate determinations difficult. As in all engineering matters, there must be a considerable factor of safety to ensure satisfactory intercommunication. It is generally considered by telephone administrations that from 42 to 46 miles of the above-named standard cable is the effective commercial limit although conversations have been held by experts over sixty miles of such a cable.

A lengthy series of experiments has been made on all classes of Post Office conductors, overhead, underground, and submarine, and they have been balanced by means of a standard apparatus to their equivalent lengths of actual standard paper cable. The equivalent lengths have also been calculated by Pupin and Campbell's formulæ, and the following table shows the degree of concordance in the results. It will be observed that the calculated limits of speech based on attenuation agree absolutely with experimental results on all the underground cables. There are, however, variations in the calculated and observed results obtained on overhead lines, and these are no doubt due to variations in insulation and to slight disturbances which affect the audibility materially when approaching the limits.

Loading Coils for Telephone Cable Circuits.

(*Western Electric Co. Ltd.*)

The use of loading coils improves the efficiency of telephonic circuits, and thereby increases the distance over which telephonic transmission is possible. The method generally adopted in adding the required inductance to the telephone line consists of inserting inductance coils at calculated intervals.

The two most important factors which enter into every problem of telephone transmission are the attenuation and the distortion of the high frequency waves which constitute telephonic currents. By attenuation is meant the loss of energy of the waves of the telephonic (or voice) currents. Distortion is the impairment of the many component waves of which the voice currents are composed.

In a telephone circuit, where loading coils are not used, the waves are rapidly altered, both in form and in amplitude, as they progress along the line. An increase in the inductance of the line, however, such as results from the introduction of loading coils, has the effect of largely preserving the original wave form, as well as maintaining the initial wave amplitude, and is therefore highly desirable from the standpoint of transmission efficiency.

In an ordinary paper insulated air space telephone cable, the high attenuation limits to comparatively short distances the length of cable over which speech can be commercially transmitted. With properly selected loading for such a cable, the rate of attenuation is so reduced that a very large increase in range of transmission is obtained. Thus, it has been found by practical tests that, with proper coil-loading and with suitable terminal conditions, the transmission efficiency of the loaded cable may be increased more than six times for 2·5 mm. (·099 in.) cable, and over four times for 1·3 mm. (·051 in.) cable, as compared with a non-loaded cable of equal length. It should be particularly noted that the increased transmission efficiency, obtained by means of loading the cable, is obtained at a very much smaller cost than would be possible by any other method—as, for example, increasing the weight of line copper. Two representative cases are cited below, one for a ·915 mm. loaded cable, the other for a 1·27 mm. loaded cable. In each case the loaded cable is compared with a non-loaded cable of such design as to give the same transmission efficiency. The same number of pairs have been allowed in either case.

TABLE SHOWING ECONOMIES FROM LOADING.

Type.	Number of Pairs in Cable.	Diameter of Condrs.		Weight of Condrs.		Diameter of Lead Sheath.		Weight of Lead Sheath.		Relative costs of Cables.
		Inch	Mm.	Lbs. per Mile.	Kg. per Km.	Inch.	Mm.	Lbs. per Mile.	Kg. per Km.	
				Case No. 1.						
Non-Loaded Cable	40	·096	2·46	150	42·3	2·78	70·6	32,200	9,137	3·75
Loaded Cable .	40	·036	·915	20	5·6	1·08	27·4	7,336	2,080	1*
				Case No. 2.						
Non-Loaded Cable	25	·137	3·48	300	84·6	2·94	74·6	36,344	10,313	3·8
Loaded Cable .	25	·050	1·27	40	11·2	1·15	29·2	8,450	2,400	1*

* Including cost of loading equipment.

It will be noted from the above table that the cost of the non-loaded cable in either case is nearly four times as great as that of the equivalent loaded cable.

The efficiency of loaded cable is even more strikingly illustrated by the following case: A cable having 1·83 millimetre (·072 in.) conductors (weighing 80 lbs. per mile or 22·5 kg. per kilometre), if loaded, would have an attenuation constant equal to ·0129 per mile or ·0080 per kilometre. In order to obtain the same attenuation constant with a non-loaded cable, it would be necessary to use 8·2 millimetre (·32 in.) conductors, weighing 1,600 lbs. per mile or 450 kg. per kilometre. A cable, having a weight of copper at 450 kg. per kilometre of conductor, would be entirely uncommercial, so that it is evident that it would be impossible to obtain the same transmission efficiency by the use of non-loaded cable as is very readily obtained by means of loading. It would be necessary to use an open wire line of approximately 35 kg. per kilometre if it were desired to obtain the required transmission efficiency with a non-loaded circuit.

Whenever a new cable is planned or designed it should be remembered that the use of loading coils permits of a considerably smaller sized conductor to give equally good transmission.

Cables of ordinary or twin type used for junction working, trunk junctions and terminal cables from long-distance aerial lines can be improved, if suitably equipped with loading coils. Aerial cables, which, in many instances, contain small gauge conductors, can also be improved by loading and their speaking distances increased.

The advantages gained by loading underground and aerial cable circuits can be obtained in many cases for long-distance open-wire circuits. In fact, it is not possible to maintain, economically, efficient telephonic service over distances approximating 1,000 miles without the use of loading coils.

The loading coils manufactured by the Western Electric Company Ltd. are designed to give the highest efficiency under all conditions of service. Commercial conditions, such as manhole space, demand that the loading coils shall be of a minimum size per unit of inductance. In order to meet this demand it is necessary to include iron in the magnetic circuit of the coil. The loading coils are wound on a ring-shaped core, which consists of finely divided, well insulated iron wire. This construction has the advantage of giving the loading coil a closed magnetic circuit which obviates mutual interference between coils mounted closely together. The grade of iron wire used, and the method adopted in the winding of the coils, produces a loading coil which combines a low effective resistance with high inductance to alternating currents of telephonic frequency. By effective resistance is meant the resistance of the coil to direct current plus the energy loss resistance equivalent, produced by eddy currents and hysteresis.

Practical tests have proved, conclusively, that loading coils, so designed, eliminate undesirable distortion of the telephonic waves to practically the same extent as do coils in which iron has been eliminated from the magnetic circuit. These tests also revealed the interesting fact that the waves of the highest frequency of the voice currents were not reduced to such an extent as to affect materially the quality of the transmitted speech. In other words, the sound of the voice did not lose its timbre.

The Western Electric Company Ltd. is now in a position to supply and install loaded cable in which the superimposed (or phantom) circuits are guaranteed to be entirely free from overhearing. In this arrangement, in addition to the gain in transmission, derived from the use of loading coils, there is the further economy of 50 per cent. more circuits in the same sized cable as compared with the ordinary (or twin) type of cable, while the extra (phantom) circuits obtained are more efficient than the metallic circuits, from which they are derived.

As an example of a cable successfully loaded on the superimposed principle, may be mentioned the direct trunk telephone cable between London and Birmingham. This cable was manufactured, laid, spliced and equipped with loading coils by the Western Electric Co. Ltd., and was put into service by the British Post Office in July 1915. The superimposed loaded circuits in this cable are in commercial use, research and service tests having proved the absence of overhearing between any of the superimposed and physical circuits. A detailed description of the London-Birmingham cable was published in the *Telegraph and Telephone Journal* for November 1915.

Loading coils can be designed to meet almost any inductance requirement. It has, however, been found convenient to establish certain standard types of coils, which cover the range of inductance required in most cases. These are, broadly speaking, classified (according to the amount of inductance) as 'extra light,' 'light,' 'medium, and 'heavy' loading coils. The inductance of these coils covers a total range of from 60 to 250 millihenrys. Each type is carefully adjusted to meet the particular inductance requirement desired.

The coils are potted in strong cast-iron cases, which are made air- and water-tight. These cases are designed so as to maintain a very high insulation even under adverse conditions of installation. Thus, if a loading coil case is placed in a manhole, which becomes flooded periodically, this will in no way interfere with the loading coils or their operation, as the cases are made absolutely watertight. Cases can be supplied to hold any desired number of coils, ranging from 2 to 98

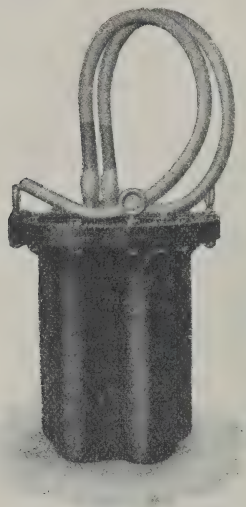

FIG. 41.

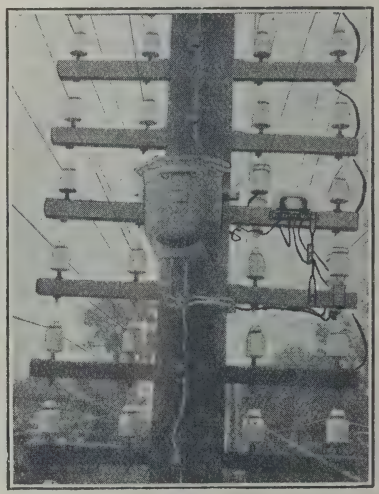

FIG. 42.

Fig. 41 shows a typical case, designed to hold 50 coils. The leading-out wires are contained in two short cables, which are connected to the main cable, the coils thus being inserted in the circuits.

These cases are placed in manholes along the route of cable to be loaded, and the coils are connected to the cable through a suitable junction box.

Fig. 42 shows the method used in connecting a loading coil to an aerial circuit. The containing case holding one loading coil is mounted on the pole itself. Fitted on the cross-arm, to the right, is a lightning protector, enclosed in a small cast-iron case.

Poles for Telegraph and Telephone Lines.

Report No. 139, 1921, of the British Engineering Standards Association provides a specification for red fir poles. They should be felled when the sap is down, and contain the natural untrimmed butt of the tree. After seasoning, the poles should be impregnated with a minimum of 12 lbs. of creosote oil per cu. ft., the specific gravity of the oil being between 1·015 and 1·07 at 38° C. The properties of the oil are detailed in the Report, together with the methods of determining them, and the limiting dimensions of light, medium, and heavy poles, from 16 to 85 ft. long, are tabulated.

RADIO-TELEGRAPHY.

In a radio-telegraphic system electric impulses from a transformer cause sparks across a spark gap, which charges, discharges, and recharges the aerial. If the inductance and capacity of the aerial have values of, say, 0·56 microhenry (L) and 0·00004 microfarad (C),

then there will be oscillatory waves in the aerial whose time interval between the crests of successive waves is given by the formula $2\pi\sqrt{LC}$, which with the foregoing values of L and C gives the time interval as ·03 millionth of a second. The wave length, that is the distance between the crests of successive waves, or more strictly, between points of equal intensity of electric stress, is equal to the velocity of propagation, multiplied by the time interval. Hence, in the case of the oscillator just considered, the wave length is $300 \times 10^6 \times \frac{0{\cdot}03}{10^8} = 9$ metres. In practical wireless telegraphy the oscillating circuits employed have much larger values of L and C, and the wave length is from 300 to 6,000 metres.

A plain aerial radiates energy rapidly, that is to say, it is a good radiator. After each discharge there are only three or four rapidly damped oscillations, whereas a much greater number is necessary for long-distance work. If the voltage of the charge is too great, the air breaks down at the top end of the aerial, by what is known as a brush discharge, and thus a limit is fixed to the energy which can be imparted to the short train of electro-magnetic waves. The practical result is that the maximum range obtainable is about seventy miles.

For long-distance working it is necessary to impress a large amount of energy on the aerial without requiring too great a voltage, and at the same time to produce a long series, or train of waves, with very little damping. An arrangement of this kind is adopted in the Marconi system, as shown by fig. 43, and is the foundation of all the practical wireless telegraphy of to-day: it has enabled commercial working to be carried out at a range of 2,400 miles, between Clifden, Galway, and Glace Bay, Nova Scotia.

The arrangement consists of an oscillatory circuit into which a large amount of energy can be put, and an aerial oscillatory circuit which receives energy from the oscillatory circuit and radiates it in the shape of electro-magnetic waves. These two circuits must have the same period—that is, must be tuned—and they are inductively connected by means of a transformer, called a 'jigger,' the primary of which is in the oscillatory circuit and the secondary

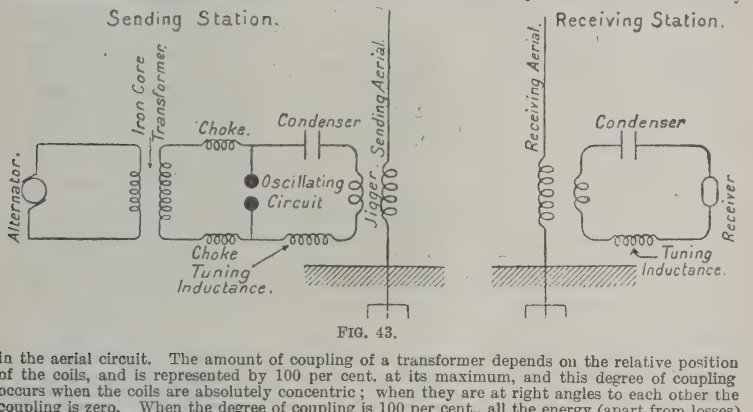

FIG. 43.

in the aerial circuit. The amount of coupling of a transformer depends on the relative position of the coils, and is represented by 100 per cent. at its maximum, and this degree of coupling occurs when the coils are absolutely concentric; when they are at right angles to each other the coupling is zero. When the degree of coupling is 100 per cent., all the energy (apart from losses) is transferred from the primary to the secondary in half a cycle, but if it is desired to transfer only a small portion of the energy at each oscillation from the primary to the secondary, the degree of coupling must be small. In wireless telegraphy the coupling is about 6 per cent. or even less.

Fig. 43 also shows the receiving arrangement, the signals being received on a telephone receiver. The receiving apparatus can be so arranged that it will not respond to signals sent out with wave lengths other than those to which it is tuned. In this way, a receiving station can isolate itself from other wireless stations, and thus not be interfered with when receiving a message from its own station. The train of electro-magnetic waves maintains oscillations in the receiving aerial, which are inductively transmitted to the oscillating circuit, and being properly timed, the energy is accumulated therein, and becomes sufficient in amount to actuate the receiver, and give signals in the telephone. Unless the time period of both the small and large systems is the same as that of the waves, there will be no accumulation of energy in the large system at the receiving station, and the energy transmitted to the oscillating circuit will be insufficient to actuate the receiver. The oscillating circuits and the aerials at the sending and at the receiving stations must therefore be tuned to the same period, which must be the period adopted for the electro-magnetic waves.

For small stations, the condenser takes the form of an ordinary Leyden jar with inner and outer coatings of tinfoil. In some cases, for portable wireless stations, the test-tube form is

adopted, and the tinfoil at the bottom is strengthened by a copper cap. Recently, however, test-tube condensors have been used, coated inside and out with electrolytically-deposited copper. It is important that the capacity of each jar or tube of a set should have the same capacity. For ship stations, thin zinc sheets are placed either in wooden boxes lined with zinc, or else in galvanised-iron boxes which are filled with special oil of high flash point and high dielectric strength. The capacity of these condensers is 0·065 microfarad, and they are arranged in groups so that they can be connected either in series or parallel. For this purpose a commutator—known as a Swiss commutator—is used, and the connections are made by long plugs split in two directions. For land stations, a satisfactory type of condenser consists of glass plates coated on both sides with tinfoil, a large number of such plates being immersed in oil contained in glazed earthenware vessels. At some high-power stations air-condensers are used; in the latest, they consist of thin zinc sheets suspended from the roof and placed about 6 ins. apart. The cubic space occupied by such a condenser is necessarily large. Thus for a capacity of 1·8 microfarad the space required is 200,000 cubic feet. The primary of the high-frequency air core transformer or 'jigger' consists of a few turns of conductor and is placed in the oscillating circuit; the secondary has more turns than the primary and is placed in the aerial circuit.

The secondary of the jigger, which is included in the aerial circuit, consists of a few turns of conductor, and it is connected to an inductance fitted with a suitable arrangement for putting more or less turns in circuit for tuning purposes. The size and nature of the conductor used, and the number of turns both in the primary and in the secondary, depend on the size of the station. Excepting for very large stations, the same aerial is used, both for sending and receiving. Three principal types are in use, namely, 'T,' 'L' and 'Umbrella.' With the Umbrella type the electro-magnetic waves are radiated equally in all directions, with the T type, which is that generally adopted for ship work, the radiation is almost uniform in all directions; but with the L type there is a very distinct directional effect, and in this case, the aerials are arranged with a comparatively short vertical height and a long horizontal length pointing away from the station to which it is desired to send messages.

For ship work the masts of the ship are utilised; for land work frequently wooden masts, similar to those on ships, are employed, but recently tubular steel masts have been adopted, built in sections consisting of half-cylinders bolted together by means of flanges. The longitudinal flanges are placed alternately at right angles to each other, and by an ingenious arrangement the mast forms its own scaffolding for erection. Steel masts of lattice form are also employed. The earth connection consists of wires led to ground plates, and great care is needed to obtain a good earth. This is a matter which requires expert knowledge. Sometimes, instead of the actual earth, a wire-gauze net is spread on the ground, and in this case the earth connection is obtained partially by a condenser effect.

The following table gives the results of observations as to the range, the power absorbed, and the wave length:—

Power Required.	Range in Nautical Miles.				Wave Length (Metres).
	Oversea.	Over Land.			
		Flat.	Hilly.	Mountainous.	
300 watts	100	77	30	13	300
	100	95	73	52	1200
1½ kw.	220	170	67	28	300

	470	450	330	240	1200

(*Sankey.*)

Thermionic Valve.

During the war the 'thermionic valve,' based upon an invention of Dr. J. A. Fleming, was developed to such a degree as to revolutionise practice in wireless telegraphy, and to render wireless telephony commercially practicable; it has also been usefully applied in connection with long-distance wire telephony, and in other directions. Its action depends upon the emission of electrons from a heated filament in an evacuated bulb, and their reception upon a cold plate in the same enclosure, together with a controlling 'grid' to which an electromotive force is applied. In wireless telegraphy the grid is energised through a transformer, by the infinitesimal currents received on the antenna, with the result that variations are produced in the current flowing between the plate and filament, which are far greater than the original waves; these effects can similarly be magnified, almost without limit, and thus the reception of wireless signals sent halfway round the world has become possible. The magnified signals, within limits, are practically free from distortion, a fact which enables the device to be used for telephony, speech being

reproduced with great clearness and fidelity. Besides acting as a detector of minute electric oscillations, the valve can also be used to rectify currents which oscillate in direction, and by making the valve react upon itself it can be used as a generator of high-frequency oscillations. In conjunction with the microphone, the valve is used to vary the amplitude of the waves emitted, thus solving the problem of wireless telephony. The valves are extremely economical of energy; it is stated that wireless telephonic communication can be maintained over a distance of sixteen miles with an expenditure of only ten watts. In ordinary telephony the valve is used as a relay on long lines, in which capacity it is far superior to any type of mechanical relay.

Thanks largely to the three-electrode valve, for long-distance transmission much smaller antennæ now serve, and the continuous-wave system is generally adopted; for receiving signals, so great is the magnifying power of the valve that a fixed antenna is almost superfluous, a coil of wire wound on a frame a few feet square sufficing for the purpose. The ratio of magnification of the signals may be several hundred thousand times. Wireless telephony has been accomplished over distances of several thousand miles between land stations, and is perfectly feasible between vessels at sea, and between aircraft, over considerable distances.

The essential features of the three-electrode thermionic valve or 'triode' are shown in fig. 44, which is a curve plotted between the plate current I (a few milliamperes), and the grid voltage or P.D. between the grid and the filament, V, the pressure applied between the plate or anode and the filament being constant. It will be seen that when the grid is slightly negative to the filament at A, the plate current is completely stopped; when the grid voltage is zero, the plate current

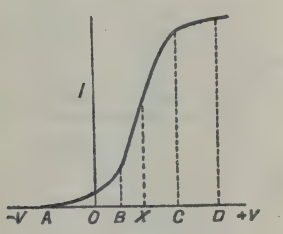

FIG. 44.

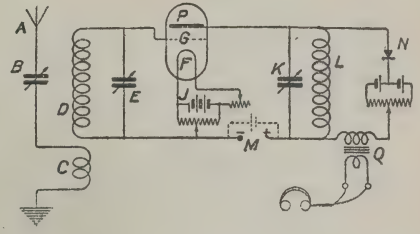

FIG. 45.

has a low value, but as the grid becomes more positive to the filament the plate current increases very rapidly (between B and C), until a maximum or 'saturation' value is reached at D. Assuming the grid voltage to be at the value corresponding to point X on the curve, obviously an alternating voltage applied to the grid will cause an alternating current to flow in the plate circuit, with greatly increased amplitude, but of similar wave-form. Under these conditions the valve acts as an amplifier. When the grid voltage is that corresponding to point B on the curve, a slight increase in the positive voltage of the grid will produce a current wave in the plate circuit as before, but a slight decrease in the voltage of the grid will have little effect on the plate current, the result being that, when an alternating voltage is applied to the grid, a series of practically unidirectional currents will flow in the plate circuit. The valve under these conditions acts as a combined rectifier and amplifier. Similar rectifying effects are produced at the point C, but in the reverse direction. The shape of the curve and its position vary with the temperature of the filament and the pressure applied to the plate, but the curve is always of the same nature.

The variations in the connections and combinations of apparatus used in conjunction with valves are limitless; precise knowledge as to the phenomena which take place within the valve is not yet available, but its practical operation is well understood. We give below some examples of its principal uses in the simpler forms. Fig. 45 shows the connections of a single valve used as a high-frequency amplifier in wireless telegraphy; the aerial antenna A is connected to earth through a variable condenser B and coil C, and is tuned by means of the condenser, with added inductance if necessary, to the wave-length to be received. The coil C with coil D forms an air-core transformer or 'jigger,' by which the electrical oscillations received on the antenna are transferred to the grid circuit, consisting of coil D and a variable condenser E, tuned to the same wave-length as the antenna. One terminal of the condenser E is connected to the filament F by way of a regulating potentiometer, and the other terminal to the grid G in the valve. The filament is kept incandescent by the small battery J, with a regulating resistance. The plate circuit of the valve consists of the anode or plate P, inductance coil L and variable condenser K, and a high-voltage battery M, of which the negative terminal is connected to the filament. Shunted across the plate circuit inductance is a rectifying crystal N, and the primary of an iron-cored transformer Q, the secondary of which is connected to a pair of telephone receivers. The plate circuit is tuned to the wave-length of the incoming signals and a current flows round this circuit through the valve.

The incoming oscillations, transferred from the antenna to the grid circuit by the 'jigger,' set up a magnified alternating electromotive force between the grid and the filament, superposed upon the potential difference due to the battery J. Owing to the characteristic properties of the valve, an oscillatory current of much greater amplitude is set up in the plate circuit, which is rectified by the crystal and affects the telephone receiver. A number of valves may be connected together in cascade to produce successive amplifications, the final ratio being of the order of 20,000 or more; with suitable arrangements it is possible to detect with certainty an alternating current in the input circuit corresponding to one-ten-thousand-millionth part of one volt.

Fig. 46 illustrates the use of the valve as a rectifier. It will be seen that the plate circuit consists only of the high-voltage battery, shunted by a condenser, and the primary coil of the telephone transformer, no crystal being necessary. In this application the grid voltage is adjusted to such a value that the valve is working at the bend of the characteristic curve of the plate current (point B in fig. 44). Besides rectifying the current, the device affords a large measure of amplification, and by using a rectifying valve at the end of a series of amplifying valves a highly sensitive and efficient receiving apparatus is obtained.

Fig. 47 shows the connections of a valve used as a generator of continuous oscillations, for the reception of signals on the 'continuous-wave' system, by 'beats.' The frequency of vibration of the incoming signals being far above the limits of audition, a very efficient method of

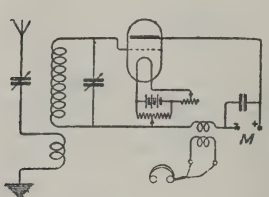

FIG. 46.

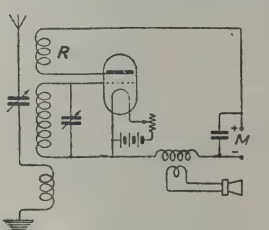

FIG. 47.

rendering the signals audible is by combining them with locally generated oscillations at a slightly different frequency, producing 'beats' as in music, the frequency of the beats being equal to the difference between the frequencies of the two sets of waves. It will be seen that the circuits are almost the same as those of fig. 46, the only change being the addition of a reaction coil R magnetically coupled with the inductance in the grid circuit. The arrangement is known as a 'self-heterodyne,' the valve performing the three functions of rectifying, magnifying, and heterodyning by the production of local oscillations. These oscillations are produced by the reaction of the current in the plate circuit on the grid circuit, and the necessary adjustment is made by varying the position of the reaction coil with regard to the inductance. The grid potentiometer, which is omitted from fig. 45, can be dispensed with in the other diagrams also, the valve being adjusted by the plate potential. When it is desired to use the valve as a transmitter, impressing continuous waves on the antenna, the plate and high-voltage battery are connected to the tuning circuit, and the grid to the reaction coil, the telephone being omitted. For wireless telephony a microphone is added, so arranged as to vary the amplitude of the oscillations in accordance with the speech vibrations. The foregoing illustrations are taken from the *Wireless World*.

The evolution of the valve has made possible wireless telephony over a distance of 1,800 miles with only 2·5 kw.; communication with aeroplanes at a distance of 200 miles with 75 watts; the recording of time signals with an accuracy of 0·02 second; and the determination of the direction of a source of wireless signals, with portable apparatus. Other uses to which the valve has been put are to actuate a calling-up device on board ship, to maintain a tuning-fork in vibration, to produce the rotation of a toothed disc by a direct current, and to measure infinitesimal currents and pressures.

INSULATING MATERIALS.

'MINERVA' INSULATING VARNISHES.

These varnishes (*Messrs. Pinchin, Johnson & Co., Ltd.*) are made in a great variety (nineteen) according to requirements.

When circumstances permit, the work to be treated should be dipped, but if this method is not convenient the varnish can be brushed on. When varnish is applied by dipping, best results can be obtained by placing armature and field coils in an oven at a temperature above

the boiling-point of water for one to two hours before immersing the same in the varnish. After this preliminary stoving, the coils should be taken from the oven and dipped at once in varnish, allowed to drip over the dipping tank and again placed in the oven and then thoroughly baked. In following this method, the first cost of treating coils is slightly increased. The value of this treatment, however, is apparent. The moisture is driven out, the air in the coil expands, allowing proper penetration, and the coat of varnish given the coil immediately upon being taken from the oven, effectually prevents further absorption of moisture. The life of apparatus thus treated is materially lengthened.

The oven should be ventilated at the top to permit the escape of gases which form while the varnish is in process of drying. Provision should also be made for the ingress of air at the bottom of the oven, thus permitting free circulation of fresh air with its accompanying oxygen over the work to be dried. Uniformity of heat throughout the stove is essential, and this is accomplished by placing the pipes which carry the heat near the floor and on *all sides* of the oven. Care should be exercised not to overbake the varnish, otherwise its elasticity will be destroyed.

Elastic Insulating Varnish (*Clear*).—This type of clear insulating varnish (No. 481) possesses the essential properties which go to make up a clear, baking, insulating varnish. It has high and uniform insulating properties, is flexible and elastic, and withstands the action of heat for a long period without becoming brittle. It is waterproof and oilproof. It should be baked six to eight hours at a temperature of 200° F.

Quick-drying Insulating Varnish (*Clear*).—Under favourable climatic conditions, a thinned coat of this varnish (No. 482) will air dry over night. On account of its heavy body it will admit of considerable thinning and still give a strong, elastic coat of high insulation. It is especially recommended to electric railways and manufacturers for use on coils and other work where facilities for stoving are not available, although it may also be used as a stoving varnish. When artificial heat is employed for drying, the varnish can be used at its full body. It should be allowed to 'set,' however, one to two hours on all dipped work, before subjecting it to heat. It can then be dried thoroughly in four to six hours, baking at a temperature of 175°F. or 80°C. It effectually resists the action of moisture and lubricating oils.

Voltalac (*Air-Drying*).—'Voltalac (No. 485) has been used for some years by electric railways, tramways, etc. It is made especially to withstand the severe service to which windings of electric traction railway motors are subjected. It is a black, combined, air-drying and baking varnish, waterproof and water-repellent. The initial puncture test, alternating current, is about 1,000 volts per mil (430 v. per 0·01 mm.) of thickness, and this puncture value is maintained indefinitely. It is permanently plastic, a quality which enables Voltalac to retain its insulating and waterproofing properties indefinitely, under long periods of heat and excessive vibration. The varnish may be used to advantage on former-wound armature coils of dynamos and motors, dynamo and motor field coils, overhead and underground connections, backs of switch and panelboards to keep off moisture and prevent surface leakage, slight breaks in insulation of armatures and fields of dynamos and motors in service, and on street railway motor armatures, etc., wherever high insulation and moisture-resisting properties are requisite. It may be applied either by dipping or with a brush.

Glimalac.—Glimalac (No. 495) is used for making up mica plates into 'micanite.' It is specially good for making commutator segments, mica collars, cones, etc. It has exceptional sticking power and ability to dry absolutely hard. It has also great flexibility before baking and can be quite readily moulded into any shape, without losing any of its virtue, and can then be baked hard as desired. The method of using this varnish consists in building up the plates in the ordinary way with thin pieces of mica and putting into moulds or press. Steam (or heat) should be applied for about ten minutes to allow the varnish to 'set' before putting on pressure. Pressure, in conjunction with steam to the moulds or press, is then applied for about half an hour. This will vary according to the amount of heat applied. The press or moulds can then be cooled off as quickly as desired. Standard hydraulic press and moulds are recommended.

(*Messrs. Pinchin, Johnson & Co. Ltd.*)

Maconite.

This insulation material (introduced by *The Macintosh Cable Co., Ltd.*) has been used for some years by one of the principal railway companies in this country, in long tunnels where corrosive fumes and fluids are always present.

In appearance and texture, the material resembles a black rubber. In toughness, according to grade, it varies from something rather stronger than ordinary vulcanised insulating rubber, up to a point not far short of that possessed by the tough rubber known as C.T.S., etc., whilst its elasticity and durability are very high.

Whilst the measurable insulation of Maconite is lower than that of some vulcanised rubbers, this insulation is constant and is unaffected by prolonged immersion in water or in a saturated solution of caustic soda; also its resistance to breakdown pressure is high.

The following are details of tests to which Maconite has been satisfactorily subjected Except where specifically mentioned, no tests of less duration than some thousands of hours are given:—

Extremes of temperature.—

(1) Freezing Maconite Cable in a block of ice for several days, and testing at 1,000 volts A.C. for 30 minutes. Then thawing out in running water and again testing at 1,000 volts A.C.

(2) Boiling in water and for 3 hours in a weak solution of caustic soda.

(3) Exposure for several months in temperature of 100° F. above boilers and brass furnaces.

In all these cases, not only did the cable withstand the tests, but its flexibility was found to be absolutely unimpaired at the end.

Exposure to Chemical Action.—

(1) Immersion in dilute uric acid.
(2) ,, copper pickling acid.
(3) ,, 50 per cent. solution of sulphuric acid.
(4) ,, 5 per cent. solution of nitric acid
(5) ,, 50 per cent. solution of hydrochloric acid.
(6) ,, slaked slag water.
(7) ,, two samples of corrosive pit waters.
(8) Immersion in saturated solution of caustic soda.
(9) ,, saturated solution of common soda.
(10) ,, 10 per cent. solution of ammonia.
(11) ,, saturated solution of common salt.
(12) ,, sea water.

In all these cases the cables withstood the tests, the cables carrying direct current at 250 volts, two cables being on test in each solution, and being connected to the positive and negative poles of the system respectively. This was done in order to be certain that the material would withstand osmotic action.

The general results of the tests indicate that cables insulated with Maconite are particularly suited for installation in chemical works, steel works, dye works, long railway tunnels, etc., etc., where corrosive fumes or liquids are always present.

The material may prove to be suitable as a sheath for cables in the place of lead alloys or bitumen. It is already being used as a sheath for a surface wiring system which requires no bonding or earthing.

Experiments are being conducted with a view to using Maconite sheath on paper insulated cables.

Dexonite.

This material (*Dexine Ltd., Stratford, London, E.*) possesses the properties of vulcanite and ebonite, but unlike the two latter it retains its normal degree of hardness under high temperature. It is easy to tool, screw, and tap, is not brittle, and is capable of being moulded into any shape or size. It has a high electrical resistance, and is non-corrosive and acid resisting. *Specific Gravity* at 60° F., 1·2765. *Tensile Strength*: Stress per sq. in. at maximum load, 6,765 lbs., equivalent to 3·02 tons.

Articles made from Dexonite include insulating parts for electrical apparatus, medical requisites, binocular parts, etc. It is also supplied in sheet, rod, or tube form to any convenient sizes.

'Willesden' Paper (*The Willesden Paper and Canvas Works, Ltd.*) is a material largely used for electrical insulation, chiefly on the field magnets and armatures of continuous current dynamos, and is found by manufacturers to be of great value, as it is less hygroscopic than other materials formerly employed. It can also be used with advantage instead of vulcanised fibre in many places such as small switches, washers on fuse and switch boards, and for telephone work, etc.

'Press Paper,' and mica in thin lamina or built up into thicker plates and rings, are much used as insulating materials.

Asbestos Millboard Tubes (*Turner Brothers Asbestos Co. Ltd., Rochdale*), for the construction of electrical resistances and other electrical appliances, are made in all lengths and diameters with walls of any thickness.

Switch and Transformer Oil.

For switches, to prevent explosions from taking place, the best quality mineral oil should be used. It should contain no trace of animal or vegetable oils. It must be free from dust or foreign matter and be well filtered. If the oil be heated for long periods whilst in contact with air, no trace of acidity should develop, nor should it dissolve moisture when standing in a damp

atmosphere. A flash point below 375°F. is to be avoided. At 140°F. the viscosity should not be more than 850, and at 70°F. not less than 100, as measured in Redwood's viscometer. The oil must not show any tendency to sludge. The dielectric strength should be such that the oil will withstand an alternating pressure of 12,000 volts between a needle point and a disc ·125 apart without breaking down, the diameter of the disc being $\frac{1}{2}$ in. A similar specification would be suitable for a transformer oil, but the flash point need not be so high nor the viscosity so strictly specified.

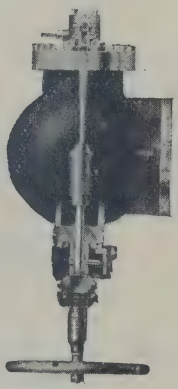
The presence of ·025 per cent. of moisture reduces the insulating properties of oil 70 per cent.; it is therefore important to test transformer oil before using it, and if necessary extract the moisture by filtering through dry blotting paper, or by any other approved method. Dry oil will withstand pressures up to 50,000 volts (alternating) between brass discs 0·5 in. in diameter with a separation of 0·2 in. For use in high-voltage transformers the oil should be required to withstand a test of 45,000 volts under the above conditions.

The seal at the bung of the containing drum should have a rubber or lead washer so as to completely exclude moisture.

Test for Moisture in Transformer Oil.

While a thorough test for the suitability of oil for transformers and oil switches can be made only with high-tension testing apparatus, very good indications of the presence of moisture have been obtained by Mr. J. K. Mackie, superintendent of the Connecticut Power Co., as follows:— A sample of the oil to be tested is drawn from the bottom of the transformer, oil switch, or storage tank. (Samples from the upper parts of the tank are not considered suitable for the test, as water is heavier than oil and usually collects at the bottom.) In the sample thus taken is placed powdered anhydrous copper sulphate. If moisture is present the copper sulphate will be dissolved, producing a blue colour that will diffuse through the oil if moisture is in suspension. Since enough copper sulphate is added to ensure a saturated solution, the intensity of the blue tint will be a measure of the amount of moisture present. As small percentages of moisture have a very deleterious effect on the dielectric strength of oil, however, the lightest shade of blue is sufficient indication that the oil should be dried by filtering. It may be pointed out that other substances giving a deeper tint than copper sulphate may be used, the only requirement being that they dissolve quickly in water but not in oil.

Relation between the Breakdown Voltage and the Dielectric Strength of an Insulator.



If d = thickness of dielectric in millimetres; V = potential difference in volts; c = a constant representing the potential difference in volts necessary to break down a sample of the dielectric 1 mm. thick; then

$$V = cd^{\frac{3}{2}}.$$

Values of c:— Dry air, 3,300; Empire cloth, 12,500; Fuller board, 19,000; Mica, 58,000. (*Baur.*)

(Contributed and Revised by Professor Percy A. Hillhouse, D.Sc., M.I.N.A., and James Thomson, M.I.N.A.)

DIMENSIONS OF SHIPS.

Moulded Dimensions.

LENGTH L = 'Length between Perpendiculars' = Length on load water-line measured from the fore side of the stem ('F.P.,' or 'Fore Perpendicular') to the aft side of the stern post ('A.P.,' or 'After Perpendicular'), or fore side of rudder stock if there is no stern post.

BREADTH B = 'Moulded Breadth' = Breadth measured over the widest part of the frame at the middle of the length L.

DEPTH D = 'Moulded Depth' = Depth measured from top of keel to top of deck beam at side at the middle of the length L. To avoid error the name of the deck to which the depth is measured should be stated.

Registered Dimensions.

LENGTH = Length from fore part of stem head to aft side of stern post, or fore side of rudder stock if there is no stern post.

BREADTH = Breadth measured over the outside of the shell plating at the widest part.

DEPTH = 'Depth of Hold' = Depth measured from top of ceiling to top of deck beam at the centre line of the vessel at the middle of the length. This depth is measured to the 'tonnage deck,' which is the 'second deck from below.'

Overall Dimensions.

LENGTH = 'Length Overall' = Length measured from the foremost point of the stem or figure-head (but excluding bowsprit if any) to the aft side of the taffrail, or cruiser stern.

BREADTH = 'Breadth Extreme' measured over the outside of the shell plating or belting or paddle sponsons, if any.

DEPTH = Depth from top of keel to top of deck amidships.

Drafts of a Ship.

The DRAFT d of a ship is the distance of the lowest point of the keel (or of the line of the keel produced) below the water line.

The MEAN DRAFT is half the sum of the drafts at the forward and after perpendiculars, or at the stem and the stern post.

The MOULDED DRAFT δ is the distance of the top of the keel (or of the line of the top of keel produced) below the water line.

The LIGHT DRAFTS of a vessel are the drafts forward and aft when the vessel is floating complete, but without coal, cargo, stores, water or other loads.

The LOAD DRAFT of a vessel is the mean draft of the vessel when floating complete and ready for sea and with all coal, cargo, passengers, crew, baggage, stores, spares, water, and other loads. The maximum load draft is determined by the freeboard tables of the Board of Trade; for passenger vessels the actual draft is limited to that determined by the spacing of the water-tight bulkheads, in accordance with the recommendations of the Convention for the Safety of Life at Sea. This draft is called 'The Bulkhead Draft.'

The FREEBOARD of a vessel is the height of the top of the wood deck at side at the middle of the length above the water line. The minimum freeboard allowable for any vessel entering or leaving a British port is fixed by law. It is assigned for each vessel by the Board of Trade and must be marked upon each side of the vessel amidships by the 'Freeboard Disc' or 'Plimsoll Mark.'

The 'TRIM' or 'LEAD' of a vessel is the difference between the drafts forward and aft. It is said to be 'by the head' or 'by the stern' according as the draft forward or the draft aft is the greater. When the drafts forward and aft are equal, the vessel is said to be 'on even keel.' 'Change of Trim' is the arithmetical sum of the changes of draft forward and aft.

Displacement.

The DISPLACEMENT of a vessel is the amount of water displaced by the underwater portions of her hull. It may be stated either by volume or by weight. The weight of the water displaced by a floating vessel is equal to the total weight of the vessel and her contents. If the vessel be floating in salt water, her displacement in tons, Δ, is equal to $\frac{1}{35}$ of her volume of displacement, V, in cubic feet. If in fresh water, $\Delta = \frac{V}{35{\cdot}8}$.

The TONS PER INCH of a vessel at any draft is the number of tons weight which must be placed on board in order to increase the mean draft one inch.

$$\text{Tons per inch, in salt water} = \frac{\text{area of water plane}}{420} = \frac{A}{420},$$

$$\text{Tons per inch, in fresh water} = \frac{A}{430},$$

where A is the area of the water plane in square feet.

Coefficients of Displacement.

The BLOCK COEFFICIENT, or *Coefficient of Fineness*, C_b, is the ratio of the immersed volume of displacement to the volume of the circumscribing parallelepipedon.

$$\text{Block coefficient} = C_b = \frac{V}{L\,B\,\delta} = \frac{35\,\Delta}{L\,B\,\delta} \text{ in salt water} = \frac{35{\cdot}8\,\Delta}{L\,B\,\delta} \text{ in fresh water.}$$

Where V = Immersed volume of displacement in cubic feet.
Δ = Displacement in tons.
L = Length on load water-line, in feet.
B = Moulded breadth in feet.
δ = Moulded draft in feet.

The PRISMATIC COEFFICIENT, C_p, is the ratio of the immersed volume of displacement to the volume of the circumscribing cylinder having the same form of cross section as the vessel below the water line amidships.

$$\text{Prismatic coefficient} = C_p = \frac{V}{La} = \frac{35\,\Delta \text{ or } 35{\cdot}8\,\Delta}{La},$$

where a is the immersed area of the midship section to outside of frame in square feet.

The MIDSHIP SECTION COEFFICIENT, C_m, is the ratio of the area of the midship section up to the waterline to the area of the circumscribing rectangle.

$$\left.\begin{matrix}\text{Midship section coefficient}\\ \text{or midship area coefficient}\end{matrix}\right\} = C_m = \frac{a}{B\,\delta}.$$

From the above values for the three coefficients it is easily seen that

$$C_p \times C_m = C_b.$$

Wetted Surface.

The WETTED SURFACE or IMMERSED SURFACE of a vessel is the total area of the surface of the shell plating, keel, bilge keels and rudder in contact with the water in which the vessel is afloat.

Approximately,

$$\text{Wetted surface} = S = L\,(1{\cdot}7\,\delta + C_b B) + \text{surfaces of keel, bilge keels, and rudder.}$$

Or again,

$$\text{Wetted surface} = S = 15{\cdot}4\sqrt{L\Delta} + \text{surfaces of keel, bilge keels, and rudder,}$$

where L = length between perpendiculars, in feet,
δ = moulded draft, in feet,
C_b = block coefficient,
B = moulded breadth, in feet,
Δ = displacement, in tons,
S = wetted surface, in square feet.

Curves of Displacement, etc.

As the draft of a vessel changes, the displacement, area of water plane, coefficients, etc., also vary, and it is customary to record these changes by means of curves whose vertical abscissæ represent draft, while the horizontal ordinates represent areas, displacements, coefficients, etc.

The ordinate of the curve of displacement at any draft is proportional to the area of the curve of water plane areas up to that draft.

The PRISMATIC CURVE for any draft is a curve whose horizontal base represents to scale the length of the vessel on load water-line, and whose ordinate at any point is proportional to the immersed area of the corresponding transverse section of the vessel. This curve shows the longitudinal distribution of the displacement which has an important bearing upon the resistance.

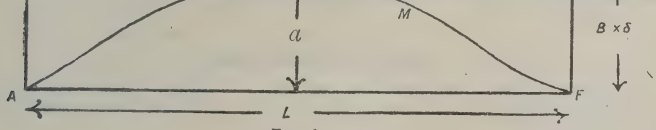

FIG. 1.

Let A M F (fig. 1) be a prismatic curve, inscribed within a rectangle C F of height representing the area of the midship section, and surrounded by another rectangle B F of height representing the area of the rectangle circumscribing the midship section. Then

Area of prismatic curve is proportional to displacement.

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle C F}} = \frac{V}{L \times a} = \text{Prismatic coefficient.}$$

$$\frac{\text{Area of prismatic curve}}{\text{Area of rectangle B F}} = \frac{V}{L \times B \times \delta} = \text{Block coefficient.}$$

$$\frac{\text{Height of rectangle CF}}{\text{Height of rectangle B F}} = \frac{a}{B \times \delta} = \text{Midship section coefficient.}$$

Centre of Buoyancy.

The CENTRE OF BUOYANCY, B, at any draft, is the centre of gravity of the volume of displacement at that draft. The vertical position of the centre of buoyancy is the same as that of the centre of gravity of the curve of water plane areas, and its longitudinal position is the same as that of the centre of gravity of the prismatic curve.

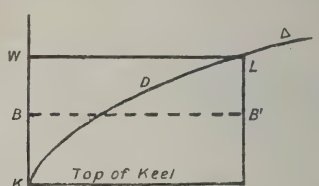

FIG. 2.

To find the height, K B, of the centre of buoyancy above the top of keel, draw the line BB′ across the displacement curve so that the area of the rectangle WB′ is equal to the area W L D K above the displacement curve.

MORRISH'S RULE.

Very approximately $K B = \frac{\delta}{6}\delta - \frac{V}{3A}$;

where K B is the height of the centre of buoyancy above top of keel, in feet

δ is the moulded draft, in feet;

V is the displacement, in cubic feet;

A is the area of the water plane, in square feet;

$\frac{V}{A}$ is called 'Rankine's Mean Draft.'

Centre of Flotation.

The CENTRE OF FLOTATION is the centre of gravity of the water plane. The two waterlines defining any small change of trim intersect at the centre of flotation.

Transverse Metacentre.

If a vessel be slightly inclined to one side the centre of buoyancy, B, will move slightly from the middle line towards that side, say to B′, and the vertical line through B′ representing the upward pressure of the water will cut the inclined middle line at the point M called the 'Transverse metacentre.'

$$BM = \frac{I}{V}.$$

where BM is the height of the transverse metacentre above the centre of buoyancy,
I is the transverse moment of inertia of the water-plane about its middle line,
and V is the volume of displacement.

The METACENTRIC HEIGHT, GM or m, in any condition of loading is the vertical distance between the transverse metacentre, M, and the centre of gravity, G, of the whole vessel and her contents. If, in the upright condition, G lies above M the vessel is unstable and will not remain upright; if G lies below M, the vessel is stable and will return to the upright position. GM is a measure of the vessel's 'Initial Stability.'

The value of GM can be obtained either by separate calculation of the heights of G and M or by an inclining experiment.

Inclining Experiment.

In carrying out an 'Inclining Experiment' on a vessel, to determine the height, KG, of the centre of gravity, the following procedure should be observed :—

Have the vessel free from wind, tide, current, transverse mooring ropes, gangways, and particularly from loose water or other weights liable to move when the vessel is inclined. Have no men on board except those engaged on the experiment. Read the drafts carefully at each end from a small boat. Move any known weight w (enough to produce an inclination of about 2°) transversely across the deck through a total distance, a, and observe the corresponding deflection d, of a simple pendulum of length l, suspended anywhere on board. Several shifts of the weights are usually made to each side of the ship and the mean value of d taken. From the draft readings and the curves of displacement and transverse metacentres we can obtain the value of Δ, and of KM.

Then GM as inclined $= \frac{w\,a\,l}{\Delta\,d}$, w and Δ being in tons, GM and a in feet, and l and d in inches

and KG as inclined = KM − GM.

These results apply only to the vessel in the inclining condition. To obtain the metacentric height for any other condition it is necessary to make suitable corrections for the different amounts and positions of the various items of loading and for the new values of Δ and KM.

It is usual to estimate the value of GM for the following conditions :—

Light Condition.—Ship and machinery complete, boilers and condensers full, but no coal, cargo, passengers, crew, baggage, stores, spares, fresh or salt water, or reserve feed-water on board.

Docking Condition.

Load Condition.—Fully loaded condition : ship and machinery complete, boilers and condensers full, and with all coal, passengers, crew, baggage, stores, spares, fresh and salt water, reserve feed-water, and holds filled with homogeneous cargo of such density as to bring the vessel to her load draft.

Spent Condition.—Same as full load condition, but with all coal, water, and stores consumed.

Ballasted Condition.—Same as spent condition, but with water-ballast tanks filled.

Any other special conditions likely to arise in practice.

Rolling Period of a Vessel.

In Smooth Water.

K = Radius of gyration of the vessel and all weights on board, about a longitudinal axis passing through her centre of gravity.

m = Metacentric height.

2 T = Time of double roll, say from port to starboard and back again, in seconds.

g = Force of gravity = 32·2.

Then $T = \pi\sqrt{\frac{K^2}{g\,m}} = \cdot 554\frac{K}{\sqrt{m}}$.

The period 2T of a double roll varies from about 3 to 30 seconds ; in large Atlantic liners it is about 20 seconds.

Stability.

The INITIAL STABILITY of a vessel is the measure of the tendency of the vessel to return to the upright if she is forcibly inclined to a small angle, θ, of not more than about 10°.

Initial Stability or Righting Moment at the inclination θ = $RM_\theta = \Delta\,m\,\theta$ foot-tons,

where Δ = displacement in tons,

m = metacentric height in feet,

θ = angle of heel in circular measure,

= inclination in degrees ÷ 57·3.

Curve of Stability.—When a vessel is inclined to any angle θ (fig. 3), large or small, the centre of buoyancy moves to one side (B to B'). The upward force of buoyancy, Δ, now acts through B', while the weight acts downwards through G, the centre of gravity. These two forces form the righting couple, whose arm is GZ (the righting arm) and whose moment is W.GZ

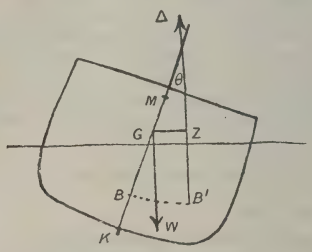

Fig. 3.

(the righting moment). When θ is small, B'Z passes through M, as already stated, and $GZ = m\theta$; at larger angles GZ must be separately calculated, and it is customary to obtain its value at each 10° of inclination and to connect the series of righting arms by a curve which is called the curve of stability (fig. 4).

OR is called the 'Range of Stability,' H the 'Maximum Righting Arm,' occurring at some

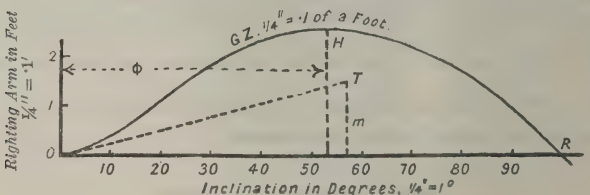

Fig. 4.

angle ϕ, while the initial slope of the curve is measured by the metacentric height, m, set up at 57·3° ($\theta = 1$), as shown in the figure, where OT is tangent to the curve at the origin O. (The scales marked are those to which the curves are usually drawn, but of course do not apply to the reduced figure.) The area of the curve of stability up to any angle is proportional to the work which must be done (by wind or other external forces) in order to incline the vessel to that angle. The work so done is called 'Dynamical Stability.'

Longitudinal Metacentre.

If a vessel be slightly inclined about a transverse horizontal axis, the centre of buoyancy will move longitudinally, and the point in which the vertical line through the new centre of buoyancy cuts that through the centre of buoyancy corresponding to even keel is called the 'longitudinal metacentre.'

The height of the longitudinal metacentre above the centre of buoyancy = LBM = $\frac{I}{V}$, where I is the moment of inertia of the waterplane about a transverse axis through its centre of gravity, and V is the volume of displacement.

The Longitudinal Metacentric Height, LGM, is the height of the longitudinal metacentre above the centre of gravity = LBM − BG = M.

The longitudinal GM is used in calculating changes of trim. If any weight, w, be moved longitudinally through a distance, a, the 'moment to change trim' is wa.

The 'moment to change trim one inch' or 'inch trim moment' $= {}''M = \frac{\Delta M}{12L} \overset{\cdot}{=}^{*} \frac{I}{420L}$

Approximately, ${}''M = \frac{30\,t^2}{B}$

where ${}''M$ = inch trim moment, in foot tons.
Δ = displacement, in tons.
L = length between perpendiculars, in feet.
t = tons per inch.
B = moulded breadth, in feet.
I = longitudinal moment of inertia of water plane.

The *change of trim* in inches due to any moment $w\,a$ is $\frac{w\,a}{{}''M}$. Of this total change of trim half is usually added to the draft at the end towards which the weight w was moved, and half deducted from the draft at the other end.

If instead of merely moving a weight already on board, we desire to find the alteration of drafts due to placing a new weight on board, first imagine the weight to be placed at the centre of flotation F. This will increase the drafts both forward and aft equally by an amount $\frac{w}{t}$. Then imagine the weight moved longitudinally to its assigned position and calculate the change of trim. Then combine these changes of drafts with the additional immersions $\frac{w}{t}$ and so find the total changes of draft forward and aft.

Curves connecting the mean draft with the position of the centre of flotation, the tons per inch, and the inch trim moment should be prepared to facilitate such calculations.

For large additions of weight the above method is not accurate, and it is necessary to prepare a complete list of all the items making up the displacement, together with their moments forward or aft of midships. Then

$\frac{\text{Total moment}}{\text{Total weight}} = \text{G}\boxtimes$ or $\boxtimes\text{G}$ = distance of centre of gravity aft or forward of midships.

From a curve connecting draft with the distance of the centre of buoyancy for even keel from midships, we can find the value of $\text{B}\boxtimes$ or $\boxtimes\text{B}$, and hence the value of GB or BG, that is the longitudinal distance of the centre of gravity aft of or forward of the centre of buoyancy. The moment to change trim is then $\Delta \times \text{GB}$, and the change of trim $\frac{\Delta\,\text{GB}}{{}''M}$

RALSTON'S STABILITY AND TRIM INDICATOR.

This useful piece of apparatus (fig. 6) determines the metacentric height and trim of a vessel by mechanical means instead of by calculation. It consists of a capacity profile of the vessel

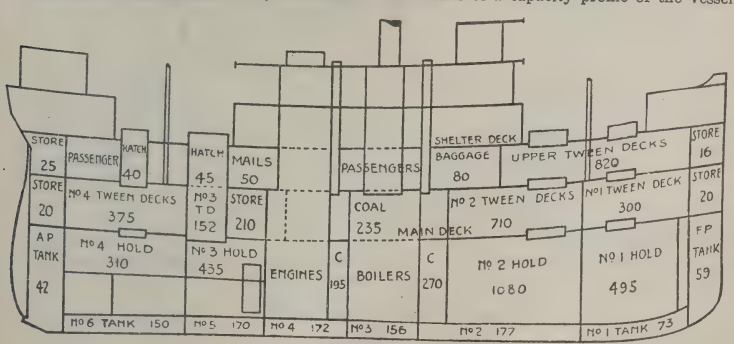

FIG. 5.

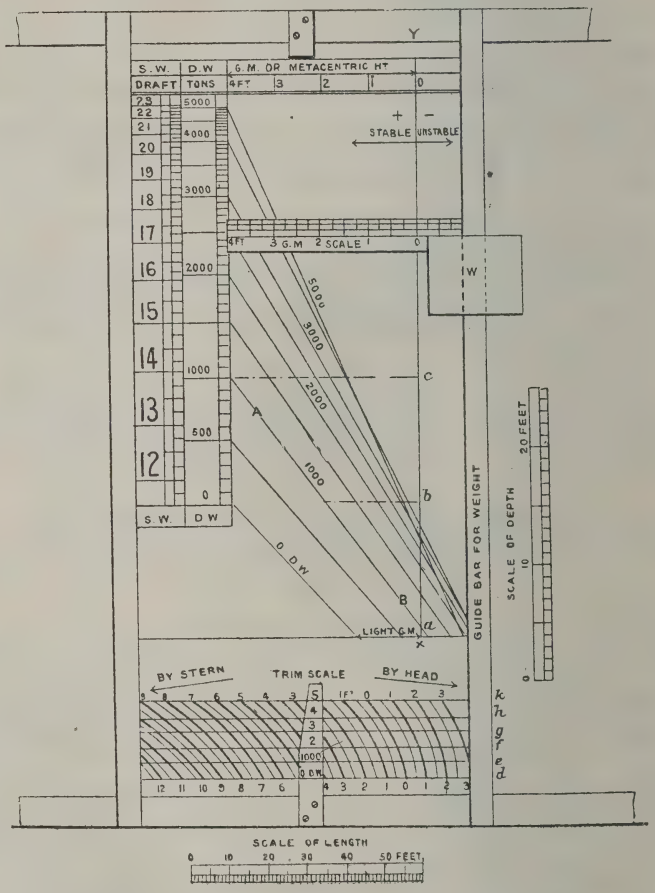
(fig. 5), the vertical scale of which, for convenience, is made greater than the longitudinal scale. This profile is mounted on a swinging table and is surmounted by a longitudinally-sliding

* $\overset{\cdot}{=}$ is the symbol for 'approximately equal.'

RALSTON'S STABILITY AND TRIM INDICATOR.



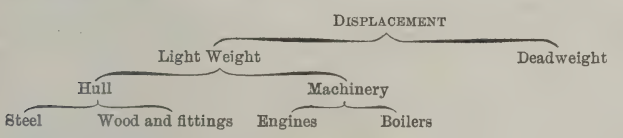


FIG. 6.

diagram which in turn carries a vertically-sliding balance weight (fig. 6). The diagram gives mean drafts, metacentric and trim curves for various deadweights, and the balance weight is provided with a G.M. scale. The combined weight of table and sliders is made proportional to the light weight of the ship and in the zero position of the sliders the common centre of gravity corresponds in position to that of the ship in the light condition. The weights of cargo, coal, stores, water, etc., are represented by a series of small brass weights which are placed in position on the capacity profile so as to represent any condition of loading for which it is desired to know the metacentric height and trim. The table is then supported firstly upon a longitudinal axis passing through the light C.G. and the vertical slider moved until a balance is obtained. The mean draft and metacentric height can then be read off from the curve corresponding to the total deadweight. The table is next supported on a vertical axis passing through the light C.G. and the longitudinal slider moved until the whole is in equilibrium, when the amount of trim can be read from the scales. The movements of the sliders are effected by means of racks and pinions. The instrument is simple, ingenious, and accurate; it takes into account all the features of the vessel's form and weight-distribution, obviates a considerable amount of calculation, and is being extensively adopted in the mercantile marine.

Weights.

The total weight or displacement of a merchant vessel may be subdivided as follows :—

The *Weight of Steel* includes :—
Steel and iron plates and bars of all kinds.
Structural forgings and castings, whether of steel or of bronze.
Pillars.
Steel masts.

The *Weight of Wood and Fittings* includes :—

Carpenter work.	Deck machinery and piping.	Cement.
Joiner work.	Electric lighting installation.	Insulation.
Plumber work.	Refrigerating machinery.	Rigging and sails.
Wood masts and spars.	Heating installation.	Canvas covers and awnings.
Upholstery.	Ventilation.	Sheet iron work.
Boats.	Galley outfit.	Fixed ballast.
Smithwork.	Paint.	Deck Coverings. Etc.

The *Weight of Engines* includes :—

Main propelling engines.	Sanitary and fresh-water pumps.	Piping in engine-room and tunnel.
Shafting and propellers.	Floors, ladders, and gratings in engine spaces.	Water in condensers and piping.
Condensers and circulating pumps.	Feed water.	Tools etc.
Air-pumps and bilge-pumps.		

The *Weight of Boilers* includes :—

Main boilers and donkey boiler.	Piping in boiler rooms.	Floor-plates, ladders, and gratings in boiler-rooms.
Uptakes and funnels.	Feed-pumps.	Tools.
Fans and fan engines.	Feed water.	Etc.
	Hot water in boilers.	

Deadweight includes :—

Spare gear.	Salt water for ship's use.	Provisions.
Crew and effects.	Reserve feed water.	Stores.
Passengers and baggage.	Water ballast.	Bedding and napery.
Coal in bunkers and on fire-bars.	Bilge water.	Cutlery and crockery.
Fresh water for ship's use.	Mails and cargo.	Glass and silverware.
	Oil fuel in tanks and pipes.	Etc.

Hull weight may be estimated either in detail or as a whole. Detail calculation requires that complete plans of the vessel are available, together with reference lists giving weight-rates or actual weights of all varieties of fittings. An accurate record of the finished total weights of the various items of the outfit of previous completed vessels is of great value in this connection.

For preliminary work, where a rapid estimate of the weights is required, the method of coefficients is largely relied on. In this method the whole weight of the hull, or of certain sectional portions thereof, is compared with some arbitrary parameter or parameters of simple form, depending upon the principal dimensions of the vessel or of her sectional parts. For each vessel completed an accurate record of these weights is filed, and the values of the 'Coefficients of Weight' $\left(= \frac{\text{weight}}{\text{parameter}} \right)$ worked out. Then for any proposed new vessel the weight of the hull, or of any of its parts, is found approximately by multiplying the proper parameter by a suitable coefficient chosen from among those of similar finished vessels.

The most commonly used parameter is the *Cubic Number*, which is the product of the Length Breadth, and Depth, divided by 100.

Cubic number $= N = L\,B\,D \div 100$.

where L = Length between perpendiculars, in feet,

B = Breadth moulded, in feet,

D = Depth moulded, in feet, taken to the highest deck to which the shell plating extends continuously or almost continuously throughout the whole length of the vessel.

Then,

Weight of Hull, $H = N \times$ Coefficient of Weight of Hull

$= N \times C_h$

Similarly,

Weight of Steel, $S = N \times Cs$.

Weight of Wood and Fittings, $W = N \times Cw$.

The weights of deck machinery, refrigerating machinery, insulation, etc., may either be included in the wood and fittings coefficient or separately estimated.

The following table gives average values of these coefficients :—

Type of Vessel.	*Cs.*	*Cw.*	*Ch.*
Torpedo Boat Destroyer	·27	·10	·37
Cruiser	·34	·12	·46
Battleship	·33	·12	·45
River Paddle Steamer	·20	·10	·30
Channel Steamer	·25	·13	·38
Coasting Steamer	·32	·20	·52
Cargo Tramp	·35	·12	·47
Intermediate Liner	·42	·17	·59
Fast Mail Liner	·42	·16	·58
Oil Tanker	·38	·06	·44

Other parameters sometimes used for estimating the weight of wood and fittings are

$(L \times B)$ and $L\,(B + D)$.

Weight of Machinery.

In making preliminary estimates, the weight of machinery can be taken as proportional to the horse-power, the number of horse-power per ton of total machinery weight being recorded for all vessels completed and tried. A more accurate method is to record separately the weight of engines and the weight of boilers per horse-power, and to employ these rates when estimating the weights of proposed machinery of similar type. The weight of reciprocating engines may be taken as proportional to the volume of the low-pressure cylinder. For the greatest accuracy the weights of both engines and boilers must be made up in detail from the drawings and the detailed weight records of previous jobs. The following table gives the relative weights and spaces occupied by various types of machinery.

COMPARATIVE FIGURES FOR DIFFERENT TYPES OF MACHINERY.

A. Cleghorn (Transactions of Engineers and Shipbuilders in Scotland).

Deadweight.

The total deadweight may either be specified by the owner or must be made up in detail from the particulars of the service to be performed.

Spare Gear.—Make up the weight in detail from the specified list of spares or allow a total approximate amount by reference to the actual weights carried by similar steamers. The amount may vary from about two tons in river paddle steamers and fast Channel steamers to about 40 tons in an Atlantic liner.

Crew and Effects.—Allow about one ton per ten men.

Passengers.—Allow one ton for every fifteen persons in ordinary cases and for every twenty persons in excursion crowds including women and children.

Baggage.—For the hand baggage of excursion passengers allow about one ton for every 250 persons. For long voyages allow about three tons for every ten persons.

Fuel in Bunkers = horse-power at sea, including that of auxiliaries × pounds of fuel consumed per horse-power per hour ÷ 2240 × distance between fuelling stations furthest apart ÷ service speed, + coal for galleys etc. + allowance for use in port + a margin of 10 to 20 per cent. for emergencies.

For rates of coal consumption see tables on pages **1995, 2013.**

Coal on Bars.—Allow about 35 lbs. per square foot of grate area.

Fresh Water.—Allow about one ton per day for every 25 first or second-class passengers and about one ton per day for every 75 third-class or steerage passengers and crew.

Salt Water.—For sanitary purposes from ½ ton to 5 tons according to the extent of the sanitary accommodation.

Reserve Feed Water.—Allow about 4 tons per 1,000 H.P. per 24 hours for short voyages and about half as much in vessels where distilling apparatus is carried.

Provisions.—Allow about one ton per day for every 75 first and second-class passengers and about one ton per day for every 250 third-class or steerage passengers and crew.

Water Ballast.—As may be required for purposes of immersion, stability or trim during the voyage. Say one-half of weight of consumables.

Bilge Water.—Is more or less inevitable, but should not amount to much if proper care in pumping is continually taken. Allow about one-fifth of the vessel's 'tons per inch.'

Mails, cargo and stores.—As required by owners.

Bedding and napery
Cutlery and crockery } Together about one ton for every 15 persons on board.
Glass and silverware

Resistance of Ships.

The total resistance to the ahead motion of a ship is made up of three parts :—

1. 'Skin-friction resistance,' or 'skin resistance.'
2. 'Wave-making resistance,' or 'wave resistance.'
3. 'Eddy-making resistance,' or 'eddy resistance.'

The two latter are usually considered together under the name 'residuary resistance,' or 'wave resistance' merely, since eddy resistance is very small in comparison with the other two.

HORSE-POWER.

The horse-power required to overcome any of these resistances is proportional to the resistance multiplied by the speed, and is called the 'effective horse-power.' It is from about ·63 to ·45 of the corresponding indicated or shaft horse-power developed within the vessel, the remainder of the power developed being absorbed by engine and shaft friction and losses in the propeller. The ratio of effective horse-power to indicated or shaft horse-power is called the 'propulsive efficiency.' or 'propulsive coefficient.'

$$e = \frac{\text{E.H.P.}}{\text{I.H.P.}} \text{ or } \frac{\text{E.H.P.}}{\text{S.H.P.}}$$

= from ·63 to ·45.

Skin Effective Horse-Power.

Skin E.H.P. is directly calculable :—

$$\text{Skin E.H.P.} = E_s = \frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2\cdot83}.$$

where S = wetted surface in square feet.
F_{10} = Skin E.H.P. per 100 square feet at 10 knots.
K = speed in knots.

The following table gives the values of F_{10} and of $\left(\frac{K}{10}\right)^{2\cdot83}$ for various lengths and speeds :—

L.	F_{10}.	L.	F_{10}.	K.	$\left(\frac{K}{10}\right)^{2\cdot83}$	K.	$\left(\frac{K}{10}\right)^{2\cdot83}$
50	1·999	450	1·832	10	1·00	18	5·28
100	1·918	500	1·826	11	1·31	19	6·15
150	1·888	600	1·816	12	1·68	20	7·11
200	1·873	700	1·807	13	2·10	25	13·37
250	1·863	800	1·798	14	2·59	30	22·40
300	1·854	900	1·790	15	3·15	35	34·65
350	1·846	1000	1·782	16	3·78	40	50·56
400	1·839			17	4·49		

From these figures curves may be drawn upon squared paper from which intermediate readings can be obtained.

Wave Effective Horse-Power.

The wave effective horse-power is not directly calculable, although several empirical formulæ and curves of coefficients have been published.

Taylor gives :—

$$\text{Wave E.H.P.} = E_w = B_0 \frac{\Delta^{\frac{2}{3}}}{L} \times \cdot0030707\ K^5.$$

Where B_0 = from ·35 to ·55, according to the degree of fulness of the vessel and her ratio of length to breadth.

The most accurate method of estimating E_w is by using the results of model experiments or of actually tried vessels, and Froude's 'Law of Comparison.' The Law of Comparison may be stated thus :—If two vessels of exactly similar form, but of different size, are run at speeds proportional to the square roots of their lengths, then their wave effective horse-powers will be proportional to the products of their displacements by their speeds. If, then, we are designing a vessel n times as long as a model or similar smaller ship whose speeds and corresponding wave E.H.Ps. we know, the following ratios which various elements of the design bear to corresponding elements of the prototype may be used :—

Linear dimensions	n	Speeds	$\sqrt{n}$
Surfaces	n^2	Wave resistances	n^3
Displacements	n^3	Wave E.H.Ps.	$n^3\sqrt{n}=n^{3\cdot5}$

Speeds related as above are called 'Corresponding Speeds,' and the ratio $\frac{K}{\sqrt{L}}$ of speed to square-root of length is called the 'Speed-Length Ratio.'

Model experiments give us the total E.H.P. at any speed. From this the wave E.H.P. can be obtained by separately calculating the skin E.H.P., as above described, and deducting it from the total. The wave E.H.P. for the full-size ship will be $n^{3\frac{1}{2}}$ times that of the model, and the skin E.H.P. for the full-size ship can be separately calculated. The sum of these two results gives the total E.H.P. for the full-size ship. It is then finally necessary to assume a suitable value for e, the propulsive coefficient, and calculate the I.H.P. or S.H.P. by dividing the total E.H.P. by e. If we are designing from the trial results of a similar completed vessel, the procedure is slightly different :—

I.H.P. or S.H.P. of Type Ship $\times e$ = E.H.P. of Type Ship

$\frac{S}{100} \times F_{10} \times \left(\frac{K}{10}\right)^{2\cdot83}$ = Skin E.H.P. of Type Ship } at K knots.

Difference = Wave E.H.P. of Type Ship

Multiply by $n^{3\frac{1}{2}}$

and so obtain Wave E.H.P. for Design

$\frac{S'}{100} \times F'_{10} \times \left(\frac{K'}{10}\right)^{2\cdot83}$ = Skin E.H.P. for Design } at $\sqrt{n}$ K knots.

Sum = Total E.H.P. for Design

Divide by e

To obtain I.H.P. or S.H.P. for Design

Where
S = wetted surface of type ship, in square feet,
$S' = n^2S$ = " design "
K = speed of type ship, in knots,
$K' = \sqrt{n}\,K$ = corresponding speed of design, in knots,
F_{10} = skin E.H.P. per 100 square feet at 10 knots for type ship,
F'_{10} = " " " for design.

D. W. Taylor's book, 'The Speed and Power of Ships,' which contains a series of curves based on model experiments and covering a large range of proportions of dimensions and speeds, will be found to give very accurate estimates of effective horse-power.

For fast, fine vessels, the paper 'On some Results of Model Experiments,' by R. E. Froude, published in the 'Transactions of the Institute of Naval Architects for 1904,' may be advantageously consulted. Many other experimental results have now been published, both in Great Britain and America.

Admiralty Coefficients.

The 'Admiralty Coefficient of Performance' $= \frac{\Delta^{\frac{2}{3}} K^3}{P} = C$

Where
Δ = displacement, in tons,
K = speed, in knots,
P = I.H.P. or S.H.P.

Conversely $P = \frac{\Delta^{\frac{2}{3}} K^3}{C}$, so that if C is known or can be correctly assumed, P can readily be calculated. In similar ships at 'corresponding speeds' $\Delta^{\frac{2}{3}} K^3$ varies as $(n^3)^{\frac{2}{3}} (\sqrt{n})^3$, that is, as $n^{3\frac{1}{2}}$. Hence, if P were also to vary as $n^{3\frac{1}{2}}$, the values of C would remain the same. And also, if for any given vessel P varied as K^3, C would be the same for all speeds. For these reasons C is sometimes called the 'Admiralty Constant,' but as the above relations are theoretical assumptions only, and C is found to vary from speed to speed and from ship to ship, it is better to use the term 'Admiralty Coefficient.'

Although wave-making power follows the law of comparison, and therefore varies as $n^{3\frac{1}{2}}$, skin-friction power does not obey the same law and only increases at the lesser rate

$$n^2 \frac{F'}{F} (\sqrt{n})^{2\cdot83} = \frac{F'}{F} n^{3\cdot415}.$$

And hence larger ships have relatively less power and larger values of C than smaller vessels. In the case of large vessels, also, a lesser proportion of power is lost in overcoming internal friction and eddy-making, and a further increase of C is the result.

In spite of its known defects, the 'Admiralty Coefficient' is largely used for estimating horse-power, the assumed value being based upon that for a similar, or nearly similar, completed vessel at 'corresponding' speed, and suitable allowances made for variations in size and proportions.

If the prismatic coefficient of the type ship differs from that of the proposed vessel, we may still find suitable values for C by modifying the 'corresponding speed' of the type ship, thus :—

$$K = K' \sqrt{\frac{L}{L'} \cdot \frac{1 - C_p}{1 - C'_p}}$$

where K, L, and C_p are the corresponding speed, length between perpendiculars, and prismatic coefficient respectively for the type ship, and K', L', and C'_p the desired speed, length, and prismatic coefficient for the proposed vessel.

Economical Speeds.

For each vessel there is a certain 'suitable' or 'economical' speed, determinable in relation to her length and fineness, above which she would be wasteful of power or 'overdriven' and below which she would be unnecessarily fine.

The following table (A) expresses these relations, and Table B gives possible values of the Admiralty coefficient for vessels agreeing with Table A :—

TABLE A.

$Cp.$	$\frac{V}{\sqrt{L}}$	$Cp.$	$\frac{V}{\sqrt{L}}$
Prismatic Co-efficient	Speed Length Ratio.	Prismatic Co-efficient.	Speed Length Ratio.
·61	·925	·73	·758
·63	·897	·75	·730
·65	·869	·77	·703
·67	·842	·79	·675
·69	·814	·81	·647
·71	·786		

TABLE B.

L.	C.	L.	C.
Length on Waterline.	Admiralty Coeffi-cient.	Length on Waterline.	Admiralty Coeffi-cient.
100	137	500	307
150	188	550	310
200	227	600	312
250	255	650	315
300	275	700	317
350	289	750	319
400	297	800	321
450	303	850	323

Table B assumes an efficiency, *e*, of about 55 per cent.; for large turbine work *e* appears to be about 50 per cent., so that in estimating shaft horse-power in such cases C should be taken at about 10 per cent. less than is given by the above table. For single-reduction geared turbines *e* = about 54 per cent.; for double-reduction geared turbines *e* = about 57 per cent.

The formula $C_b = 1{\cdot}06 - {\cdot}5\ V \div \sqrt{L}$ has also been proposed as expressing a suitable connection between block coefficient and speed-length ratio.

Admiralty Coefficient applied to Coal Consumption.

A variation of the Admiralty Coefficient much used by superintendent engineers, when comparing performances at sea, consists in substituting the daily coal consumption in tons for horse power in the formula $C = \frac{\Delta^{\frac{2}{3}} K^3}{P}$. We thus get :—

$$\text{Coal Coefficient of Performance} = \frac{\Delta^{\frac{2}{3}} K^3}{T}$$

where Δ = mean service displacement in tons,
K = mean service speed in knots,
T = daily coal consumption in tons.

Rudders.

The area of a vessel's rudder is determined by dividing the product of her length and load draft by about 30 to 40 in the case of warships, 60 to 70 for fast liners, 90 to 100 for slow cargo tramps. The most efficient angle is about 35° from the middle line, at which angle the total pressure upon the rudder in tons is about $\frac{AK^2}{700}$, where A is the rudder area in square feet and K her speed in knots. The centre of pressure at 35° is found by assuming that the pressure on each elementary horizontal strip is applied at a point, $\frac{3}{8}$ths of the breadth of the strip from its loading edge, summing the moments for each strip, and dividing by the total area.

Let h be the distance of the centre of pressure from the axis in inches, and P the total pressure upon the rudder in tons. Then T, the twisting moment in inch-tons, $= Ph$, and

$$D = \text{diameter of stock, in inches} = \sqrt[3]{\left(\frac{16\,T}{\pi F}\right)}$$

where F = maximum allowable shearing stress in material in tons per square inch.

$$\text{If } F = 5{\cdot}1,\ D = \sqrt[3]{T}$$

In practice the diameters of the rudder stocks of all classified vessels are determined by the rules of the Classification Societies.

Estimate Sheet.

When making preliminary estimates of dimensions, weights, power, etc., the following form will be found convenient;—

Number of Enquiry. Type of Vessel. Owners. Date.

Conditions.

Length × Breadth.

Type. Length × Breadth × Depth. Cubic Number.

S Steel Weight. Steel Coefficient.

W Wood and Outfit Weight. W. & O. Coefficient.

M Machinery Weight. H.P. per Ton.

D Deadweight.

$$\frac{\text{Displacement}^{\frac{2}{3}} \times \text{Speed}^3}{\text{Admiralty Coefficient}} = \text{Horse Power.} \qquad \frac{\text{Length} \times \text{Breadth} \times \text{Draft full}}{35} = \text{Block Number}$$

$$\frac{\text{Block Coefficient}}{\text{Displacement}}$$

For example, in figures :—

Enquiry No. 42. Cargo and Passenger Steamer. Messrs. Brown and Black. 3.3.22.

To carry 6000 tons and steam 13½ knots on 24 ft. draft. Class, 100 A1 at Lloyd's. Sixty first-class. 100 second-class.

	19200		
T.S.S.	400 × 48 × 30		5760
S.	2200	·382	
W.	850	·147	
M.	750	4·54	
D.	6000		

$$\frac{9800^{\frac{2}{3}} \times 13\tfrac{1}{2}^3}{313} = 3400 \text{ I.H.P.}$$

$$\frac{400 \times 48 \times \overset{24'\ 0''}{\overset{2''\text{ keel}}{23'\ 10''}}}{35} = 13080$$

$$\cdot 75$$

$$9800$$

These figures are arrived at by a process of trial and error-correction until a satisfactory balance is reached between weights and displacement, block coefficient and speed length ratio, horse-power and weight of machinery.

BASES OF ENGINE AND BOILER DESIGN.

Cylinder Ratios.

Considerations of weight and space usually limit the dimensions of cylinders for the machinery of high speed cross-channel vessels. For ordinary merchant and mail steamers these considerations are of minor importance; coal consumption however is of the utmost importance and consequently a higher ratio of expansion of steam is utilised, involving larger cylinder dimensions, in order to obtain maximum economy of coal consumption. In fast passenger vessels with high revolutions per minute, four-crank triple-expansion engines are invariably adopted, there being one H.P., one M.P., and two L.P. cylinders. This arrangement admits of a satisfactorily balanced engine being obtained, reducing vibration to a minimum, and the weight of the moving parts of the L.P. cylinders is considerably reduced compared with the ordinary three-crank triple engine or four-crank quadruple. The following table of cylinder area ratios is in accordance with modern practice for various types of marine engines:—

TABLE SHOWING CYLINDER AREA RATIOS.

Type of Engine.	Boiler Pressure. Lbs. per Sq. In.	Ratio of Cylinder Areas.			
		L.P. / H.P.	2nd M.P. / H.P.	1st M.P. / H.P.	H.P.
Quadruple expansion . .	200 to 220	8 9	4·0 4·3	2·0 2·08	1 1
				M.P. / H.P.	
Triple expansion, ordinary merchant practice . . .	160 to 180	6·5 to 7·5		2·5 to 2·7	1
Cross-channel steamers . .	180 to 200	6·25		2·4	1
Compound engines, screw .	100 to 140	4 to 5		—	1
,, ,, paddle .	90 to 130	3·5		—	1

The reciprocating engine is now, however, being displaced by direct or geared turbines in all classes of vessels, from fast passenger and mail steamers and cross-channel boats to cargo vessels, even of the tramp class, owing to the reduction obtainable thereby in fuel consumption.

Mean Pressures and Expansion of Steam.

The total power developed in an engine may be varied by altering the point at which steam is cut off in the H.P. cylinder, and generally provision is made to enable the cut-off in each cylinder to be independently adjusted if necessary to equalise the powers developed in each cylinder. For the maximum designed power the cut-off in the H.P. cylinder takes place at from ·65 to ·75 of the stroke, and the total number of expansions of the steam is

$$= \frac{\text{Volume of L.P. cylinder}}{\text{Volume of H.P. cylinder at point of cut off}};$$

or

$$\frac{\text{Ratio of } \dfrac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}}{\text{Cut off in H.P. cylinder (expressed in fraction of stroke)}}.$$

The total expansion of the steam is usually considered with clearance neglected and neglecting also the fact that release takes place before the end of the stroke. In estimating the mean pressure obtainable in any multiple-stage expansion engine it is referred to the L.P. cylinder, the mean pressure thus obtained being that necessary if the whole of the power were developed in the L.P. cylinder. The actual referred mean pressure is, therefore, in the case of a triple expansion engine equal to

$$\text{Mean pressure in L.P. cylinder} + \frac{\text{Mean pressure in M.P. cylinder}}{\text{Ratio of L.P. to M.P. cylinder area}} + \frac{\text{Mean pressure in H.P. cylinder}}{\text{Ratio of L.P. to H.P. cylinder area}}.$$

The theoretical referred mean pressure may be calculated, assuming that the steam is moderately moist, the curve of expansion being a hyperbola. It depends upon the designed number of expansions and the absolute admission pressure of the steam.

Let Pa = absolute initial pressure.

Pm = absolute theoretical referred mean pressure.

r = total number of expansions.

$\frac{1}{r}$ = cut off, or reciprocal of r.

$$Pm = Pa \frac{1 + \text{hyp. log. } r}{r}.$$

PRESSURE OF STEAM IN CYLINDERS OF COMPOUND AND TRIPLE-EXPANSION ENGINES.

The values of $\frac{1 + \text{Hyp. Log. } r}{r}$ for Various Expansions are given on page 1398.

The initial pressure, Pa, should be taken 5 to 10 lbs. below the absolute boiler pressure to allow for the drop between boilers and engines, and the back pressure, which must be deducted from Pm as found above, should be taken at not less than 4 lbs. per square inch absolute.

Diagram Factor.

Owing to the losses which occur while the steam is expanding in the various cylinders the actual referred mean pressure obtained from indicator diagrams is less than the theoretical referred mean pressure, and consequently the latter must be multiplied by a diagram factor which takes into account the losses due to clearance, condensation, radiation, friction of ports, compression, drop in pressure between the cylinders, and other losses. The value of this factor is obtained by experience, and, when possible, should be derived from engines similar to the one projected, and working under similar conditions. The values for various types of engines are approximately :—

Quadruple-expansion engines	·63 to ·68
Triple-expansion engines, merchant service	·6 to ·65
,, high-speed cross-channel engines	·56 to ·63
Compound engines	·63 to ·70

When cylinders are jacketed the diagram factors may be increased by about 5 per cent.

The power is usually divided equally among the cylinders of an ordinary compound, triple, or quadruple-expansion engine, and if N is the number of cylinders and P the referred mean pressure (i.e. theoretical mean pressure × diagram factor) the mean pressure in the various cylinders of a triple-expansion engine, for example, will be :

$$\text{L.P. cylinder mean pressure} = \frac{P}{N}$$

$$\text{M.P. ,, ,, ,,} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{M.P. cylinder area}}$$

$$\text{H.P. ,, ,, ,,} = \frac{P}{N} \times \frac{\text{L.P. cylinder area}}{\text{H.P. cylinder area}}$$

In the case of four-crank triple-expansion engines the power developed in each L.P. cylinder is usually five-eighths that of the H.P. or M.P. cylinder.

Piston Speed.

The mean piston speed is usually reckoned in feet per minute and is equal to stroke in feet × 2 × revolutions per minute.

The power which may be obtained from a given weight of engine varies almost directly with the piston speed ; the wear and tear of the engine, however, is increased with the higher speeds on account of the increased inertia stresses involved.

Piston speed may be increased either by increasing the stroke and keeping the revolutions constant or by increasing the revolutions, keeping the stroke constant.

By adopting the former method the cost, dimensions, and weight of the engines are increased, whilst by adopting the latter method there is practically no increase in any of the items mentioned. It is evident, therefore, that in cases where weight and space are limited high piston speed must be obtained by high revolutions; these have a limit, however, on account of the stresses due to the inertia of the reciprocating parts.

The piston speed and revolutions of engines fitted in various types of vessels are as shown in the following table :—

TABLE SHOWING PISTON SPEED AND REVOLUTIONS OF RECIPROCATING MACHINERY FOR VARIOUS TYPES OF STEAMSHIPS.

Description.	Number of Cranks.	Piston Speed in Feet per Minute.	Revolutions per Minute.
Large mail steamers	4	800 to 900	75 to 90
	3	600 ,, 750	70 ,, 80
Cargo vessels	4	650 ,, 800	70 ,, 100
	3	550 ,, 650	60 ,, 100
Channel steamers	4	800 ,,1000	170 ,, 200
	3	750 ,, 900	130 ,, 180
Paddle steamers	—	550 ,, 650	45 ,, 55

(Also see remarks about propeller revolutions for geared turbines.)

Calculation of Cylinder Diameters.

In determining the diameter of cylinders required for an engine of a given I.H.P., the type of vessel for which the engine has to be designed to a certain extent determines the piston speed and cylinder ratios, due consideration being given to the boiler pressure, the number of expansions being increased as higher boiler pressures are adopted.

Having decided the piston speed and the mean pressure referred to L.P. cylinder as already described, the area of the L.P. cylinder may be calculated, and from the cylinder ratios decided upon the areas of the remaining cylinders are determined.

Let piston speed = S feet per minute.

referred mean pressure = P lbs. per square inch.

Then

$$\text{Indicated H.P.} = \frac{\text{Area of L.P. cylinder} \times P \times S}{33{,}000}$$

or

$$\text{Area of L.P. cylinder} = \frac{\text{I.H.P.} \times 33{,}000}{P \times S}$$

$$\text{Area of M.P. cylinder} = \text{Area of L.P. cylinder} \times \text{Ratio of } \frac{\text{M.P. cylinder area}}{\text{L.P. cylinder area}}$$

$$\text{Area of H.P. cylinder} = \text{Area of M.P. cylinder} \times \text{Ratio of } \frac{\text{H.P. cylinder area}}{\text{M.P. cylinder area}}$$

Combined Recipro-Turbine Machinery.

In vessels of say under 18 knots the direct coupled turbine installations are not suitable, since the comparatively low rotational speed necessary for an efficient propeller necessitates for an efficient turbine a considerable increase in dimensions and hence increase in weight and cost. In such cases a combination of reciprocating engines and turbines was employed, there being two reciprocating engines to deal with the high-pressure steam and one or two turbines to expand the exhaust steam down to the lowest possible pressure. In the steamer 'Otaki' this system is credited with a saving of about 17 per cent. in the coal consumption; it has also been fitted to the White Star Liners 'Laurentic' and 'Olympic,' the Orient Liner 'Orama,' and other vessels.

In the 'Reina Victoria Eugenia' a four-shaft 'combination' arrangement was adopted, the two inner shafts being driven by reciprocating engines and the two outer shafts by low-pressure turbines. At low powers the reciprocating engines produced about three-quarters of the total power and the turbines one-quarter; at full output the proportions were about two-thirds and one-third respectively. The steam consumption was only about 11 lbs. per h.p. per hour or about 20 per cent. less than that required for quadruple expansion reciprocating machinery.

The WEIR CLOSED FEED System

G. & J. WEIR Ltd. CATHCART, GLASGOW.

F. 1995

The revolutions of the reciprocating engines were about 113 per min., those of the turbines about 480. The sister vessel 'Infanta Isabel de Borbon' had the usual three-shaft combination, the revolutions of the turbines at full power being 276 per min. and of the reciprocating engines 116 per min.

In a three-shaft combination installation with 92 revolutions per min. for the reciprocating engines and 250 for the turbines, the reciprocating portion of the machinery produced 56 per cent. and the turbine portion 44 per cent. of the total full power, but the propulsive effect of the turbine propeller is rather disappointing. This machinery has been displaced by the geared turbine.

TURBINES.*

The development of the steam turbine as a motor for ship propulsion has progressed rapidly in the last decade. In the earlier stages of its adoption, when the turbine was directly coupled to the propeller shafting, the high revolutions necessary to obtain suitable blade speeds for low steam consumption without abnormally increasing the size and weight of the turbines entailed small propellers which were inefficient except for fast vessels, and even in these the turbines were run at an uneconomically low speed in order to improve the propellers.

The introduction of single-reduction gearing between the turbines and propellers enabled advantage to be taken of high-blade speeds and fairly efficient propellers for vessels of over about 16 knots speed, and for all speeds of vessels double-reduction gearing permits the turbine and propeller designers to select the revolutions most suitable for their individual purposes so as to obtain the maximum efficiency of turbine and propeller respectively. The revolutions of the most efficient propeller for a vessel depend on horse-power, speed and form of vessel, and should be worked out in conjunction with experimental results such as those published by Taylor and Froude, but the following method gives very satisfactory results for turbines, gearing and propellers :—

R = revolutions of propeller per minute.
SHP = shaft horse-power of each shaft.
V = speed of vessel in knots on trial.

$$R = C\sqrt{\frac{V^3}{SHP}}.$$

Note.—In 3 and 4 the speeds of the turbine vessels are higher than the corresponding vessels with reciprocating machinery. If the speeds had been equal the saving would have been greater than as recorded.

Arrangement of Turbines.

The turbine machinery may be arranged to drive one, two, three, or four lines of shafting as shown by figs. 8 and 9.

In mercantile vessels with direct-coupled turbines three lines were adopted, the centre shaft being driven by a high-pressure turbine, the steam from which was exhausted into two low-pressure turbines driving the two wing shafts. Astern turbines were incorporated in the aft end of the l.p. ahead turbine casings, and during normal ahead running revolved idly in vacuum. A separate high-pressure steam connection was fitted to each astern turbine, and also to each low-pressure ahead turbine. When manœuvring in and out of harbour the wing turbines only were employed, each turbine being controlled independently of the other.

In some installations of turbine machinery in large mail steamers four shafts were employed and the steam expanded in series through an h.p. and i.p., and two l.p. turbines. This arrangement, while introducing more complication in the intermediate receiver connections, enabled a higher efficiency to be secured than in the usual three- or four-shaft arrangement.

In torpedo boats and torpedo destroyers the practice was to adopt a three-shaft arrangement similar to that described above. Most of the vessels fitted in this manner were provided with h.p. and i.p. cruising turbines in order to maintain economy at low speeds, and these turbines were cut out of action as the power increased.

FIG. 9.

More recent experience has shown that there are several objections to this arrangement, and in particular to the weight of these cruising turbines, and as a consequence the 'independent type of turbine has been adopted. Where direct turbines are still fitted the installation usually consists of twin screws driven by turbines of the Parsons' or Brown-Curtis types, having the astern turbine incorporated in the same casing as the ahead turbine.

In light cruisers the machinery usually consists of two independent sets of single-geared turbines fitted in compartments separated by longitudinal or transverse bulkheads, and so arranged that in the event of damage to the one set the other will be available for use. Geared cruising turbines have also been fitted for low power.

In battle cruisers and battleships the turbine installation usually consists of two complete sets arranged in two or three compartments divided by longitudinal bulkheads. In the latter arrangement the h.p. turbines are placed in the wing compartments and the two l.p. turbines in a common central compartment, while in the former the bulkhead is placed between the l.p. turbines.

On each outer shaft there is a h.p. ahead turbine forward and an independent h.p. astern turbine aft. On each inner shaft there is a l.p. ahead turbine, having incorporated with it in the same casing a l.p. astern turbine. All four shafts are thus in use for manœuvring either ahead or astern, the steam exhausting from the h.p. ahead or astern to the l.p. ahead or astern turbine, as the case may be, and from thence to the condenser.

With geared turbines each shaft is driven by an independent unit consisting of one h.p. ahead turbine and one l.p. ahead turbine with an astern turbine incorporated in the same casing with the latter.

With double-reduction gearing the high pressure unit is sometimes divided into an h.p. and i.p. in separate casings so as to reduce the length of rotor between bearings and enable higher revolutions to be run without 'whipping.' Where manœuvring requires greater astern power than can be transmitted by one pinion an h.p. astern turbine is fitted at the end of the h.p. or i.p. ahead turbine separately or in the same casing with a diaphragm to prevent astern steam entering the l.p. ahead turbine and vice versa. This arrangement is also preferred with superheated steam to minimise the change of temperature in the astern turbine when reversing.

For marine propulsion the two principal types which have been adopted are the Parsons and the Brown-Curtis. In the merchant service turbines of both types with single-reduction gear have been extensively fitted in high-speed steamers for cross-channel mail and passenger service, and the more recent development of double-reduction geared turbines is now being extensively adopted in vessels where the speed is lower, and on that account the propeller revolutions of single-reduction gear are not suitable.

The direct-coupled turbine is rarely fitted now owing to the many advantages and greater economy of the geared installations.

For naval service, so far as this country is concerned, either Parsons' turbines or Brown-Curtis turbines with single-reduction gearing are now being fitted in all battleships, cruisers, or torpedo-boat destroyers. The Brown-Curtis, being of the impulse type, and in consequence not having of necessity, fine blade tip clearances as in the Parsons' reaction type, is able to make use of superheated steam with less risk of blade stripping due to distortion of the turbine casing under high temperature. In practice it is found that an economy of about 1 per cent. in steam consumption is obtained for each 10° Fah. of superheat.

In a number of recent installations of Parsons' turbines an impulse wheel has been fitted at the inlet end of both the ahead and astern turbines. The steam supply in these cases is admitted as in the case of Brown-Curtis turbines, through a group of valves on the turbine end, to the nozzles which direct the steam to the impulse wheel, each valve controlling the steam supply to a section of nozzles, and each section having from three to twelve nozzles. The section of nozzles through which steam is admitted is adjusted to suit the power required. At full power all the valves will be open, at extreme low power only one may be open. The steam pressure in the nozzle valve chest is maintained at a maximum, and the reduction in pressure takes place in doing useful work passing through the first set of nozzles, thereby economy at low powers is improved as compared with turbines having only the usual Parsons' reaction blading where the reduction in steam pressure at low powers takes place at the regulating valve without doing useful work. This arrangement dispenses with the very short first-stage blades, shortens the turbine, and reduces the pressure on the gland and end thrust of rotor.

Parsons' Geared Turbines.

A set of Parsons' turbines of 3,000 s.h.p. with double-reduction gearing is shown in figs. 10, 11, and 12.

There is one h.p. and one i.p. ahead turbine each developing approximately one quarter of the total power and driving separate pinions geared to one first reduction gear-wheel. The l.p. turbine develops one half power and is geared to the first reduction gear-wheel on the opposite side of the main wheel. An h.p. astern turbine is incorporated in the same casing as the i.p. ahead turbine but separated from it by a diaphragm and the l.p. astern turbine is also incorporated with the l.p. ahead.

Owing to the high revolutions at which turbines can run with double-reduction gearing, the desired blade speed can be obtained with a small diameter of rotor and consequently the end thrust due to steam pressure is low enough to be taken entirely on a thrust block of the pivoted

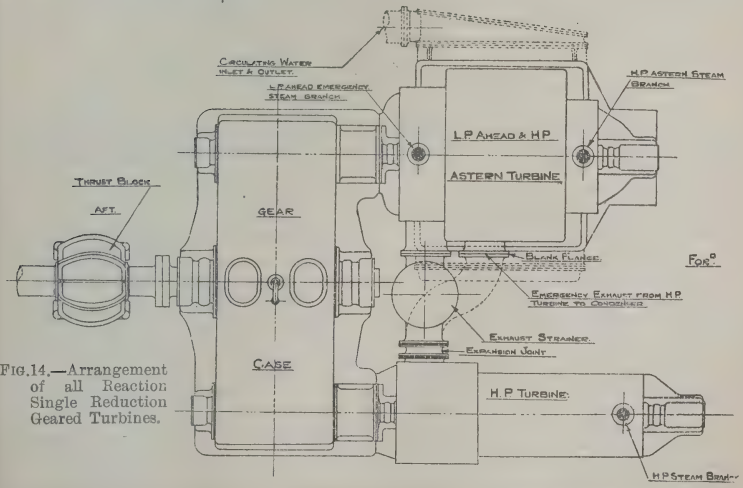

FIG. 14.—Arrangement of all Reaction Single Reduction Geared Turbines.

type, thus dispensing with dummies and the leakage caused by them. In addition, the blade heights to pass the steam are greater than in large rotors of equal power, but as the clearance is not increased the percentage loss due to leakage past the tips is much less in the geared turbine. As a result of these and other advantages the steam consumption is much reduced from that required for direct-coupled turbines, and if superheat is used, say 200° F., the consumption for turbines only, exhausting to 28 inches vacuum, will be from 8 to 8½ lbs. per hour.

Figs. 11 and 12 show the arrangement of the double-reduction gearing for this set of turbines.

Fig. 13 shows an alternative arrangement with two turbines instead of three. There is one h.p. and one l.p. ahead turbine with a corresponding astern turbine in each casing.

This arrangement is simpler, but the consumption is slightly higher than in the three-turbine arrangement.

Fig. 14 shows a set of single-reduction geared turbines with one h.p. and one l.p. ahead turbine and an h.p. astern turbine incorporated with the latter.

This arrangement is suitable for low powers or where the propellers can be run at higher revolutions as in channel or shallow-draught steamers.

Brown-Curtis Turbines.

Figs. 15, 16, and 17 show a set of Brown-Curtis turbines for a double-reduction geared installation for one shaft of a liner.

The h.p. turbine is sometimes designed with three wheels each with two rows of buckets or moving blades, and at others with one two-bucket wheel and several single-bucket wheels. The m.p. and l.p. ahead turbines have single bucket wheels, and in the astern turbines there are usually two three-bucket wheels, or if a greater proportion of astern power is required, one three-bucket and two two-bucket wheels.

The turbines are arranged with the h.p. and m.p. in line and coupled together, driving one pinion of the gearing and the l.p. turbine driving a separate pinion. This arrangement enables the designer to choose the revolutions most suitable for each turbine.

The astern turbines are arranged with the first or h.p. stage in the low pressure end of the m.p. ahead turbine casing, but separated from it by a diaphragm, and the l.p. astern in the corresponding l.p. ahead casing exhausting through the common pipe to the condenser. The astern drive is thus distributed over both pinions, and especially with superheated steam the change in the casing temperature of the first stage when astern steam is turned on is not so great.

The casings and diaphragms are of cast iron, except where superheated steam is used, when the casing of the h.p. is of cast steel and the diaphragms of special bronze.

The rotors and wheels are of mild steel and specially designed to avoid ' whipping ' and to withstand the stresses caused by the high speed of rotation. The blades or buckets are of special bronze capable of maintaining its strength at high temperatures, and the nozzles are formed of steel plates embedded in the diaphragms during casting. The rotors pass through glands at each end of the casing, which are packed with carbon rings to prevent the egress of steam at the high pressure or inlet of air at the low pressure stages.

The end thrust of the rotor is small and is taken up by a thrust block, usually of the Michell type.

The Ljungström Turbine.

(The British Ljungström Marine Turbine Co. Ltd.)

In the Ljungström reaction turbine special attention has been given to the effect of hot steam on its components, and arrangements have been made so as to avoid any unfavourable influence of varying steam pressure and steam temperature on the adjustment of the different parts. The expansion and contraction of the material may take place without altering either the centring and balancing of revolving parts or the clearance between revolving and stationary parts ; consequently the working safety of the turbine is insured both at high and at low temperatures, so that the system can be applied in conjunction with the highest steam temperatures and steam pressures that are attainable with existing types of boilers and superheaters.

The turbine consists of a number of blade rings concentrically arranged and fixed on two turbine discs. The live steam enters at the centre of the turbine inside of the innermost blade ring, and from thence passes through the blade rings outwards in a *radial* direction. The blade rings in one disc run between the blade rings in the other. The two discs run with the same number of revolutions but in opposite directions. The blades in one disc act as guide blades for directing the steam jets blowing against the blades in the other disc. As a result of this arrangement of moving guide blades, the system enables the extraction of mechanical work from the steam with only one-fourth the number of blade rings otherwise necessary. Partly for this reason, and partly owing to other constructive features, the turbine requires considerably less space than turbines built with stationary guide blades. In the system of double rotation, introduced by Messrs. Ljungström, the guide blade rings are similar in design to the blade rings, and the two turbine discs are practically identical one with the other. The live steam enters at the centre of each turbine disc inside of the innermost blade ring through a number of holes in the hub of the disc which is specially shaped. An important point is the slanting-off angle at the ends of the blades, which is kept within a certain limit. The connections between the ring sections are made by strengthening rings which also are attached to the outer edges of the blade rings, and serve to take up the centrifugal stresses acting on the blade system.

Aggregate Equivalent in Indicated Horse Power,

118,000.

THE BRITISH LJUNGSTROM MARINE TURBINE CO., LIMITED,

195 STRAND, LONDON, W.C. 2.

F. 2007

A characteristic feature of the Ljungström turbine is the design and execution of the blades and blade rings. A turbine of 1,000 k.w. has about 40 blade rings.

The turbine blades are retained in their positions by means of thin sheet-iron strips in which are punched holes of the same cross section as the blades and at a distance corresponding to the pitch or spacing of the blades. The strips are applied in their places simultaneously with the assembling of the blades and welding discs, the angles of the blades being thus properly adjusted, and the blades prevented from being wrung out of place during the welding operation. On the completion of the welding, the sheet-iron strips are cut away and the welding discs turned off; the turbine blades are thus practically bound together into a firm, rigid system. The blade rings are inserted in corresponding grooves in the turbine disc and are tightly secured there by means of the caulking strips, so that they possess sufficient rigidity to exclude all risk of their changing their circular shape. An 'expansion ring' transmits the heat between the turbine wheel and the blade ring, and prevents such increase of temperature as would produce detrimental stresses in the blades, and influence the ring diameters and clearances.

Fig. 18 is a longitudinal section of a 1,000 k.w. turbine with turbine wheels and other internal parts. The outer blade rings are of larger cross sections than the inner rings in order to resist the higher stresses produced in the former by the centrifugal force. The blade rings are all made with blades in one uninterrupted length.

Due to the very powerful securing produced by the welding and to the methods of manufacture, the blading system employed in the Ljungström steam turbine affords a very high degree of safety as regards strength and resistance to distortion, both during the erecting of the turbine and after it has been put in regular service.

The part of the shaft situated within the turbine casing, and subjected to heating by the steam, is made hollow, the object of this arrangement being to accelerate the heating so as to make the fluctuations of temperature in shaft and hub follow one another, and thus avoid play between the hub and the shaft.

The axial balancing, or counteracting of the steam pressure axially on the inner side of the turbine wheel, is effected by the aid of two dummy discs provided with a number of concentric labyrinth packings, one of the discs being located at the back of the turbine wheel and the other being attached to the stationary steam chests or 'side discs' of the turbine. Steam is admitted between these discs from the centre of the turbine. In the inner labyrinth packings, accordingly, the full steam pressure prevails, while in the remainder of the packings the pressure gradually decreases in proportion to the distance of the packing from the centre, until it finally drops to that of the condenser outside of the outermost labyrinth packing. The labyrinth packings are divided into one inner and one outer section. Any axial motion of the rotating wheel affects the clearances in these two sections differently, a movement in one direction increasing the passages in the outer section but not in the inner one, while a shifting in the other direction enlarges the inner passages but not the outer ones. By this means the entrance and discharge of the steam, and at the same time also the steam pressure on the labyrinth discs, is varied in such a manner that the labyrinth disc fixed on the turbine wheel will *quite automatically* occupy the axial position required for making the steam pressure on the entire dummy disc fixed to the turbine wheel exactly equal to the steam pressure on that side of the turbine disc to which the blade rings are fastened. As this position is very distinct, and practically remains constant at all steam pressures, no thrust bearing is required in the Ljungström turbine for fixing the axial position of the rotors.

The packings around the shafts for excluding the atmosphere from the interior of the turbine are composed of labyrinth rings. All these rings are of the same thickness. When the steam passes through, therefore, they will all be heated equally thickly, and as a consequence the clearances between the ribs will be the same in both hot and cold state. Accordingly, the clearances will be comparatively small, and the steam quantity transmitted per unit of time will be unimportant. The leaking steam is discharged by special pipes from the shaft packings to a feed-water heater for the boiler, the steam being thus utilised, so that practically the flow of steam through the packing boxes involves no loss of heat nor increased fuel consumption.

Great radiation of heat is avoided in the turbine, and as a result the engine-room can be kept almost at ordinary room temperature.

Speed regulation is effected by a centrifugal governor mounted on the same vertical shaft as the oil pump.

Owing to its construction, the turbine is specially adapted for the full utilisation of *high steam temperatures* and *high pressures*, and mention may be made of the fact that a turbine generator of the system designed for a normal output of 5,000 k.w. will at a steam pressure of 300 lbs. per square inch, a steam temperature of 750° Fahr., and an absolute back pressure in the steam exhaust of 1 inch of mercury, consume about 6·5 lbs. of steam per b.h.p. an hour.

LJUNGSTRÖM STEAM TURBINE.

An installation of the Ljungström turbine driving the propeller by means of electrical transmission and mechanical gearing was fitted on the single-screw steamer, 'Wulsty Castle.'

In the six hours dock trial the power delivered to the propeller shaft was 1,117 k.w. or 1,496 s.h.p. The power generated by the main turbine sets was 1,281 k.w., and rating the steam consumption on the shop trial at 12·72 lbs. per k.w. the steam consumption is 10·9 lbs. per s.h.p. per hour for all propelling purposes, and including steering gear and electric light, but excluding bilge and sanitary pumps, heating and cooking and evaporator for make-up feed. This consumption is based on a steam pressure of 181 lbs. at stop valve superheated 247° F. and a vacuum of $\frac{28 \cdot 74}{30}$ ins. In smaller sets the consumption will be slightly higher, but with increased power it will be decreased to 10½ lbs.

The weight of the installation is approximately 20 per cent. less than reciprocating machinery of corresponding power, and is approximately equal to a modern geared turbine installation.

The space occupied is slightly less than with turbines, and if the motors are arranged aft and the boilers and generators amidships a gain of 5 per cent. in cargo capacity can be obtained.

Reduction Gear for Propulsion.*

The rapid development of the turbine during recent years has led the way to the adoption of indirect transmission between the turbine and propeller in order to utilise to the fullest extent the economy to be derived from running the turbines at high relative speeds and the propellers at reduced speed, as compared with direct-driven turbines. The importance of saving a few ounces of coal per h.p. per hour, or one or two per cent. in propeller efficiency in modern large power ships, either naval or mercantile, is obvious. In the former the radius of action with available fuel supply is increased, and in the latter a substantial reduction is made in the annual fuel bill.

The two systems which so far have proved successful and may be now considered beyond the experimental stage are :—

(*a*) Parsons' mechanical gearing.
(*b*) Fottinger's hydraulic transformers.

Each system will have certain fields of application where its particular advantages render its use desirable. The relative advantages and disadvantages of the two systems are briefly as follows :—

MECHANICAL GEARING.

Advantages.

(1) Reduction in weight from 10 to 15 per cent. compared with direct-driven turbines.
(2) Reduced coal consumption of 8 to 10 per cent. on same basis.
(3) High mechanical efficiency of gearing, approximately 98 per cent.
(4) Large speed reduction ratio permissible, as high as 30 : 1.
(5) Simplicity of mechanism.

Disadvantages.

(1) Separate turbines for astern running necessary, and having only 60 to 70 per cent. of ahead power.
(2) Noise in engine room. This, however, has been minimised to a great extent by recent improvements in gear cutting.
(3) Wear on teeth. Experience has shown, however, that this is very slight under normal conditions of working.

HYDRAULIC TRANSFORMERS.

Advantages.

(1) Astern turbines dispensed with and about 85 per cent. of ahead power available for astern running with reversible transformer.
(2) Absence of noise.
(3) Relatively no wear.
(4) Practically no limitation in power to be transmitted, the driving turbine being the limiting power.
(5) Increased manœuvring power due to greater astern power and practically instantaneous reversal.
(6) Increased economy and saving in weight as compared with direct-driven turbines.

Disadvantages.

(1) Lower efficiency, about 89 per cent., as compared with mechanical gearing.
(2) Limitation in speed reduction ratio, the maximum being about 6 : 1.
(3) More complicated mechanism.

* See also pages 888, 1581.

Parsons' Gearing.*

This gearing consists of a large gear wheel with double helical teeth about $\frac{7}{16}$ in. pitch, coupled to the propeller shaft, and driven by either one or two pinions, coupled to the turbines. The connection between the pinion spindle and turbine spindle is by means of a claw coupling, which under running conditions permits of any slight lateral movement due to the expansion of the turbine rotor under steam being taken up. The gearing is completely enclosed in a cast-iron casing, which also forms the support for the bearings of the gear wheel shaft and pinion spindles. Jets of lubricating oil from the forced lubrication system impinge on the teeth at the point of contact of the pinion and wheel, and the spindles and shaft bearings are also connected to the forced lubrication system. The double helical gear ensures the transmission of pressure from one tooth to another without shock or vibration, and as the teeth are of true involute form complete line contact exists during the time they are in mesh. The pinions are made of nickel steel, having a tensile strength of about 40 tons per sq. in. with 25 per cent. elongation, and the gear wheels of carbon steel having a tensile strength of about 32 tons per sq. in. with 26 per cent. elongation. Absolute accuracy in cutting the gearing is essential, and any corrective process or hand work after the gear is cut is inadmissible. The machines employed are the result of extensive and costly experiments, both in design and construction. In the double reduction gears the pitch of the teeth in the intermediate pinion and large wheel is about 1 inch.

Marine Reduction Gears.

(*The Power Plant Co. Ltd., West Drayton.*)

According to the ratio of reduction of the turbine speed to the propeller speed, single or double reduction gears are employed; for instance, single reduction gears are quite practicable and a large number of vessels are running with a reduction up to 20 to 1.

This last reduction has recently been effected for two Dutch Royal Mail steamers by the above company.

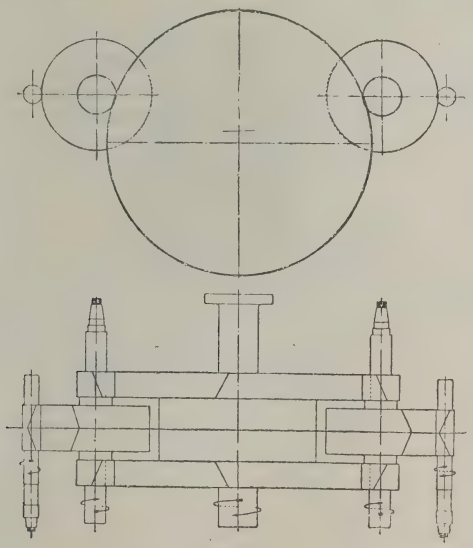

Fig. 19.

Where, however, a power exists about 4,000 h.p., and for any reduction from 20 to 1, the low speed wheel becomes too large for practical purposes; recourse must then be made to double reduction gears.

* See also page 1581.

PARSONS' GEARING.

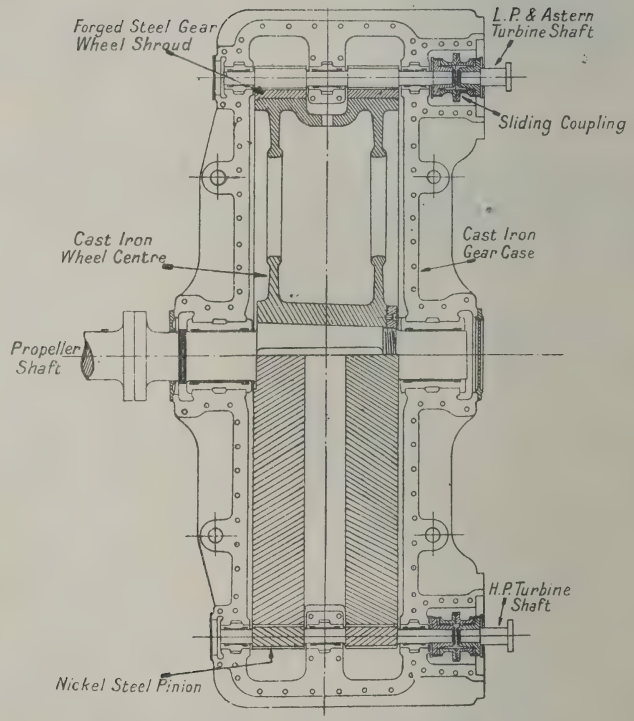

FIG. 20.—Plan with top casing removed.

Up to the present time double reduction gears have been supplied for a total reduction ratio of 70 to 1, but there is no reason why 100 to 1 could not be effected just as easily. The general arrangement of a typical double reduction set is shown in figs. 12, 19, and 20.

The essential feature of these gears is the use of two independent high-speed gear trains, each driven from one turbine, and a second reduction with a common wheel for the drive from both turbines, the low-speed train being arranged symmetrically relative to the high-speed trains. The advantages of the arrangement are that the power from each turbine is transmitted to the final wheel independently, whereby an even distribution of pressure on the teeth of same can be relied upon. The housing of all the gear trains in one casing effects a considerable saving in space fore and aft, where space is of most value, and reduces the gear weight without sacrifice of strength and rigidity. The gear wheels and bearings forming an arrangement symmetrical at right angles to the shafts, the deflections caused by the load are reduced to a minimum. The use of a single gear case simplifies the oiling arrangements and greatly simplifies the construction of the gear seatings in the vessel. The reduction of the number of bearings required to a minimum improves the overall efficiency and simplifies supervision.

With regard to efficiency, single reductions will go up to 98½ per cent., and double reductions up to 97 per cent.

The first steamer to be equipped with reduction gearing (made by *The Power Plant Co., Ltd.*) was the 'Vespasian,' a single-screw steamer of 2,150 tons. This gearing, as tested by Sir Charles Parsons, gave 98½ per cent. efficiency, and a fuel economy of about 13 per cent. was obtained. The cross-channel steamers, 'Normannia' and 'Hantonia' (with gearing made by The Parsons Marine Turbine Co., Ltd.), with a gear ratio of about 7 : 1, consumed only 43 tons of coal per trip, as compared with 70 tons per trip required by direct-driven turbine vessels of similar dimensions and speed, engaged in the same service.

Mechanical gearing for turbines has developed enormously in recent years, and is now being used extensively for ships of all powers and classes. Double reduction gearing is now being introduced, making it possible to run the turbines twenty or thirty times as fast as the propellers with a consequent gain in overall efficiency.

FOTTINGER'S HYDRAULIC TRANSFORMER.

The hydraulic transformer (fig. 21) consists of two centrifugal pump wheels, A, keyed to the primary shaft, which is driven by the turbine. On the secondary, or propeller, shaft three impulse reaction water turbine wheels are mounted, the after two, B and C, for ahead driving, and the forward one, D, for astern driving. The wheels for ahead driving absorb the energy

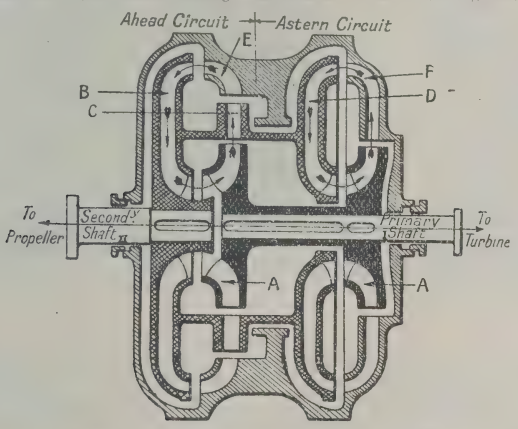

FIG. 21.—Fottinger's Hydraulic Transmitter.

delivered to them from the water discharged by the pump wheel in two stages, the primary stage, C, being connected to the astern water turbine wheel, D. Having given up part of its energy in the primary ahead stage, the water moves in continuous compact flow through guide vanes, E, in the casing to the second stage ahead wheel, B, which absorbs the remaining energy in the water. The discharge from the second stage wheel flows back to the beginning of the circuit in the pump wheel, giving up to it the remaining energy of discharge. In the same way the astern driving wheel, D, receives its energy from the water discharged by the forward pump wheel guided into it by the stationary vanes, F, in the casing.

The vanes in the ahead and astern turbine wheels are spaced in opposite directions to each other, thereby giving the reversed motion.

A change valve, controlled by a lever, admits the water from either pump wheel to the corresponding turbine wheel to give the desired direction of rotation.

The wheels and vanes of the transformer are made of bronze, and the casings of cast iron.

The efficiency of the transformer decreases with an increase of speed reduction ratio on account of the higher velocities causing increased fluid friction.

Fresh water is used in the system, and on account of the work done upon it by friction during its passage through the vanes heat is generated. Part of this heat, which would otherwise be lost, is saved by using the water for feeding the boilers, the quantity of water in the transformer system being maintained by filling up with colder water from the air-pump discharge.

COCKBURNS' GEARED TURBINE EMERGENCY SHUT-OFF AND POSITIVE CONTROL MANŒUVRING GEAR FOR SATURATED AND SUPERHEATED STEAM.

In this arrangement, fig. 22, the manœuvring valves are of the single handwheel type. Rotation in one direction from mid position opens the ahead valve, and by the opposite direction the astern valve is opened. With the arrangement shown it is impossible to have the two valves open at the same time.

The emergency valves are incorporated in the bulkhead valves and are steam operated by an automatic governor on the turbine rotors. They shut off steam completely, which, in the case of a broken shaft, prevents the turbine from being spun, as would occur with the ordinary butterfly throttle, through the quantity of steam that passes the latter valve when it is closed

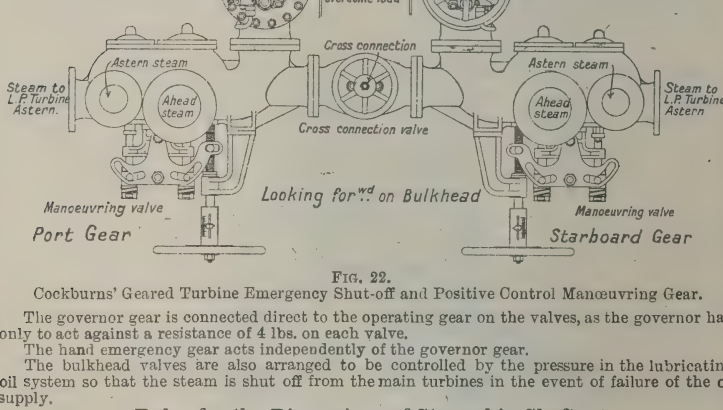

FIG. 22.
Cockburns' Geared Turbine Emergency Shut-off and Positive Control Manœuvring Gear.

The governor gear is connected direct to the operating gear on the valves, as the governor has only to act against a resistance of 4 lbs. on each valve.

The hand emergency gear acts independently of the governor gear.

The bulkhead valves are also arranged to be controlled by the pressure in the lubricating oil system so that the steam is shut off from the main turbines in the event of failure of the oil supply.

Rules for the Dimensions of Steamship Shafts.

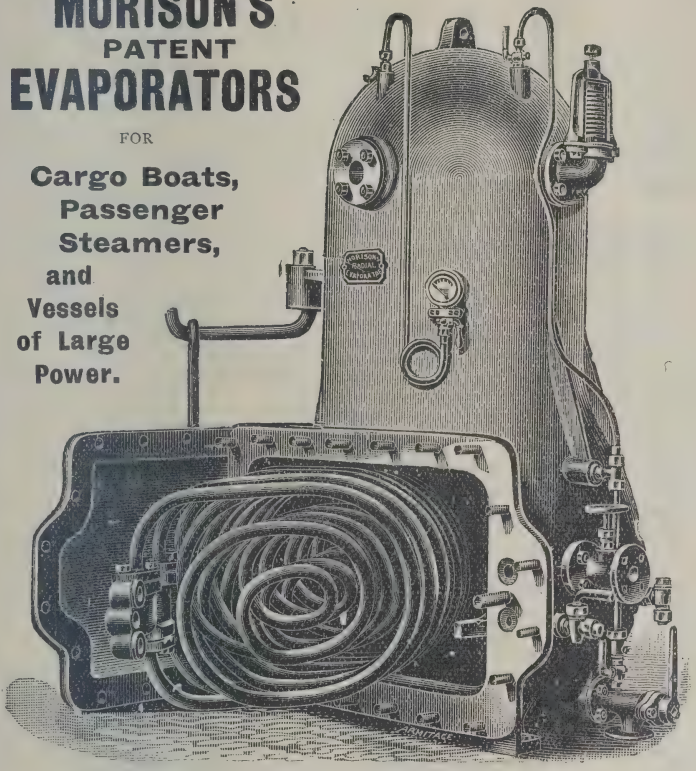
See pages 923–926.

BOILERS.

In determining the principal dimensions of a boiler, or boiler installation, consideration must in the first instance be given to the system of draught employed, whether it is to be forced or natural draught, and since the quantity of steam which a boiler is capable of generating depends on the weight of coal consumed, it follows that the dimension which must first be decided is that of the grate area, the heating surface being proportioned from the grate area depending upon the type of boiler employed. The efficiency of the boiler largely depends on the rate of evaporation per square foot of heating surface, which should be kept as low as possible.

Coal Combustion.

The weight of coal which can be burnt per square foot of grate area per hour under varying conditions of draught is approximately :—



Natural draught	16 to 20 lbs.	Forced draught 2 ins. air pressure	45 to 50 lbs.
Forced draught ½ in. air pressure	20 to 25 lbs.	,, 3 ins. ,,	55 to 60 lbs.
,, 1 in. ,,	30 to 35 lbs.	,, 4 ins. ,,	60 to 70 lbs.

With cylindrical boilers and water-tube boilers for cruisers and battleships the maximum combustion per square foot of grate rarely exceeds 40 lbs. when working with closed stokeholds and 30 lbs. under Howden's system of forced draught; with the express type of water-tube boiler as fitted in torpedo boats and torpedo boat destroyers the combustion varies from 60 to 80 lbs. of coal per square foot of grate.

Boiler Surfaces.

The heating surface and grate area for a required boiler is determined by the method of draught employed, whether natural or forced, the kind of coal used on account of the difference in calorific values of different varieties of coal, and the type of engine to which steam is being supplied, quadruple expansion engines, for instance, requiring less boiler surface than compound engines on account of the greater economy in steam consumption per I.H.P. of the former.

Economy in coal consumption is attained by using natural draught, which for this reason is generally employed in cargo vessels; where, however, considerations of weight and space are of importance, as in naval machinery and fast passenger vessels, forced draught to a greater or less degree is invariably employed, in which case the coal consumption at maximum power is greater than when natural draught is used.

The following table gives the average I.H.P. developed per square foot of grate, and the ratio of heating surface to grate area of different types of boilers and average consumptions of coal for various types of engines.

TABLE SHOWING PARTICULARS OF BOILERS OF VARIOUS TYPES OF STEAMSHIPS.

Draught.

The two systems of forced draught most commonly adopted are closed stokeholds and Howden's system (page 1793) with closed ashpits. In the former an air pressure is maintained in the boiler rooms by forcing in air with fans, all openings in the boiler room are closed down with doors, and air locks fitted for access purposes. With Howden's system the boiler room is open, no air locks being required, and the air is forced by fans over the surface of a nest of tubes situated in the uptakes, through which the products of combustion pass on the way to the funnel. The air is raised to a temperature of about 250°F. by contact with the hot tubes, and passes through passages on either side of the uptake into a reservoir surrounding the furnace fronts, from which reservoir the air is admitted to the furnaces by valves in the furnace fronts, at the sides and the top, to the ashpit and above the fire respectively. Valves are fitted to control the admission of air above and below the fires : these must be shut before opening the furnace door to fire the boiler, otherwise the flame would be blown out into the stokehold. The proper use of the top valve prevents excessive smoke without reducing the boiler efficiency or the amount of evaporation per lb. of coal. Special strips of twisted steel ribbon called ' retarders ' are placed in each boiler tube, causing the hot gases traversing the tubes to take a spiral course and be retained longer in contact with the tubes than they otherwise would.

The latest type of furnace fronts has the side valves controlled by one handle, and is also fitted with a safety guard, so that the furnace doors can only be opened when the air valves are shut, thereby preventing the possibility of any flame coming back through furnace door when it is opened.

On account of the abstraction by the air of what would otherwise be waste heat passing up the funnel, a considerable measure of increased boiler efficiency is attained compared with the closed stokehold system, and the uniform condition of furnace temperatures which Howden's system ensures tends to reduce the wear and tear of the boiler.

A more uniform efficiency of furnace can be maintained with forced draught and it may be readily controlled to suit any desired rate of combustion, being quite independent in this respect of prevailing atmospheric conditions.

Furnaces and Firebars.

If forced draught is employed it is not desirable to have firebars longer than 6 ft. on account of the tendency for large quantities of air to pass through the firebars if the fire should burn into holes. With Howden's system 5 ft. 6 ins. is the maximum length of firebar generally adopted. In naval practice with modern water-tube boilers working at full power under a moderate forced draught of 0·5 in. to 0·75 in. of air pressure, grate bars having a maximum length of 7 ft. are frequently employed ; this, however, requires skilful firing, and extreme care to ensure the boiler efficiency being maintained at a maximum. For natural draught the length of grate bar should not exceed 6 ft. 6 ins., but increased boiler efficiency will be attained by using shorter bars, on account of the greater control over the fires. The diameter of furnaces for cylindrical boilers (figs. 23 and 24) should not be less than 32 ins. nor greater than 48 ins., and the number of furnaces which can be fitted in boilers of the following dimensions is :—

Boilers up to 9 ft. 0 ins. diameter	1 furnace
„ „ „ 13 ft. 0 ins. „	2 furnaces
„ „ „ 15 ft. 6 ins. „	3 furnaces
„ exceeding 15 ft. 6 ins. „	4 furnaces

The grate area of a cylindrical boiler is equal to :—Length of firebars × mean diameter of furnace × number of furnaces.

Length of Cylindrical Boilers.

The length of a cylindrical boiler is determined by the length of combustion chamber tubes or the furnace which is practically the same length as the tubes, the length of the combustion chamber and the water spaces at their backs. The combustion chamber measured horizontally should be as long as possible and usually is about 30 ins. in single-ended boilers and from 50 to 57 ins. in double-ended boilers. The water space between the back of the combustion chamber and the back end-plate of the boiler should be from 5 to 7 ins. at the bottom and wider at the top, the taper being about $\frac{1}{2}$ in. per foot on the combustion chamber back.

Heating Surface.

The heating surface of cylindrical boilers consists of the external surface of the tubes, the length being measured between the tube plates, the surface of the furnaces above the firebar level, and the surface of the combustion chambers. The surface of the front tube plate on the boiler end, although in contact with the hot gases, is not usually reckoned as effective heating surface, and should not be included in the total heating surface of the boiler. The heating surface of a water-tube boiler is the total external surface of the tubes in contact with the fire and hot gases.

CYLINDRICAL MARINE BOILER.

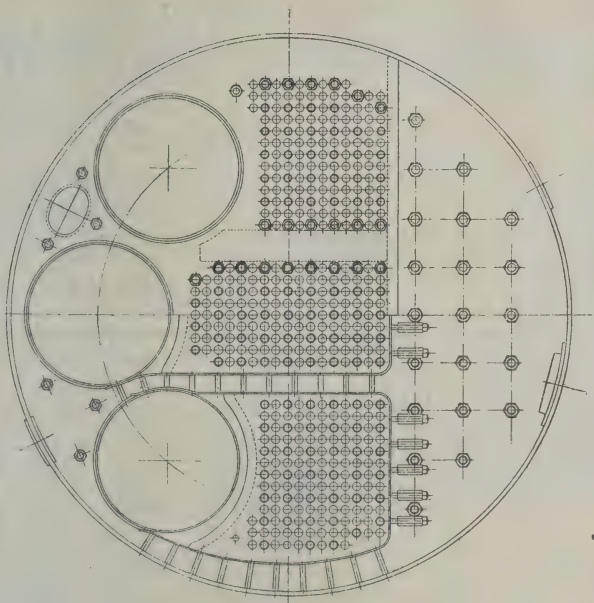

FIG. 24.

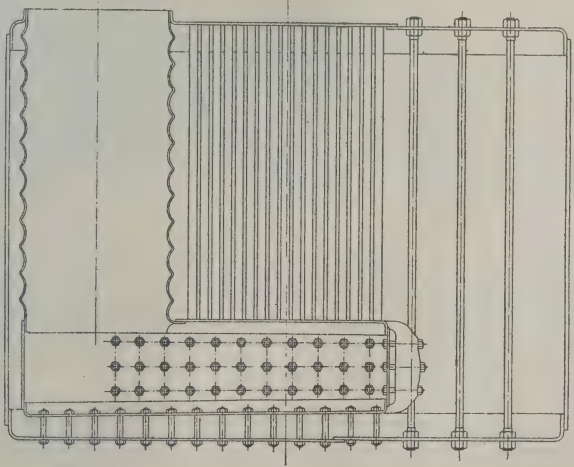

FIG. 23.

Diameter of Tubes for Cylindrical Boilers.

In forced-draught boilers the combustion chamber tubes are generally $2\frac{1}{2}$ or $2\frac{3}{4}$ ins. diameter, and in natural-draught boilers the diameter is 3 ins. to $3\frac{1}{2}$ ins., the increased sectional area being necessary to reduce the resistance to flow of the products of combustion.

Thickness of Cylindrical Boiler Shells.

The shell plates of cylindrical boilers must be of the following thickness to satisfy the requirements of the revised rules of the Board of Trade, Lloyds, British Corporation, and Bureau Veritas.

The thicknesses shown assume the steel to have a minimum ultimate tensile strength of 28 tons per sq. in., and the longitudinal joint to have double butt straps with an efficiency of riveting equal to 84 per cent.

WATER-TUBE BOILERS.

Water-tube boilers are divided into two distinct classes, viz. :—Large-tube boilers as fitted in cruisers and battleships and to a limited extent in merchant vessels, and small-tube boilers as fitted in torpedo boats, torpedo boat destroyers, and launches.

The principal advantages of water-tube boilers as compared with cylindrical boilers are :—

(1) Rapidity with which steam can be raised.

(2) Capability to endure forcing to a great extent.

(3) Reduced weight.

(4) Reduced space occupied.

The large-tube boilers now adopted in the British Navy are of the Babcock & Wilcox type (figs. 25, 26) and the Yarrow type, both of which have straight tubes, the former $1\frac{1}{16}$ in. diameter and the latter $1\frac{3}{8}$ in. diameter. The tubes in the Babcock & Wilcox boiler are expanded into front and rear headers, sinuous in form and constructed of forged steel. Opposite each tube in the headers handholes are fitted, giving access for expanding, cleaning and renewal when necessary. The front headers are connected at the top by short tube nipples to the steam drum, and by similar nipples at the bottom to the mud drum. Return tubes about 4 ins. diameter connect the rear headers to the steam space in the steam drum.

The Yarrow large-tube boiler is a development of the Yarrow express type, and is very similar in design and construction. It consists essentially of a central upper steam drum, and two smaller water drums, the latter being situated about the level of the firebars. The generating tubes are expanded into the steam drum and each of the water drums, a manhole being fitted in the front end of each drum for access when expanding or cleaning of the tubes is necessary.

Water-Tube Boilers—Express Type.

The small tube or express type of water-tube boilers principally adopted in British naval practice are the Yarrow, the White Foster, and the Thornycroft type (figs. 27, 28). The tubes of all these boilers are from 1 in. to 1½ in. external diameter, and generally the two rows next the fire are at least ⅛ in. larger in diameter and one wire gauge thicker.

The White Foster boiler has a similar arrangement of drums, casings, and furnace to that of the Yarrow type. The tubes, however, are bent in such a way that any one can be withdrawn and received through the manholes in the upper steam drum when required.

The modern Thornycroft boilers have one upper steam drum and two lower water drums, and are suitable for burning oil and coal, separately or combined.

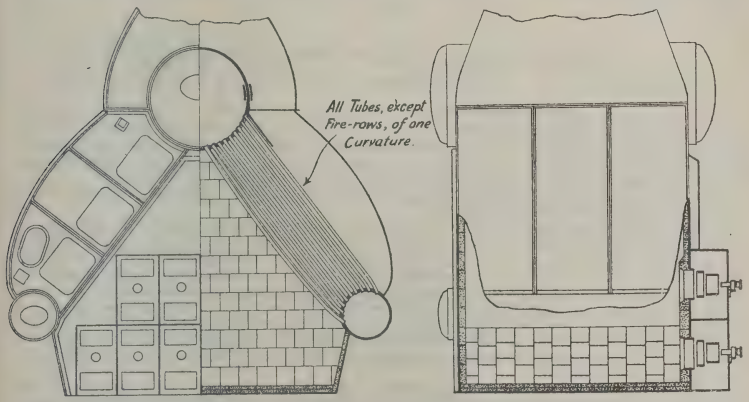

FIG. 27. FIG. 28.

The Thornycroft Boiler.
(Oil Fuel Burning.)

The tubes are straight except for a slight curve at the lower end where they enter the water drums. The tubes can be inspected throughout the whole of their length by holding a light in the lower barrel. The lower water pockets being cylindrical can be made of solid drawn steel, thus eliminating possibilities of leakage and also making a lighter and stronger construction. The tubes of any one diameter are all curved to the same radius, so that any tube will do for either row, which greatly simplifies the spares. This also allows of the lower drums being made smaller, thus saving weight.

The Yarrow Water-Tube Boiler with Superheater.

Figs. 29 and 30, page 2021, show this boiler, which consists of a top steam collector, as usual, and two lower water pockets. On the left-hand side is the superheater, and on this side of the boiler there are fewer rows of generator tubes than on the other side, where there is no superheater, it being thought desirable that the total heating surface and the resistance to the gases on both sides of the boiler should be approximately the same. In one of these boilers with a total heating surface of 6,700 sq. ft., 1,265 sq. ft. consisted of superheating surface; the total heating surface on the superheater side of the boiler being 3,453 sq. ft., and on the other side 3,247 sq. ft.

The superheater consists of a number of U tubes expanded into two longitudinal collectors, small doors being fitted so that access can be obtained to the tubes when required. The leading feature of the arrangement is that the superheater is placed on one side of the boiler only, and a damper is fitted in the up-take on the same side. If this damper is closed the whole of the gases are deflected towards the opposite side of the boiler, and no heated gases pass the superheater, the object being that if the main engines should be suddenly eased or stopped, or when raising steam, the superheater may be shut off, so as to prevent the tubes being damaged, or the steam being superheated to an excessive extent, owing to there not being sufficient circulation of steam. In this way one objection to the introduction of superheating for marine installations is overcome.

A further advantage of the arrangement is that, when the consumption of steam is suddenly reduced or stopped, not only does the damper prevent the superheater tubes from being burnt, but it also greatly diminishes the output of the boiler at the time when a reduced supply of steam is wanted, because only about one-half of the heating surface comes into contact with the hot gases. To avoid the possibility of the damper getting distorted through over-heating, it is provided with a hollow spindle, to which air is admitted and which passes from thence between the two plates of the damper, escaping at the edge, and thus keeping the damper cool. This arrangement of damper has proved thoroughly successful under the most trying conditions.

At the maximum rate of evaporation with the damper open, namely, when burning 1·237 lb. of oil per square foot of heating surface per hour, the degree of superheat was 93·5° F.; 14·6 lbs. of water were evaporated per lb. of oil per hour, with a steam pressure of 242 lbs.

The results of other experiments indicate that in a properly designed boiler of the type described, it is possible to burn, without injury to the boiler, 2 lbs. of oil per square foot of heating surface per hour.

The Clarke-Chapman Marine Water-Tube Boiler.

(*Woodeson's Patent.*)

The 'Woodeson' patent marine water-tube boiler, as shown by fig. 31, page 2022, is manufactured by Messrs. Clarke, Chapman & Co. Ltd., Gateshead-on-Tyne, and consists of two sections, each comprising steam drum, water drum, and a number of groups of tubes expanded into same; these tubes are nearly vertical and perfectly straight, and manholes are arranged on steam drums immediately over each group through which any tube can be withdrawn.

The bottom drums are absolutely hanging so that expansion and contraction can take place without causing any damage to the boiler.

In the design of the 'Woodeson' boiler, a special feature is the ease of access for purposes of examination or repairs, the time which has to be expended on the same being practically reduced to a minimum; thus in a boiler of say 6,100 square feet of heating surface, containing 456 tubes, the only work to be done to thoroughly examine the insides of this large number of tubes for their total length is the removal of the manhole doors on one end of each bottom drum, and one manhole door off each of the three steam drums: thus access can be gained to every tube, and these being perfectly straight they can be thoroughly examined for the whole of their length. The removing and replacing of the manhole doors can be done by an ordinary fireman, no skilled mechanic or complicated tools being required. There is an entire absence of screwed joints in the boiler.

Each tube being nearly vertical and perfectly straight and entering the steam drum direct without intervention of any headers, ensures a perfect steam release, and so adds to the efficiency of the boiler, as there are no sharp turns to retard the flow of the steam globules to the steam space. Also, deposits are not retained in the tubes, but are collected in the large mud-drums; thus over-heating and destruction of tubes are reduced to a minimum.

The superheater consists of a number of mild-steel tube boxes, into which are expanded the tubes, which are bent to L shape and belled out.

The superheaters are provided with the necessary fittings, including specially designed by-pass valve for regulating the degree of superheat, also a large drain valve in the lowest part of the superheater for draining.

The Niclausse Boiler.

This boiler is principally adopted by the French Navy, though it is used by 15 other navies, there being now upwards of 2,000,000 h.p. afloat in the Naval and the Mercantile Marine Services.

Fig. 32, page 2023, shows the most modern design of this type of boiler, as applied to a large French cruiser of 35,000 h.p. in course of construction. It is the high duty type referred to in the 'Engineer' of March 13, 1914, and the Institution of Mechanical Engineers' Journal of July 1914. This boiler is described on page 1432 ('Water-Tube Boilers for Land Service').

The tubes are either 84 or 60 mm. diameter and the boiler is therefore of the large tube type, but the characteristic feature of the Niclausse inner tube gives it all the advantages of the small tube type. Its special features comprise a considerable saving of space and deadweight, and in respect of the former it will be noticed that the boilers can be located back to back and adjacent to each other, all access being entirely from the front.

Marine boilers of this type are fired by either oil or coal, or both, and excellent results are claimed by the makers, who lay more stress on average than on test efficiencies. Other features are great flexibility and overload, the cleaning facilities provided, and the ability to quickly effect the withdrawal and replacement of defective tubes, which can be done within an hour from time of stop to restart under full steaming power.

The Standard Water-Tube Boilers adopted for the United States Emergency Wooden Steamships are described and illustrated (from *International Marine Engineering*) in 'Engineering,' Nov. 9, 1917.

THERE ARE AFLOAT TO-DAY

'NICLAUSSE' BOILERS

AGGREGATING OVER

2,000,000 Horse Power.

The 'Niclausse' is pre-eminently the Boiler for the Merchant Service, as it is for the Naval Services, especially if Oil Fuel is used, because:—

(1) It saves weight and space and height.

(2) No Boiler gives so high an average efficiency in ordinary service over long periods.

(3) It is not subject to the troubles experienced with those types having Headers or Drums at each end of Tubes expanded into them.

(4) It gives excellent results in Drifters, Trawlers, Tugboats, River and Lake Steamers, Tramps, Liners, and all classes of War Ships.

Installations on 35 Seine Steamers, fitted between 1895 and 1900, have since aggregated over Nine Million Miles without the changing of a single tube, or suffering any delay due to boiler troubles.

British, French and Italian War Ships, fitted with Niclausse Boilers, even though in some cases fifteen to twenty years old, are still giving excellent results in active service.

Life of Marine Boilers.

The life of a marine boiler depends to a certain extent on the care and attention bestowed on it during the first few months of its existence, provided that the plates have been properly treated at the building of the boiler—that is, all mill scale removed and the plates kept dry and free from atmospheric corrosion. The mill scale, if not removed, has a very irritant action on the clean metal of the boiler, and is most hurtful to the plates if allowed to remain on them. The greatest care and attention is needed for the first period of working of new boilers to keep the new metal free from corrosion. It is advisable on the first voyage to put into the boilers before closing them up ; 5 lbs. of lime per 1,000 i.h.p., and afterwards for a period of about six days 2 lbs. of lime per day per 1,000 i.p.h. should be passed through the hotwell as milk of lime, and 1 lb. of lime per day per 1,000 i.h.p. during the remainder of the voyage.

Rules and Regulations with reference to Boilers of Steamships.

Standard Conditions for the Design and Construction of Marine Boilers.

A set of rules has been framed and agreed to by representatives of the Board of Trade, Lloyd's Register of Shipping, the British Corporation for the Survey and Registry of Shipping, and the Bureau Veritas International Registry of Shipping, and recommended for favourable consideration and adoption. An abstract of these rules is given on pages 1416–1424.

Boiler Casings.

The casings of both the Babcock & Wilcox and Yarrow boilers are constructed of light steel plates and angles, and designed to avoid distortion due to the high temperature of the gases with which they are in contact. In way of the furnaces the casings are lined with brickwork, other parts of the casings are lined with asbestos millboard or some other non-conductor, to prevent radiation of heat to the stokeholds. In the Babcock & Wilcox type of boiler, wide use is made of 'Cellinsulate,' a special form of non-conductor which possesses greater resistance to heat transmission per unit of weight than any other form of lagging.

MARINE SUPERHEATERS.

The Robinson Superheater.

The 'Robinson' marine smoketube superheater, fig. 33 (2-furnace boiler), is composed of a number of solid-drawn mild steel pipes, manufactured from best Swedish steel billets, and headers or steam collectors, into the sides of which the ends of the superheating pipes are expanded.

In applying this superheater to a 3-furnace marine boiler, the headers or steam collectors

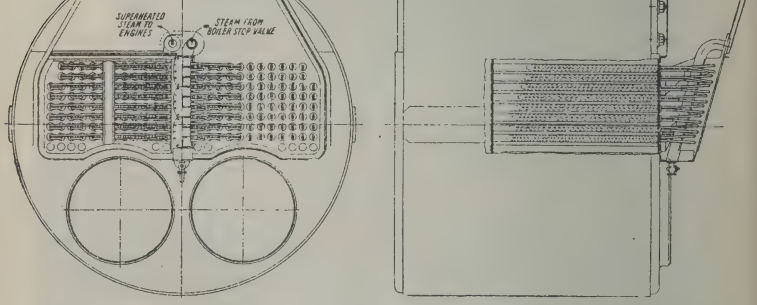

Fig. 33.—The Robinson Superheater.

are placed vertically in front of the boiler in the space between the inner row of smoke-tubes of the wing combustion chambers and the outer row of smoketubes in the centre combustion chamber.

The headers are secured to the boiler by means of suitable flanges, and are divided into a number of separate transverse compartments, several of which receive and distribute saturated

steam from the main saturated steam pipe to the superheating pipes, and the remainder of these compartments receive the superheated steam from the superheating pipes and distribute the same to the steam pipes leading to the steam chest of the engine cylinders. The superheated and saturated steam compartments are open at the front of the header to permit of the header being examined internally, for the introduction of the tube expanders into the ends of the superheating pipes, for expanding the same into holes in the sides of the header and also for removing any accumulation of incrustation which may be deposited in the header. The superheater pipes are also readily disconnected from the header by means of suitable tools, which are inserted through the front of the header. The front of the header is made steam tight by means of cover plates, secured with a number of studs and nuts.

The advantages claimed for the ' Robinson ' marine superheater are that it is of simple and substantial design and free from a multiplicity of parts. The steam compartments in the header being accessible, allow of ready examination, cleaning, and renewal of superheating pipes, and facilitate the production of good sound castings. Copper joints, rings, bridge bars, studs and nuts for securing the elements to the header are dispensed with.

Some tests have shown a saving of over 20 per cent. in coal consumption, but average conditions would indicate 10 per cent. saving of coal for 200° F. superheat.

The ' North Eastern ' Superheater.

(*The North Eastern Marine Engineering Co. Ltd.*)

This superheater is specially designed for the Scotch (or cylindrical) type of boiler, this type being the universally adopted boiler for the mercantile marine.

The superheater, fig. 34, consists of headers arranged in pairs between the nests of boiler tubes. These headers, which are fitted in the smoke box and attached to the boiler end, comprise saturated steam headers and superheated steam headers, the saturated being connected by pipes to the boiler stop valve, and the superheated by pipes, so as to deliver superheated steam to the engines.

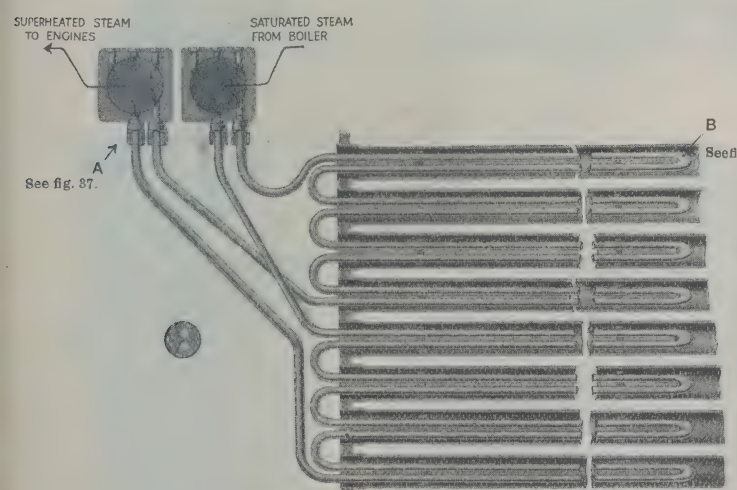

Fig. 34.—The ' North Eastern ' Superheater.

The superheater tubes, or elements, are connected between the saturated and superheated headers and consist of a series of small steel tubes of ' U ' form carried into, and out of the boiler tubes. A number of these ' U ' tubes, generally about four, are coupled in series between a saturated and its corresponding superheated steam header.

Where the ends of the elements project into the boiler tubes, and are subject to intense heat, the ends of each pair of tubes are fitted with a special steel cap, fig. 35, welded to the tubes by oxy-acetylene welding. The end of the element where joining the header, fig. 37, is fitted with a

special form of joint, consisting of a collar fixed to the end of the tube, which collar fits into a recess in the header where a steam-tight joint is made with a jointing ring. The collars are held in place by means of special steel dogs or clamps, each clamp securing a pair of collars, and screwed down to the header by means of a stud and nut.

Sugden Superheaters for Marine Boilers.

(T. Sugden, Ltd., 180 Fleet Street, London, E.C. 4.)

The Smoke Tube Superheater.

The Smoke Tube Superheater is more generally adopted than any other type, and special advantages are claimed for the arrangement and details of construction adopted.

The superheaters are constructed of mild steel throughout, and are therefore quite free from explosive and fracture risks which are incident to the use of cast-iron headers.

The elements are formed as loops of solid drawn steel tube, with the spear ends welded and reinforced, and the ends are secured to the headers by loose flange blocks, and fixed by two studs of substantial proportions.

Messrs. Sugden claim that the connection by loose flange blocks, which they have adopted, has overcome all the difficulties which have been experienced in making satisfactory and lasting joints between the headers and the tubes, and that the cost and trouble of continuously re-making these joints has been entirely overcome.

With this superheater, temperatures from 600° to 700° F. can be obtained.

The Smoke-Box Superheater.

The Sugden Smoke-Box Superheater, fig. 38, is fixed in the smoke-box, immediately below the air heater (if the boiler is provided with an air heater).

The headers are placed in a convenient position outside the smoke-box casing, immediately above the door. The elements are formed in coils, and the end of each tube is expanded into the header boxes and bell-mouthed.

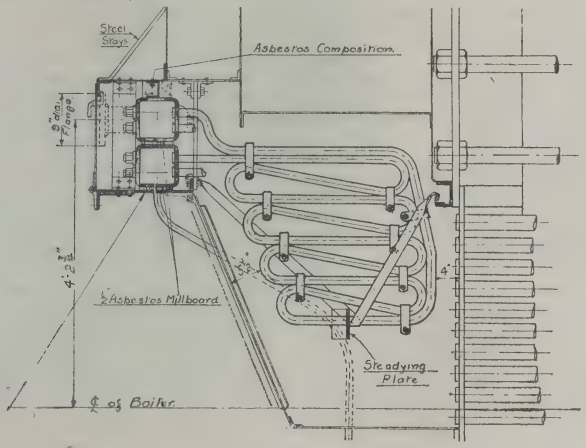

FIG. 38.—Sugden Marine Superheater (smoke-box type).

The coils hang vertical from the headers between the smoke-tubes, and are arranged so that they do not restrict access to the tubes for inspection or renewal.

The Up-take Superheater.

A special Up-take Superheater for coasting steamers and trawlers, and for the supply of steam at a moderate superheat, is also made by Messrs. Sugden.

The headers are placed across the front of the boiler shell, and the tubes are expanded into the headers.

The coils are arranged in loops which hang vertical from the headers and terminate above

the top row of the boiler smoke-tubes, and therefore offer no restriction to access for inspection, cleaning, or renewal of the boiler smoke-tubes.

For conditions where a moderate degree of superheat is required, the up-take design of superheater is very convenient. It requires little alteration to an existing boiler, and can be readily fitted at a very low cost.

The expanded method adopted for fixing the tubes of marine superheaters is one which Messrs. Sugden have successfully used for twenty years in connection with their Standard Down-take Superheater for Lancashire boilers, and Messrs. Sugden claim that general experience has proved that it is the simplest and most reliable method of making steam-tight connections for boilers and superheaters.

Oil Fuel.

The advantages of fuel oil as compared with coal are as follows :—

(1) Reduction in weight and space occupied by the boiler installation.
(2) Increased evaporation of water per lb. of fuel in the ratio of about 14 : 9 as compared with good quality coal.
(3) Utilisation of remote parts of the ship and of constricted spaces, such as the double bottoms, for stowage of fuel.
(4) Less manual labour and greater rapidity in stowage.
(5) No reduction in speed due to cleaning fires, difficulty in trimming coal from remote bunkers, or exhaustion of stokers.
(6) Reduced wages bill for boiler room staff, no trimmers, and comparatively few attendants for the burners being required.
(7) A prompt and effective control of the steam output due to the mechanical supply of the fuel, permitting of more rapid changes of speed than is the case with coal.
(8) Absence of smoke if air supply is properly controlled.
(9) No trouble due to accumulation of ashes ; ash expellers or ejectors are dispensed with.
(10) In the case of naval vessels, fueling can readily be carried on at sea.

Both water-tube and cylindrical boilers are now adapted for burning oil fuel, the direct-pressure system being the one most generally in use for naval and mercantile service.

Pressure pumps fitted in the boiler rooms have suctions from the oil tanks, and discharge at a pressure of from 50 to 150 lbs. per sq. in. through cold filters having fine mesh wire gauze grids; from thence the oil passes through a tubular heater, the oil being inside the tubes and heating steam outside. The temperature of the oil is raised to about 150° Fah. in the heater, and before finally reaching the burner it is passed through a second, or so-called, hot filter.

It is necessary to heat the oil in order to reduce its viscosity so that it can be atomised and forced through the fine passages of the burner, which are so designed as to give it a rapid whirling effect due to centrifugal force when liberated through tangential passages at the lip of the burner, and thus reduce it to a fine spray of conical formation. The air supply to the burner passes through directing slots cut in a steel truncated cone, 12 to 15 ins. diameter and about 16 ins. long. The burner is fitted at the centre of the entrance to the cone, and the admixture of the air passing through the slots with the oil spray from the burner produces almost perfect combustion.

In the case of naval vessels the closed stokehold system is adopted, the air pressure in the boiler rooms being controlled to suit the output of the burners. For cylindrical boilers in merchant steamers the Wallsend-Howden system (page 1820) with open stokeholds is now in extensive use. The arrangement of burners and air cones is similar to that described above, but the air supply is heated by the waste gases, as in the ordinary Howden forced draught system (page 1793) applied to coal burning. Each burner can pass from 400 to 600 lbs. of oil per hour, and it is possible to burn about 13 lbs. per cubic foot of combustion chamber. The area of the furnace front limits the number of burners which can be fitted, and it is desirable that the volume of the combustion chamber should be as large as possible.

(See also pages 1807, 2057.)

EVAPORATORS.

For Fresh Feed Make-up Water for Boilers.*

With the high pressures of steam (usually from 150 to 200 lbs. per square inch) now carried in steam boilers for use with modern triple-expansion and other engines, it is found necessary to provide fresh feed-water for the make-up, in order to prevent the great deposit of scale on the heating surfaces which results from these high temperatures.

* Also used in connection with distilling condensers for producing fresh drinking water instead of the old way of distilling from the donkey boiler.

The quantity of auxiliary feed-water required amounts to from 1 to 5 tons per 24 hours per 1,000 h.p.

To provide this, evaporators have come into general use.

In these evaporators the sea water is boiled by the heat from steam passing through tubes

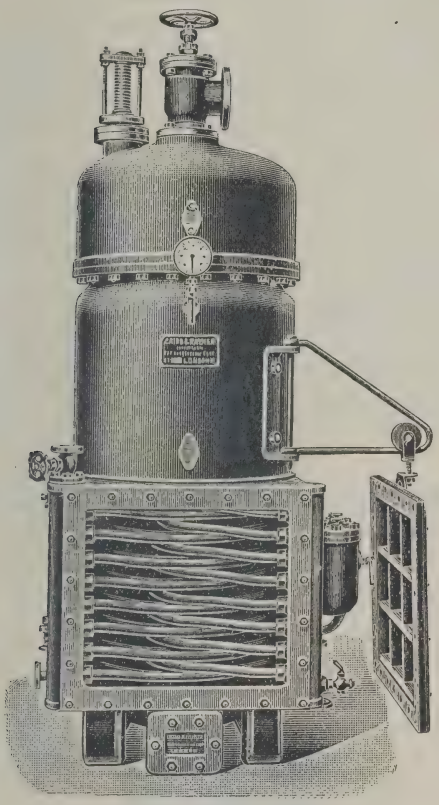

FIG. 39.

immersed in the salt water. The condensed steam from these tubes is usually drained back to the condenser or hot-well, and so back to the boiler, and the secondary steam produced from the sea water is led to the main condenser, and is there condensed along with the exhaust steam from the engines, and thus delivered to the boiler as fresh feed-water.

The scale formerly left in the boilers is deposited in the evaporators, which are arranged so as to be easily cleaned when necessary.

The Caird and Rayner Automatic Evaporator.

(Caird & Rayner, Commercial Road, London.)

In this evaporator, shown in general view by fig. 39, page 2029, live steam is led from the boilers through a series of coils of solid-drawn copper tube. Sea water being admitted to surround the coils, and automatically maintained at a constant level, is by the heat of the steam within them converted into vapour, which rises to the upper part of the evaporator, and is led hence to the condenser, where, mingling with the condensed steam from the engines, it provides the required auxiliary feed in the form of distilled water, which is pumped into the boilers by the ordinary feed pump.

The form of the heating coils is a very special feature of this evaporator, as by this their self-cleaning property is secured. The helical form gives them greater elasticity, as they expand and contract with the varying temperatures to which they are subjected in working, and especially so each time the brine is blown out and a fresh charge of cooler water admitted. This action causes the scale, which is naturally deposited on the coils, to be thrown off from time to time, and fall to the bottom of the evaporator, from which it is easily removed. This self-cleaning property of the coils, by which the heating surface is kept practically clean, secures the continued efficiency of the evaporator. The ends of the coils are connected to pockets on each side close to the front of the evaporator, so that the door can be removed, and all the joints that are subjected to primary steam pressure can be tested in full view. The pockets have suitable divisions cast in them to regulate the flow of steam through the coils suitable for the pressure of steam to be used.

An automatic feed ensures that the level of the water to be evaporated is maintained at a constant level, and also that it shall be impossible that, through any accidental neglect or carelessness, the sea water can accumulate so as to fill the evaporator and pass over into the condenser.

A series of baffle plates, specially arranged in the upper part of the shell, ensures that no priming shall take place.

In ships where there are many auxiliary engines at work, the exhaust steam from them is economically used in these evaporators on a system patented by Caird and Rayner, which has been adopted by the British Admiralty in their ships.

The exhaust steam is maintained at a pressure of about 25 lbs. by a loaded valve on the main exhaust pipe, so that any excess over that pressure can pass direct to the auxiliary condenser.

By this arrangement distilled water is obtained without any expenditure of fuel whatever.

The evaporators are usually worked under a vacuum into the auxiliary condenser, the degree of vacuum in the evaporator being regulated by a specially-designed control valve.

The evaporators will produce from 1 up to 100 tons of fresh water per 24 hours, according to size.

The Row Evaporator.

In the Row Patent Evaporator (*Royles, Ltd., Irlam, near Manchester*), the peculiar indented tube is a distinctive element in its construction. It is found that this form of tube

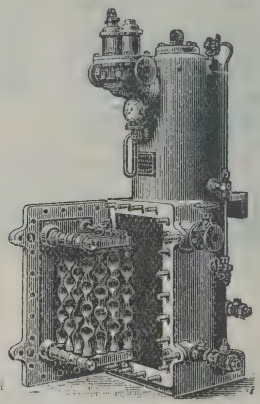

FIG. 40.—The Row Evaporator.

surface casts its scale very readily and is otherwise highly efficient as an evaporating surface. Fig. 40 shows one of these evaporators open for cleaning. All the tubes are erected

upon the inside surface of the door, so that when this latter is opened, which is done without breaking any pipe joints, all the tube surface is accessible for cleaning. The evaporator is fitted with the usual complement of fittings, and is very compact and efficient. It is made in seven sizes, to produce from 2½ to 30 tons per 24 hours.

The Weir Vertical Type Evaporator.

This evaporator is of the vertical type. The shell and dome are of the best close-grained cast iron. The heating surface is formed of heavy solid-drawn copper tubes attached to the inlet and outlet chambers by means of hollow conical couplings. The tube space is separated from the steam space by a deflector. The arrangement of this deflector allows the steam to rise, but throws down the water so that it is returned again to the water space. With this arrangement it is almost impossible to make the evaporator prime under anything like reasonable limits. The usual mountings consist of steam inlet valve, vapour outlet valve, feed check valve, brine valve, drain valve, and coupling to hot-well, blow-off cock, safety valve, gauge glass fittings, pressure gauge, compound gauge, salinometer valve, and gunmetal feed pump to work off the main engine levers.

Heating Tubes.—In the latest designs the heating tubes are arranged in elements, each element consisting of a single tube coil with special hollow couplings on inlet and outlet ends in the same plane. These hollow couplings pass through a steam chamber cast on the back or side of the evaporator, and are secured in place from the outside by means of a cap nut on the ends of each coupling. The outlet opening from the tubes is of smaller diameter than the inlet, with the exception of that in the lowest or drain tube, which is the same area throughout, and through which any steam passing through the smaller outlets from the tubes is again returned through the evaporator along with the water of condensation and drained to the hot-well. By this means the pressure in the stand-pipe chamber at the outlet end is always lower than in the chamber at the inlet end, and a constant current is kept up through all the tubes, thus preventing any accumulation of air and water.

Each element or tube can be taken out separately for cleaning, and in this way the cleaning can be more expeditiously and thoroughly done.

The arrangement also provides a means of keeping two or more elements as spares. These can be quickly substituted for elements requiring cleaning, and the evaporator set to work again while the dirty tubes are being scaled. The tube attachments are strong and substantially made, and are kept tight by screwing up from the outside against a strong shoulder on the inner portion of the coupling.

Automatic Feeding and Continuous Brining.—A water jet is so arranged as to induce the flow of brine from the evaporator and discharge the mixture overboard at any suitable level. Sea water at a sufficient pressure is obtained by a connection from the sanitary tank, which is placed at a height sufficient to give the necessary head. As the evaporator feed is now usually obtained from the same source, to permit of automatic feeding through a feed regulator, an effective and simple combination is obtained whereby the minimum of piping is required and the feed and brining arrangements may be made integral with the evaporator.

Condensers and Water Heaters.

The Weir 'Uniflux' Condenser.

This design of condenser introduced in 1909 has since become extensively adopted in this country for naval and high-class merchant steamers, and the high vacua attainable by its adoption when working in conjunction with the Weir 'Dual' type of combined wet and dry air pump has been an important factor in the improved efficiency of steam turbines.

The construction of the condenser introduces no novel features except as regards the pear-shape of shell which has been designed with the object of causing the exhaust steam to flow over the tubes at a uniform velocity without short circuiting, the steam inlet being arranged as far from the air-pump suction as possible.

The 'Dual' air-pump is of the beam type having one steam cylinder and two pump barrels, one pump for air and vapour and the other for water, air and vapour. Cold injection water is introduced at each stroke into the dry-air pump barrel to condense the vapour and cool the air, and in order to avoid the expansion of the air present in the water filling the clearance space of the dry pump at the moment of discharge the dry-air pump is arranged to discharge below the head valves of the wet-air pumps.

The combination of improved design of air-pump and condenser in conjunction with an increased supply of circulating water has resulted in a reduction of the condensing surface from 20 to 25 per cent. as compared with the condensing plant previously fitted.

The Weir Direct Contact Feed-Water Heater.

This system consists in taking a portion of the steam from the low-pressure receiver of the engine and utilising it to heat the feed water on its passage to the boiler. In actual practice on board ship, this steam is also supplemented by the exhaust from the auxiliary engines.

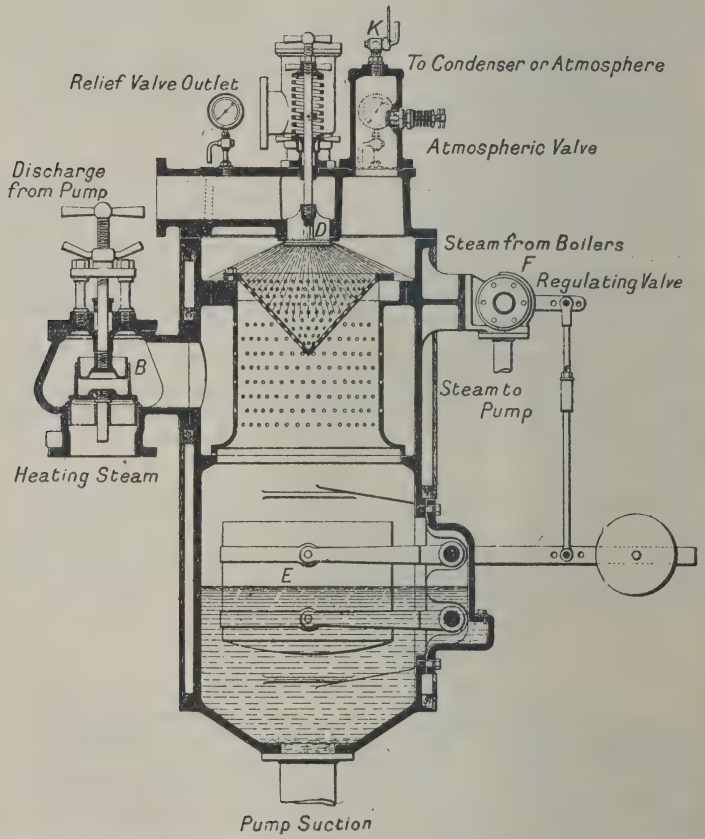

Fig. 41.

Fig. 41 shows a sectional view of the heater. The heating steam is taken from the low-pressure casing of the main engine, and the exhaust of the auxiliary engines is also led into the heater through the non-return valve B on the side of the apparatus. A perforated cylindrical waist piece forming an annular steam space round the heater, and surmounted by a conical spray piece, also perforated, is fitted to ensure the uniform mixing of the steam and water. A Weir direct-acting feed pump, or the main engine feed-pump, delivers the feed water into the heater

through the spring-loaded valve D on the cover. The feed water is forced through this valve in a thin sheet, and is instantly heated by contact with the steam. The water is further broken up into fine spray by passing through the conical spray piece, thereby bringing the greatest possible surface into contact with the steam. As the pressure in the heater is generally much less than that of the entering water, the effect of this lowering of the pressure, and sudden heating of the water, is to liberate the air in the water, and this is removed to the condenser, or to the atmosphere, by a small cock K on the air vessel placed on the top of the heater. (In the case of twin-screw

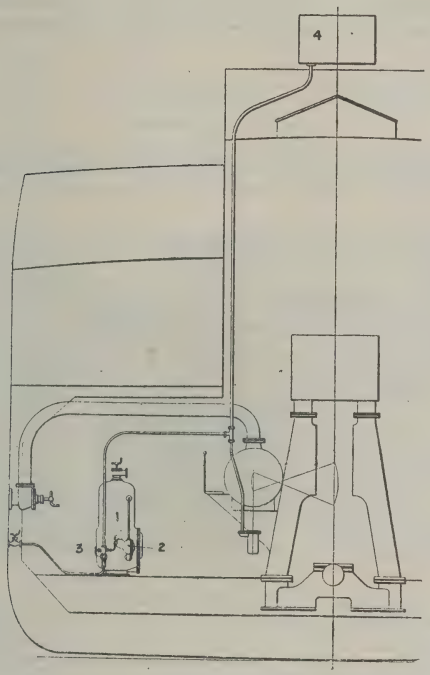

FIG. 42.—Arrangement on board ship of Evaporator with 'Weir' Feed Regulator and Brine Ejector.

1. Evaporator.
2. Feed Regulator.
3. Brine Ejector.
4. Sanitary Tank.

vessels fitted with one feed heater, the lever cock on the heater air dome is coupled up to both condensers by a T piece.) The feed water is thus rendered non-corrosive, and falls to the bottom of the heater at the boiling temperature corresponding to the pressure.

The combination, fig. 42, of the automatic regulating gear with the heater is a special feature of the Weir apparatus. The float E shown in the lower part of the heater is a pan, with water-tight bottom sides, but open on the top. It is suspended on two levers, so as to move up and down with a parallel motion; the top lever spindle is carried through the door at one end, and is balanced by a lever and weight. The float is always full of water, and the weight is adjusted to balance when one-half is immersed in water. The weight lever is connected by a rod to another

lever, which actuates the throttle valve F and controls the supply of steam to the pump drawing from the heater. When the water in the heater rises, the float is raised, and the throttle valve opened, and, when the water level is lowered, the float follows, and the valve is closed ; the level of the water is thus kept constant in the heater, and the pumps are completely filled with water.

When feed heaters are placed on the discharge side of the feed pump they are necessarily subjected to the boiler pressure, and must therefore be of a very substantial character. Such heaters are always of the surface type. Messrs. Weir have two special designs of heater of this class—the 'Multiflow' and the 'Uniflux.'

As affecting the engines, it is found that this system secures a fuel economy of from 5 to 8 per cent., according to the steam pressure carried, and the number of expansions in the engine.

The heater has been fitted by Messrs. G. & J. Weir Ltd. to over 4,000 vessels.

Bearings.

The Michell Bearing.

Michell Bearings (thrust and journal) are largely used in modern marine practice, and are manufactured by Michell Bearings, Ltd., Newcastle-on-Tyne. There are in the British Navy alone ships aggregating over ten million horse-power fitted with main thrust blocks of this type,

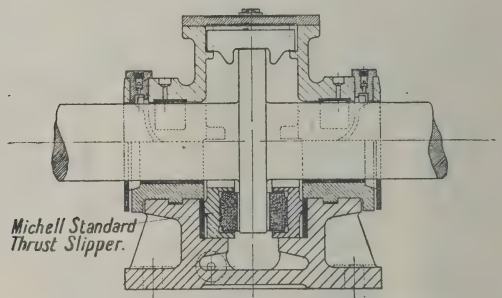

Fig. 43. Michell Slipper Type Thrust Bearing.

and in passenger and merchant ships the Michell Thrust Block is commonly used, both for reciprocating engines and steam turbines.

A standard thrust block used for light craft of all kinds is shown in fig. 43. This is self-lubricating, and can be arranged upon an extension of the engine-bed or upon a separate seating immediately aft of the crankshaft coupling. The oil level in the thrust block is usually kept just above the under-side of the shaft. The bearing surfaces are lubricated by the thrust collar carrying oil upon its edge, and the oil is scraped from this by the scraper at top, thus giving a continuous cascade of oil on the pads. The pads are so pivoted that a film of oil is led into the space between pad and thrust collar, and this oil film can withstand a heavy pressure. A feature of the bearing is that as the speed increases, the pressure per square inch can be increased.

Michell thrust blocks have a single collar shaft with a series of pivoted pads arranged forward and aft, and it will be noticed from the illustration that the pads need only be in the bottom half of the bearing. Thrust blocks, however, can be designed to utilise an existing multi-collar thrust shaft.

Large engines are usually fitted with a thrust block arranged for continuous oil circulation, and in these blocks the upper as well as the lower portion of the body sustains thrust load. Oil is introduced into the space behind the pads and compelled to travel radially across the thrust faces. This oil can be cooled and used over and over. In these blocks the upper and lower parts of the body are keyed together, and liners for adjustment are fitted behind each of the rings which carry the pads.

The Michell principle is also applied to journal bearings, and fig. 44 illustrates one as fitted to a marine oil engine. When speeds are high the ring lubrication is replaced by a continuous

supply of oil from a pump. It will be noticed that the oil is taken on to the shaft by means of a ring, and this ring is always kept in a central position, even if the ship pitches, as the central part of the oiling ring is guided by grooves in rollers arranged upon the shaft.

Considerable economy in length is effected by this bearing, as a pressure of about 500 lbs. per square inch projected journal area is satisfactorily carried at any speed.

The pivoting principle, upon which all Michell bearings work, ensures, perhaps, the nearest approach possible to perfection in lubrication. Astonishingly high pressures are quite safely

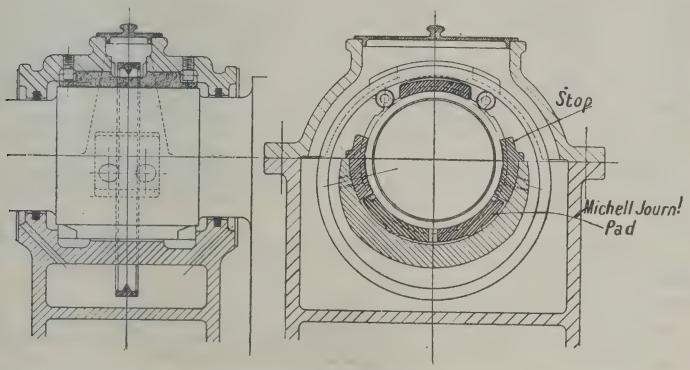

FIG. 44.—Michell Journal Bearing for Marine Oil Engine.

carried (under test as much as 5 tons per square inch has been successfully imposed), whilst speeds of any magnitude may be run by regulating the quantity of oil supplied. High speed is an advantage, inasmuch as oil film thickness increases with the speed.

MARINE DIESEL ENGINES.

Contributed by A. P. Chalkley, B.Sc., A.M.Inst.C.E.

Author of 'Diesel Engines for Land and Marine Work.'

Revised by James Thomson, M.I.N.A.

The Diesel engine as designed for marine work differs in no essential principle from the stationary type; with each manufacturing firm there are certain modifications and peculiarities of construction. On the whole the two-stroke-cycle single-acting engine is considered to have best prospects for the future, but for the very large engines for naval purposes the double-acting two-stroke-cycle motor is expected to give best results, whilst a number of firms still adhere to the four-stroke-cycle single-acting principle for moderate powers, with which type a majority of existing motor ships are fitted.

The superiority of the Diesel engine for marine work in certain cases is not entirely due to its fuel economy. This must always be an uncertain matter, dependent on the relative prices of the fuels. The consumption of oil with a Diesel marine engine is practically the same as for the stationary type, except that when the two-stroke-cycle motor is employed the efficiency is slightly lower. Generally speaking, with oil of a calorific value of about 18,000 **B.Th.U.** per lb. or 10,000 calories per kg. the fuel consumption for marine work may be taken as 0·4 to 0·5 lb. per b.h.p. hour, which is rather over than under estimated. Unlike reciprocating steam engines, and steam turbines, the larger Diesel engines possess practically no advantage over smaller ones. It is usually estimated that the weight of fuel consumed by a Diesel marine engine is $\frac{1}{2}$ to $\frac{1}{3}$ that required

for a vessel equipped with small reciprocating steam plant and about ⅓ for double-reduction geared turbines, making allowance for standby losses, etc., and it has been found that this estimate has been well borne out in practice, although owing to the difference in efficiency between large and small steam engines and turbines it cannot apply absolutely. There is, therefore, an economy of fuel costs by the employment of Diesel engines, as compared with steam, when the price of fuel oil is not more than 3 to 5 times that of coal, but a Diesel ship with the same bunker capacity of a steamship has a radius at least 3 times as great, and hence is able to take more ready advantage of buying fuel at the most economical port.

Among the most important advantages of the Diesel engine for marine work are the reduced space occupied by the propelling machinery and the smaller weight of the plant. This permits of greater cargo-carrying capacity, or a smaller vessel for the same cargo, with a corresponding reduction in the cost of the hull, although at the present time the cost of a Diesel engine is in excess of a steam engine and boiler plant. It has been estimated—and the estimate has been found nearly correct in practice—that a vessel equipped with Diesel engines has from 10 to 15 per cent. extra cargo-carrying capacity as compared with a steam engine, and this is materially increased if the amount of fuel carried is reckoned on the basis of the same radius in both cases, when considerable extra bunker space is rendered available for cargo in the Diesel ship. With special precautions, moreover, the fuel oil can easily be carried in the double bottom of the ship, which allows a further gain in space. In war vessels the advantage of the economy in fuel with Diesel engines will no doubt be utilised by increasing the possible radius, which may be taken at 4 times that of a steam vessel with geared turbines owing to the relative high economy at lower powers, this being a feature of the Diesel engine as compared particularly with the steam turbine.

In a Diesel ship the number of attendants in the engine room required is less than in a steam vessel, being usually in the neighbourhood of ⅔. Firemen are entirely dispensed with, the handling of fuel is easy, rapid, and clean, whilst the astern power is equal to the ahead, which is not the case in turbine vessels.

As a typical instance may be mentioned the motor tankship 'Juno' (5,050 tons d.w.), with two 1,100 h.p. Diesel engines, in which the engine-room staff consists of four engineers, three assistant engineers, three greasers, one donkey-man and one pump-man.

For the same speed a vessel equipped with Diesel engines usually requires slightly more power than when propelled by a steam engine for similar conditions, as the revolutions are too high for the most efficient propeller.

Types of Marine Diesel Engines.

There are three distinct types of Diesel marine engines, two of which have already been largely constructed and put into actual service, whilst of the third type several engines have been constructed, although none are yet installed in actual vessels. The first two are the single-acting engines of the four-stroke-cycle and two-stroke-cycle type respectively, whilst the third is the two-stroke-cycle double-acting engine. Four-stroke cycle double-acting engines have also been proposed for marine work, and they are occasionally employed for stationary purposes (horizontal type). The chief advantages of the four-stroke-cycle motor are its high efficiency and the long experience which has been gained with it for land work. The two-stroke-cycle single-acting engine has the advantage of reduced weight and space, simplicity in reversing arrangements and cheapness of manufacture. It necessitates the employment of scavenge pumps which reduce the overall efficiency of the motor. Larger powers can be developed in single cylinders, and although the limit is not yet certain, it is anticipated that 3,000 h.p. can be produced from a single cylinder. Up to the present 1,800 h.p. is the highest power that has been attained in a single-acting two-stroke-cycle motor per cylinder.

The reason for the employment of the double-acting two-stroke-cycle engines is to obtain the maximum power per cylinder, and engines have been built on this principle giving 2,750 b.h.p. per cylinder. The chief difficulty encountered with the double-acting engine is to get rid of the heat in the cylinder, and there is also the question of the most convenient method of operating the valves in the bottom cover of the cylinder. It is stated that these troubles have now been satisfactorily overcome.

As regards the two-stroke-cycle single-acting type, the chief difference in the design of different manufacturers, apart from details of the reversing gear, is in the method of the provision of the scavenge air. In some engines scavenge valves are employed, fitted in the cylinder cover, and through these the scavenge air enters the cylinder, whilst in other types ports are provided at the bottom of the cylinder usually extending half-way round the circumference, opposite the ports for the discharge of the exhaust, such as are always arranged in two-cycle engines. Scavenging through ports presents some difficulties in regard to cleaning out all parts of the cylinders

thoroughly, and various arrangements are employed to make it more efficacious, some of these being described later. With valves, the scavenging is excellent, but the valves must be large, and they add to the complication of reversing. The scavenging pumps usually work at a pressure of 3 to 6 lbs. per square inch, above atmosphere, and the power they absorb is generally about 8 to 10 per cent. of the output of the engine. The power developed from a single-acting two-stroke-cycle Diesel engine is about 1·5 to 1·75 times that from a corresponding four-stroke-cycle motor, and not twice as is sometimes supposed.

The question of reversing Diesel engines is not one of particular difficulty, the only requirement being a variation in the time of opening of the different valves. In the four-stroke-cycle engine this includes the exhaust valve, which is omitted in the two-stroke-cycle type, whilst if in the latter scavenge ports are provided, the matter is further simplified by the absence of scavenge valves. There are various methods of reversing, which, however, practically do not differ at all in principle, the arrangement being to alter the times of openings of the various valves relative to the crank shaft. In one arrangement which is commonly employed, a single cam shaft is provided on which are fixed two separate sets of cams, one for the ahead motion and one for the astern, each valve thus being capable of operation by either of the two cams. For reverse running the cam shaft can slide in a longitudinal direction, and this motion brings the astern set of cams underneath the levers operating the valves, so that the valves are thus set for going astern. Before the cam shaft can be moved, the rollers of the valve levers have to be moved clear of the cams in order to let them pass under.

A second method of reversing consists in having two separate cam shafts, on one of which the cams for ahead running are mounted, and on the other those for the reverse, and either cam shaft is set in a position for its cams to actuate the valve levers, according as it is required to run ahead or astern. There are various other means adopted for reversing, such as by a rotation of the cam shaft relative to the crank shaft, and utilising the same cams for both direction which necessitates special setting of these cams. In another design a combination of this method and the first is adopted, whilst there are certain other special arrangements, one of which is described later.

Burmeister & Wain Type.

The engine designed and constructed by Messrs. Burmeister & Wain, of Copenhagen, may be taken as a typical four-stroke-cycle marine Diesel motor. It is built with six or eight cylinders, according to the power, the engines of the 'Selandia' and several other boats having each eight cylinders, and developing about 1,200 to 1,300 i.h.p. at 140 revolutions per minute.

As is now common in most Diesel engines, and will, no doubt, be generally adopted in the future, crossheads with water-cooled guides and connecting rods are employed, which, although increasing the height, are of considerable advantage in dismantling and for facility of inspection. An enclosed crank chamber is used, but in front and back there are readily removable covers. The engine is not entirely self-contained, inasmuch as only the high-pressure stage of the air compressor for injection air is driven direct off the crank shaft. The low-pressure stage is separate, and driven direct by an oil engine, steam engine, or electric motor, as may be desired.

The engine may be considered as arranged in two sets of four cylinders, which is convenient for the placing of the valve gear, and manœuvring mechanism described later. The valves are fitted in the cylinder cover, as is generally the case, and each cylinder has a starting air valve, fuel inlet valve, exhaust valve, and an air inlet valve, besides a relief valve in the side of the cylinder. The cam shaft carrying the cams which operate the levers controlling the valves is not situated on a level with the top of the cylinders, as is common in many four-cycle engines, but at about half the height of the engine. Each of the valves, except the relief valve, has two separate cams for its control on the cam shaft, one for ahead and one for astern running. In order to reverse the engine, the valve levers are lifted and the cam shaft moved longitudinally a distance equal to the cam width, so that, on dropping the valve levers once more, they are now immediately above the astern cams and are in a position for running in the opposite direction. The sliding of the cam shaft is accomplished by means of a disc carried on it, which moves in a slotted drum on an auxiliary shaft, the slot slanting from left to right. The auxiliary shaft can be turned by means of an air motor controlled from the starting platform, and in turning the cam shaft moves to the left or right, according to the direction of rotation of the auxiliary shaft. The actual operation of the valves from the cams is carried out by having long hollow vertical rods, whose upward and downward motion causes the rocking levers at the top to actuate the valves. It may be mentioned that, contrary to usual practice, the injection valves open inwards towards the cylinders. The drive of the cam shaft is through helical gearing and a vertical intermediate shaft, direct from the crank shaft. Sometimes a direct gear drive is adopted.

The question of the number of fuel pumps for pumping the oil to the injection valves is somewhat controversial, as some manufacturers prefer to have one pump per cylinder, whereas others think it desirable to minimise the number as far as possible. In this engine there is but one fuel pump for each set of four cylinders and a small hand pump is employed for pumping the oil up to the valves when required, the usual overflow cocks being fitted.

In most Diesel engines, the governor controls the amount of fuel admitted to the cylinder by acting upon the suction valves of the fuel pump, and holding them open a longer period during the pressure stroke, if it is required to reduce the oil supply. In this engine the control is from the starting platform and a governor is fitted, which is only for the purpose of preventing the speed rising above 140 revolutions per minute, by cutting off the fuel

altogether. Forced lubrication is adopted for the engine, and the oil is water-cooled and circulated continuously. In some of the later engines one fuel pump is employed for each cylinder, and this appears a preferable arrangement.

There have been some very distinct modifications with the later and larger type of motor. Six-cylinder sets are now built developing 2,000 i.h.p., having a cylinder diameter of 740 mm. (29 ins.) and a stroke of 1,100 mm. (43¼ ins.). This is by far the largest output for a four-cycle marine motor that has yet been attained, although cylinders in greater dimensions are now being built. With an efficiency of 80 per cent. the corresponding brake horse-power is about 1,600. The speed of revolution is 100 per min., and the consumption of the engine is 0·32 lb. per i.h.p., or about 0·4 lb. per b.h.p. A vertical three-stage air compressor is driven direct off the main engine, having a capacity of 13·5 cub. metres of air per min., whilst the actual consumption of the engine is normally 12 cub. metres per min. Another modification lies in the fact that a separate fuel pump is provided for each cylinder. Owing to the size of the piston it is not possible to carry out the cooling by means of oil as with the smaller cylinders, and sea water is used for the purpose as with most other types of motors. It may be mentioned that some designers prefer to avoid the use of sea water for cooling purposes owing to the possibility of deposit, but the matter is largely an open question. The whole of the arrangements for operating the valves and reversing are the same as in the smaller motors, except that the camshaft, instead of being driven by two long horizontal rods, is in this case operated through spur gearing from the crankshaft, three intermediate spur wheels being provided between the crankshaft and the camshaft. It is claimed with this design that there is less likelihood of any variation in the setting of the cams due to wear and other causes.

There are many engines of this type being built, the highest powered developing 4,000 h.p. in eight cylinders. The general design of these large engines is exactly the same as the motor just described.

In fig. 45 (p. 2038) a section is given of a 2,000 h.p. Burmeister & Wain motor of the latest type, whilst figs. 46, 47 (pp. 2039, 2040) give illustrations of the control arrangements for this motor.

Werkspoor Type.

Another Diesel engine is that constructed by the Nederlandsche Fabriek, of Amsterdam, the first large engine of this design being installed in the 'Vulcanus,' and others of larger power up to 1,500 b.h.p. have now been built.

The motor, fig. 48, p. 2042, is usually of six cylinders, and in general details, such as the arrangement of valves in the cylinder cover, the division of the engine into two sets of three (or more) cylinders, etc., the design is similar to that of the Burmeister & Wain type.

The chief point of difference lies in the arrangements for operating the valves and the method of reversing. In this case two separate camshafts are provided, on one of which the ahead cams are fixed, and on the other the astern cams. Both shafts are nearly on a level with the top of the cylinders as in stationary engines, and they are driven by means of long connecting rods, operated by eccentrics on the crankshaft between the end cylinder and the flywheel. Both camshafts rotate continuously, whether the engine is running ahead or astern, and in reversing the engine the valve levers are first raised so as to be out of range of the cams, after which the astern camshaft is brought into operation by turning a forked piece carrying both shafts. The ahead camshaft then rotates idly out of range of the valve levers and these are actuated by the cams on the astern camshaft. This operation is carried out by means of a handle on the starting platform, or compressed air may be used for the purpose in larger engines. This is a totally distinct method of reversing from that already described, in which the camshaft is moved longitudinally, and illustrates the diversity of the arrangements which may be employed for reversing Diesel engines.

In large engines of this type (1,000–1,500 b.h.p.) whilst the principle remains the same, the methods of carrying it out vary. The two camshafts are on the same level as before, and are fixed in position relatively to each other, so that their distance apart is always the same. The bearings of these two camshafts are carried on flat horizontal guides, and are capable of moving transversely to the engine, thus carrying the shafts bodily towards, or away from, the centre of the engine. As the astern cams are fixed on one shaft and the ahead cams on the other, the direction of rotation of the engine depends on the position of the two camshafts. When the ahead camshaft comes under the valve lever rollers the engine is set for running ahead and *vice versâ*. The levers are, of course, lifted during the movement of the camshafts.

The motor is of the open type, contrary to the Burmeister and Wain engine, and the cylinders are supported entirely by steel columns extending from the bedplate to the cylinder, whilst there are also diagonal steel columns for stiffening. Light covers are fitted at the bottom and can be readily removed. The air-compressor is of the two-stage type, contrary to ordinary practice, and is driven by means of levers off one of the crossheads. Circulating water and bilge pumps are also driven direct off the engine. There are two fuel pumps for the six cylinders, of which only one is usually in operation.

Carels Type.

The marine engine, fig. 49, p. 2043, developed by Messrs. Carels, of Ghent, which was perhaps one of the earliest constructed, is of the two-stroke-cycle, single-acting type, and many motors of this type have been built by the firm in conjunction with their various licensees. Up to

FIG. 49.

powers of about 1,000 b.h.p., a four-cylinder design is adopted, whilst above this power a six-cylinder engine is common.

The two-stroke-cycle principle involves the employment of scavenge pumps, and these are operated from the engine crosshead by means of levers, two scavenge pumps being adopted for both the four- and six-cylinder engines. For the admission of the scavenge air for clearing the cylinder of exhaust gases, and filling it with air for the next compression stroke, four scavenge valves are fitted in the cylinder cover, this number being used in order to have a sufficient inlet area. Ports are, of course, employed for discharging the exhaust gases after expansion, these being arranged in the bottom of the cylinder, and are uncovered by the piston in its downward stroke.

Fig. 49, p. 2043, represents a four-cylinder 800 b.h.p. Carels engine of the standard design. The motor is of the open type, somewhat resembling a steam engine in appearance, a crosshead and connecting rod being employed. The cylinders are arranged in pairs, with the reversing and control gear in the centre. Hollow cast-iron columns support the cylinders, and these columns are used for conveying the scavenge air from the pumps to the inlet valves. The air compressor for the injection is of the Reavell type and driven direct off the crankshaft at the end of the engine.

For reversing, it is necessary to provide separate cams for the fuel inlet and starting air valves, whilst one cam is sufficient for the scavenge valve, provided its angular relationship to the crankshaft is altered when the direction of rotation is required to be reversed. The camshaft is driven off the crankshaft by spur gearing through a vertical shaft, as with stationary engines.

When it is desired to run the engine in the astern direction, the valve levers are lifted off the cam, the camshaft is turned through a certain angle to bring the scavenge valve cams in the right position relative to the crankshaft. An auxiliary or manœuvring shaft in front of the camshaft is moved longitudinally, and this movement alters the position of the rollers of the levers operating the fuel inlet and starting air valves, so as to bring them over the astern cams on the camshaft. The process of reversing is usually carried out by means of compressed air, a small air motor in front of the engine being employed, although it can be accomplished by hand, if necessary.

In later types some modifications were made, particularly in connection with the scavenge pumps and air compressors, the arrangements for the introduction of the scavenging air into the cylinders being unaltered. The ordinary type of reciprocating air compressor was introduced, arranged so that better balance of the engine could be maintained.

Sulzer Marine Diesel Engines.

Messrs. Sulzers' experience of both four-cycle and two-cycle engines has led them to adopt the two-cycle engine for all marine work, and they have standard designs of 4, 6, and 8 cylinder marine engines developing from 300 to 7,200 b.h.p., the latter being a unit of 8 cylinders, or 900 b.h.p. per cylinder.

The Sulzer two-cycle engine has important differences from the other engines described. Chief amongst these is the method of scavenging through a double row of ports, the upper row of which is above the exhaust port opening and is controlled by means of a rotary sleeve valve.

On the downward stroke of the piston, the upper row of scavenging ports is first uncovered, but the valve controlling these ports remains shut and the exhaust commences to take place only when the piston has descended further and uncovered the exhaust row of ports.

Scavenging commences as soon as the lower row of scavenging ports is uncovered and continues through both rows of ports, the control valve for the upper ports having been opened shortly before bottom dead centre. Finally, scavenging is maintained through the upper ports after the piston has closed the exhaust ports.

Not only is the scavenging much improved in this manner, but it will be seen that it is possible to obtain a super charge of air, i.e. a slight increase above the atmospheric pressure in the cylinder at the commencement of compression.

Messrs. Sulzers have found that the good combustion obtained by this method of scavenging, and also the simplicity of the cylinder cover design (fig. 50) enables them to maintain with safety a higher mean pressure in their two-cycle engines than in four-cycle engines.

The power for a given size of cylinder on the Sulzer two-cycle type is more than double the power of a similar size cylinder on the four-cycle type, both being assumed to run at the same piston speed.

The fuel consumption is also practically the same as the best four-cycle engine when working under service conditions, viz. 0·42 lbs. per b.h.p. hour.

Fig. 51 shows the section through working cylinder of a standard Sulzer Marine Engine of 1,350 b.h.p. running at 110 r.p.m.

The double row of scavenge ports and the rotary control valve for the upper ports are seen on the right (fig. 51), while the exhaust ports and exhaust collector are on the left.

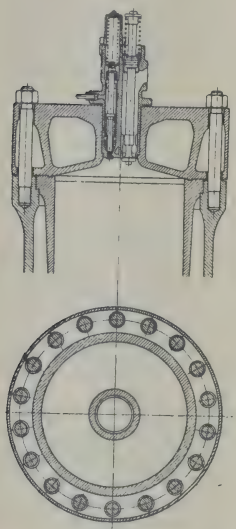

FIG. 50.

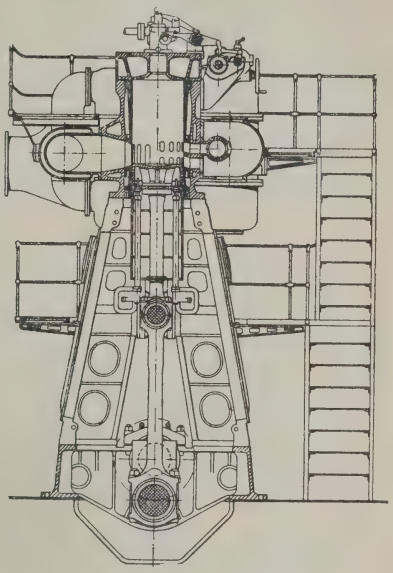

FIG. 51.

The engine shown is provided with a direct driven scavenging pump seen between the h.p. air compressor at the end of the engine and the main engine cylinders.

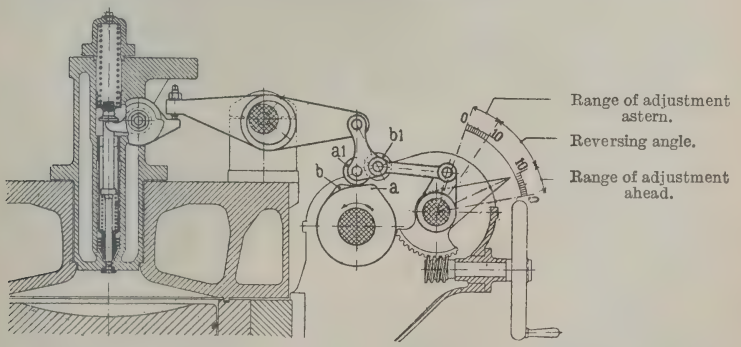

FIG. 52. Sulzer Reversing Mechanism.

In the latest type of engine, the scavenging pumps are in the form of independent rotary blowers electrically driven. This is an advantage from the constructional point of view, and the arrangement has the further gain that the scavenging pump may be speeded up independently of the main engine when it is desired to increase the power. This does not involve any

increase in the size of the electric generating sets where electrically driven winches are installed, as these latter are only running in port when the scavenging pump is idle.

The engine illustrated, when made with separate turbo-blowers, develops 1,500 b.h.p., working at approximately the same indicated mean pressure and piston speed as the 1,350 b.h.p. engine with reciprocating scavenge pumps.

Reversing is carried out with a minimum requirement of power, and is effected by bringing a second set of rollers and cams into operation (fig. 52). Each starting and fuel valve therefore has one cam and roller, a and a^1 for running ahead, and another, b and b^1, for running astern. The hand wheel shown in the above illustration brings a and a^1 or b and b^1 into operation in accordance with the required direction of running.

The weight complete of Sulzer Diesel Marine Engines is approximately 2 cwt. per h.p., i.e. 10 h.p. per ton.

Submarine engines of Sulzer two-cycle type have been built developing 4,000 h.p. in 8 cylinders, these engines being the most powerful marine Diesel engines in the world.

The 'Doxford' Engine (Fig. 53, p. 2047).

Messrs. William Doxford & Sons, Ltd., have completed a 3,000 i.h.p. Diesel oil engine of the opposed piston type, with opposed pistons working on the two-stroke cycle, for the ship *Yngaren*.

The engine consists of four cylinders in each of which there are two pistons acting outwards. The lower piston is coupled by crosshead and connecting rod to a crank below the centre of the cylinder and the piston acting upwards has a crosshead above it, extending fore and aft beyond the walls of the cylinder and coupled by two connecting rods to two cranks, one on each side of the centre crank, but arranged in line diametrically opposite to it. The fuel is injected between the pistons when they are close together, and when combustion takes place the pistons are driven apart, thus exerting an almost perfect turning moment on the crank without a reactionary load on the framework of the engine.

The products of combustion are exhausted through a port at the top of the liner, which is uncovered by the upper piston at the end of the stroke, and a corresponding port is uncovered by the lower piston in the bottom end of the liner to admit the scavenging air, which thus sweeps the entire cylinder. The covering of these ports at the beginning of the return stroke traps the contained air, which is thus compressed ready for the injection of the fuel and repetition of the cycle.

The elimination of exhaust and induction valves, with their liability to defects, is a great advantage, and in dispensing with the cylinder cover many difficulties of jointing and cooling are obviated.

The fuel oil is injected transversely across the cylinder through two spray valves placed diametrically opposite, so that the oil does not impinge on the pistons before combustion has taken place but spreads throughout the combustion space.

The valve gear is very simple, consisting of one camshaft, upon which there are two fuel and one air starting cams for each cylinder for going ahead, and a similar set for astern working. These cams are carried on a sleeve which can be moved fore and aft when reversing in order to bring the desired set under the rocking levers. The rocking levers are mounted on an intermediate shaft, arranged so that the air starting levers are engaged and the fuel valve levers withdrawn when starting up, and vice versa when fuel is to be admitted to the cylinder.

When changing from ahead to astern, all the levers are lifted by a movement of this shaft, which is worked by the main control hand wheel, which also regulates the suction-valve opening of the fuel-measuring pumps.

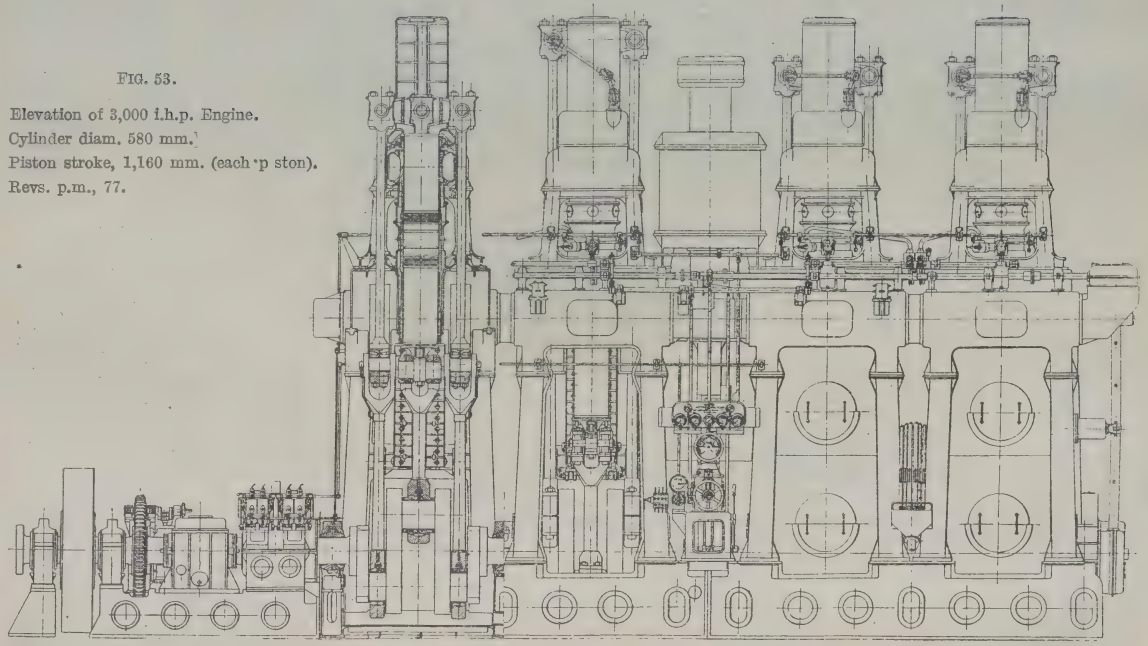
The cylinder liners and pistons are water-cooled. Messrs. Doxford ran a satisfactory trial of five weeks' duration on an experimental engine of 640 i.h.p., with an average mechanical efficiency of about 76 per cent., and a consumption of Mexican fuel oil of ·43 lb. per b.h.p. per hour. A seven days' continuous trial on the test bed of the 3,000 i.h.p. engine gave the following results :— i.h.p., 3,050 ; b.h.p., 2,610 ; revs. per min., 76·7 ; ·441 lbs. oil per b.h.p. per hour ; oil used, Anglo-American of 17,750 B.Th.U. or Anglo-Mexican of 17,680 B.Th.U. There is no difficulty in burning the heaviest oil without the use of additional or lighter oil to assist combustion, as proved byexperiments with tar oils, Mexican, and Californian oil with 40 to 50 per cent. asphaltum Roumanian, residue oil, and Russian mazut.

The Neptune Marine Oil Engine.

The Neptune Marine Oil Engine type 'A' is designed and built by Messrs. Swan, Hunter, & Wigham Richardson, Ltd., who are licensees of the Atlas Diesel Co., Stockholm.

This engine is of the reversible, inverted, single acting type, designed to burn heavy oil.

The general design of the engine is shown by the drawings reproduced in figs. 54 and 55.



This engine consists of six working cylinders, six scavenging cylinders, and one air compressor.

The scavenging pumps are arranged directly below the working cylinders, while the air compressor is driven from an extension of the crank shaft, at the forward end of the engine.

THE 'DOXFORD' MARINE OIL ENGINE.

FIG. 53.

Elevation of 3,000 i.h.p. Engine.
Cylinder diam. 580 mm.
Piston stroke, 1,160 mm. (each piston).
Revs. p.m., 77.

Each pair of cylinders is supported by three cast-iron columns at the front, which are arranged to carry the crosshead guide plates, and three cast-iron columns at the back, which are bolted to the front columns. The columns are secured to the bedplate and scavenging cylinders, and continuous bolts connect the working cylinders to the bedplate.

The crank shaft is of the built-up pattern, with two cranks in each section, two cylinders thus forming one unit, allowing this type of engine to be built with two, four, six, eight, or more cylinders. The working cylinders are fitted with a separate liner, in which are arranged the scavenging and exhaust ports.

A special feature of the Neptune engine is that the valve mechanism controlling the admission and discharge of the scavenging air to the scavenging cylinders is also adapted to control the admission and discharge of the compressed air for starting the engine, an arrangement which greatly simplifies the starting mechanism, and which has proved very successful in previous Neptune engines. The arrangement of the valve gear is clearly indicated on the drawings. The main parts of each set of the valve gear consist of a piston valve A (fig. 54), which controls the direct passage of the scavenging air or of the compressed air for starting, as the case may be, to and from the scavenging cylinders through ports in the scavenging cylinder walls, and a change valve B (fig. 54), which serves to admit either the scavenging air or the compressed air for starting to the piston valve A (fig. 54), as may be desired. The piston valve A (fig. 54) is actuated by an eccentric on the cam-shaft, the eccentric being set by an axial movement of the cam-shaft to the required position for driving the engine in the desired direction. The changing of the cams on the cam-shaft and the setting of the eccentric for the valve gear are thus effected in a single operation by imparting an axial movement to the cam-shaft. One set of valve gear is provided for each pair of cylinder units, the cranks of each unit being arranged 180 degrees apart for this reason. Above the piston valve A (fig. 54) is arranged an air receiver, consisting of a vertical pipe C (figs. 54 and 55), and a horizontal pipe D (fig. 55), from which the scavenging air passes to the working cylinders.

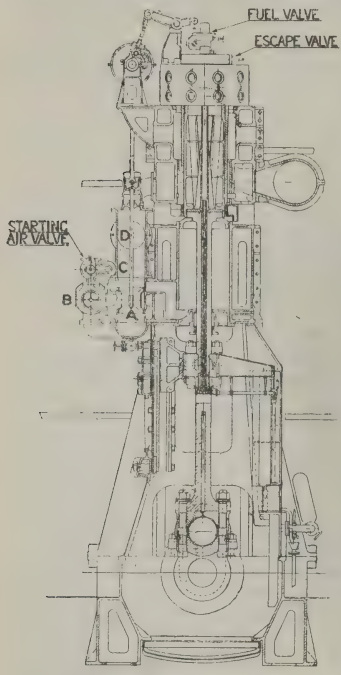


FIG. 54.—Neptune Marine Oil Engine.

Atmospheric air for scavenging purposes is admitted to the change valve B (fig. 54) through the inlet ports E, E (fig. 55), while compressed air for starting is admitted through the compressed air valve F (fig. 55). The change valves B (fig. 54) are placed in the desired position by means of a lever worked from the starting platform. In order to diminish back pressure or exhaust resistance when starting with compressed air, the change valve B (fig. 54) is arranged so that most of the air is exhausted through the ordinary air intake pipes E, E (fig. 55).

When the piston valve A (fig. 54) is below the central position, air passes through the bottom row of ports into No. 1, 3, or 5 scavenging cylinder, and at the same time the top row of ports are open and allow No. 2, 4, or 6 scavenging cylinder to discharge into the receiver C (figs. 54 and 55). When the piston valve A (fig. 54) is above the central position, No. 2, 4, or 6 scavenging cylinder is taking in air through the top ports, and No. 1, 3, or 5 scavenging cylinder is discharging into the receiver C (figs. 54 and 55), through the bottom ports.

The rotating motion of the cam-shaft is transmitted from the crank-shaft by means of eccentrics, rods, and counter-shaft (fig. 54), this arrangement of gear being very convenient for adjustment. Each cylinder is provided with a fuel injection valve situated on the top of the cylinder cover. Each valve is supplied with fuel from a separate fuel pump, and each pump is arranged with double discharge valves to prevent leakage.

The fuel pumps, which are driven through gearing from the cam-shaft, are arranged so that they are out of action during the operation of reversing, and remain so until the engine is rotating in the desired direction, when they are automatically brought into action again, thus avoiding excessive pressure in the cylinder during this operation. The suction valves of the fuel pumps are controlled by hand and by a centrifugal governor which is driven from the cam-shaft.

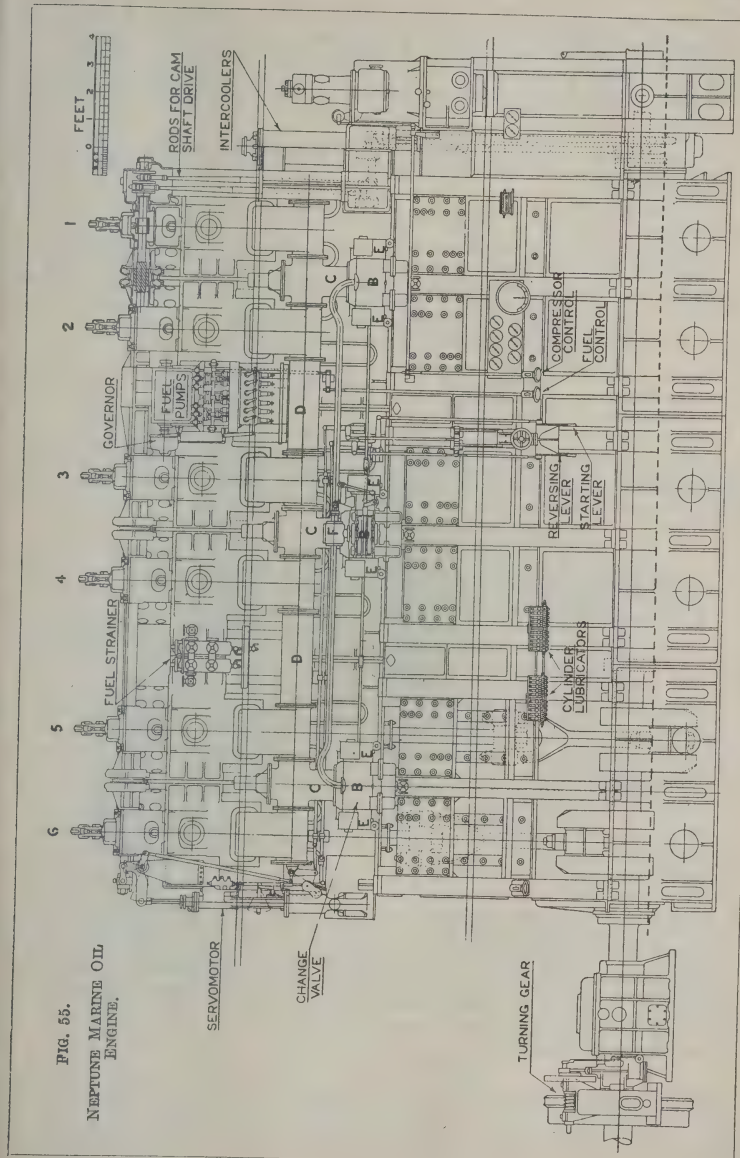

FIG. 55.
NEPTUNE MARINE OIL ENGINE.

As the starting and scavenging air is led through ports, the fuel injection valve and the escape valve are the only valves placed on the top of the cylinders, and the number of small working parts is therefore much reduced in comparison with those Diesel engines which have valves on the cylinder top for the operations referred to.

Sea-water is used for piston cooling, the water entering and leaving the piston through telescopic tubes by way of the hollow piston rod, large air vessels being provided to prevent water hammer.

The hand gear for controlling the engine is arranged so that one man can carry out the necessary operation, while the necessary pressure gauges and revolution counter are arranged in a suitable position.

For manœuvring, the cam-shaft is moved in a horizontal direction by a Servomotor located on the after end of the engine, which is operated from the hand controlling gear.

There are four cams in all for each fuel valve—two for full power, one ahead and one astern, and two smaller cams, one ahead and one astern, the latter being arranged for slow running.

The air compressor is of the single-acting three-stage crosshead type. The h.p. cylinder is fitted with a loose liner, while the other cylinder liners are cast with their water jackets.

The intercoolers, which are of the vertical tube type, are located at the forward end of the engine, as shown in fig. 55, and are fitted with separators on each stage.

The engine is totally enclosed, forced lubrication being provided throughout.

A sight feed lubricator, driven by gearing from the crank-shaft, is provided for lubricating the working and compressor cylinders.

The engine illustrated will develop 1,500 i.h.p. at about 125 revolutions per minute.

Messrs. Swan, Hunter, & Wigham Richardson, Ltd., are also developing a marine oil engine which will be suitable for vessels where the height of the engine is to be considered. All the principal details of the Neptune engine will be embodied in this alternative design, the principal difference being that the scavenging cylinders will be driven by levers, thus making a much lower engine.

The Camellaird-Fullagar Engine.

Cammell, Laird & Co., Ltd., Birkenhead, have developed the Fullagar engine for marine work, and make various sizes of engines of the two-stroke cycle, opposed piston Diesel type with the oil fuel injected by compressed air.

The principal features of the design are: the elimination of the cylinder cover, the provision of a plain cylinder liner, the straight-through scavenge from end to end of the cylinder, the perfect balance of the reciprocating parts provided by the opposed pistons, one connecting-rod and one crank per cylinder.

A 1,000 b.h.p. engine is illustrated in fig. 56. There are four cylinders, in each of which the upper piston of one cylinder is connected to the lower piston of the other cylinder by external tie rods and crossheads, so that each crank receives two impulses per revolution. The horizontal component of the pull of the tie rods is taken up by guides at the top and bottom of the cylinder. The upper crossheads are enclosed and form scavenge pumps, compressing to 1½ to 2 lbs. per sq. in. The pistons uncover air and exhaust ports at opposite ends of the cylinders, and excellent scavenging is obtained.

The Fullagar design enables double the power to be produced in the same space compared with ordinary Diesel engines, and a lighter weight per h.p. As the forces and reactions are largely self-contained by the moving parts, very little load comes on to the framework of the engine, and the construction can be correspondingly light. For marine work the engines have the great advantage of being able to run at a slow speed, also they are very accessible for overhauling.

The 1,000 h.p. engine has cylinders 18½ ins. diameter by 25 ins. stroke, and the speed is 110 r.p.m. Fresh water cooling is adopted to prevent sand and grit from being deposited in the jackets and pistons, and is therefore preferable on this account to salt water. The starting and fuel valves are in the centre of the cylinder, between the pistons, and are operated by a horizontal cam-shaft driven by skew gearing from a vertical shaft operated by crank-shaft. Governing is effected by controlling the lift of the suction valves on fuel pump in the manner usual with Diesel engines, and to reverse the direction of rotation it is only necessary to turn the hand wheel to set the vertical shaft for the ahead or astern position.

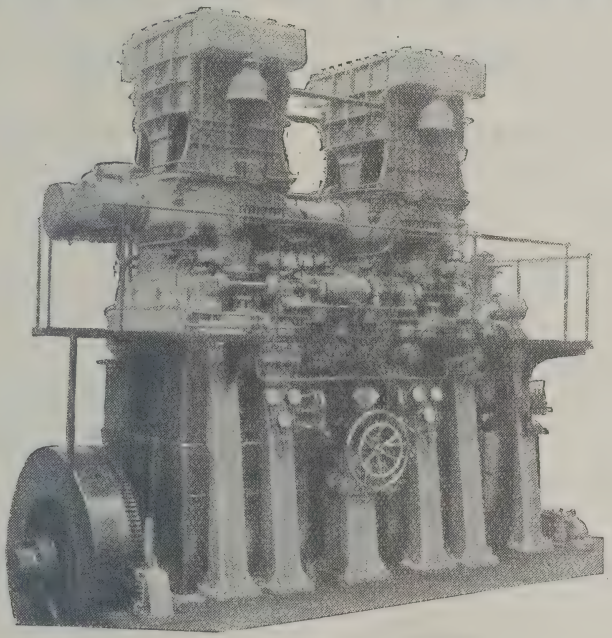
The 'White' Diesel Engine.



The Diesel engines made by Messrs. J. Samuel White & Co., Cowes, were first used for submarines, and they are now supplied for all marine purposes.

One of the White 450 b.h.p. two-stroke cycle engines was subjected to severe tests in order to prove its capabilities as regards power, flexibility and endurance. A 72-hour full load trial

Diesel Engines

FOR

LAND AND MARINE WORK,

BY

A. P. CHALKLEY, B.Sc. (Lond.), A.M.Inst.C.E., A.I.E.E.

With an Introductory Chapter by Dr. RUDOLF DIESEL.

PRESS OPINIONS.

***The Times* (*Engineering Supplement*).**

'Throughout, the subject is treated in a graphic and forceful way. Mr. Chalkley has written a very interesting book, and it should find wide appreciation.'

Gas and Oil Power.

'It gives pleasure to recommend those interested in Diesel engines, whether for land or marine work, to read Mr. Chalkley's book, as in our opinion there has not been published in England such a clear, concise, and practical work.'

Shipping World.

'Mr. Chalkley has written a book which is well entitled to the wide appreciation with which it has been received.'

Electrical Review.

'Concise, distinct, up-to-date, well illustrated, and well indexed, the book should find a place in the library of every engineer who wishes to keep abreast of modern developments.'

International Marine Engineering.

'There is hardly any successful type of Diesel engine which is not fully described in this book.'

Birmingham Daily Post.

'The author is well qualified for the work he has undertaken. He produces evidence of scientific qualification and has had practical experience with the machines he describes.'

CONSTABLE & CO., Ltd., 10 Orange St., London, W.C.2

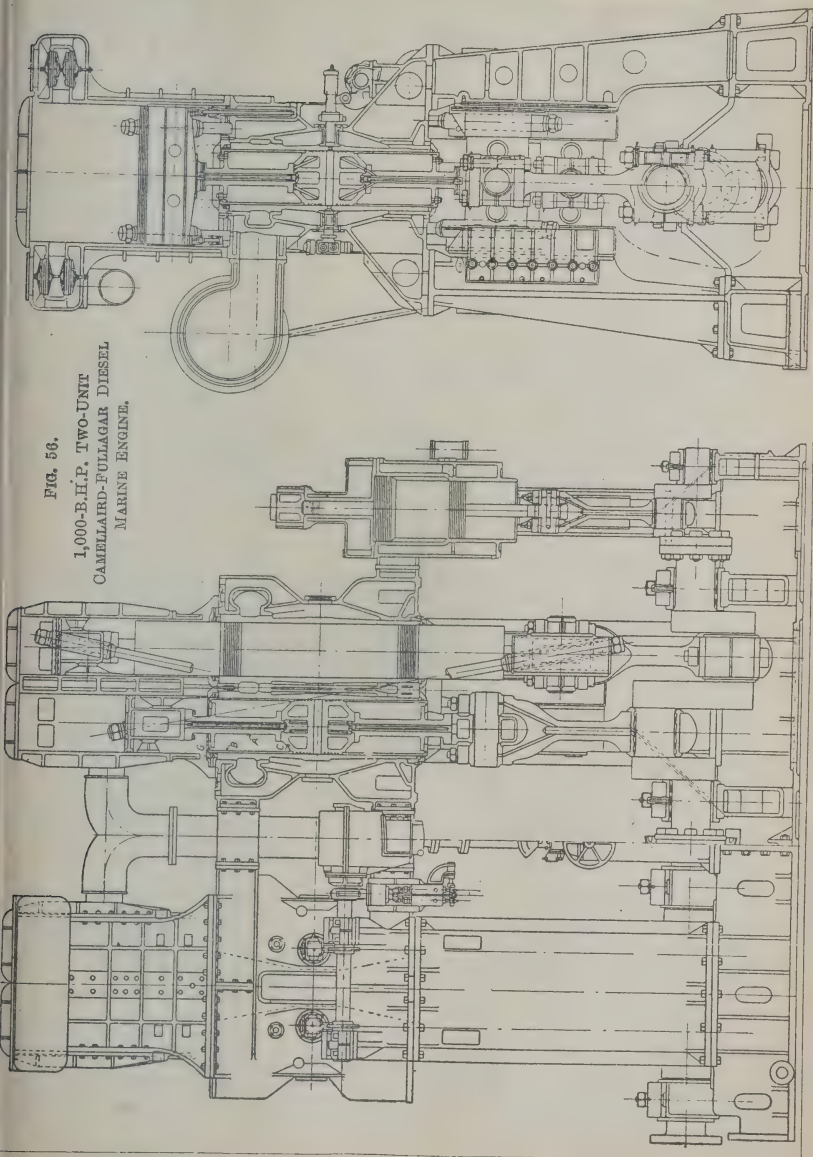

FIG. 56.
1,000-B.H.P. TWO-UNIT CAMELLAIRD-FULLAGAR DIESEL MARINE ENGINE.

was satisfactory, and it was proved that the engine did not require vigilant attention. The exhaust was practically invisible. At the end of this run the engine was slowed down to two-thirds speed and manœuvring trials were conducted. It was seen that 14 cubic feet of air at 900 lbs. per sq. in. was sufficient for starting and reversing the engine 42 times, the pressure of air going down to 90 lbs., which was insufficient for starting.

As an example of flexibility, the tests to determine the minimum speed consistent with smooth running of the engine are interesting. The speed was gradually reduced from 400 down to 150 r.p.m. with suitable power and without alteration to fuel pumps, etc. It was found that 150 r.p.m. could be maintained without fluctuations, and with a steady blast pressure of 630 lbs. per sq. in.

The White engines are vertical, with stepped pistons, the working piston having a clearance of about ·024 in. and relying for gas-tightness wholly upon its rings, while the lower portion fits the cylinder liner and takes the side thrust of the connecting-rods; this lower portion is always comparatively cool, and hence is easily kept effectively lubricated. An important feature of the latest design is the rotating scavenge valves, the sleeve within which they work forming part of the reversing mechanism of the engine.

The Beardmore Diesel Engine.

Messrs. Beardmore & Co., Dalmuir, manufacture the Tosi design of Diesel engine, of which large numbers have been supplied for submarines and other work. The engines are of the four-stroke cycle type, and are very economical, the full load fuel consumption being only 0·4 lb. per b.h.p. hour.

The engines are of the enclosed design and are noteworthy for the elegance of their appearance. They are made in a number of sizes up to 4,000 b.h.p. Before standardising the four-stroke cycle engines, Messrs. Franco Tosi constructed a two-stroke cycle engine, so that they could take comparative tests. The latter engine had six cylinders and developed 1,300 b.h.p. when running at 300 r.p.m. The results of the tests showed that their eight-cylinder 1,450 b.h.p. engine was much more economical in fuel.

Other Types of Marine Diesel Engines.

Among the other British makers of Diesel engines for marine work are Harland & Wolff, of Belfast, the North British Diesel Engine Works, Glasgow, and Scotts Shipbuilding Co. All of these makers are well known in marine engineering and, in their manufacture of Diesel engines, uphold the high traditions of British marine practice.

There are various other types of Diesel engines, but although they differ in some details from the engines already described, the points of difference are not usually important. In the single-acting two-cycle engine of the Maschinenfabrik Augsburg Nürnberg A.G., a stepped piston is adopted, the scavenge pumps being directly below the working cylinders. This arrangement has the advantage of occupying less floor space although the height is greater. The motors are not so accessible, but the amply dimensioned gudgeon pin is kept cool, and there is a large guide face. With the large low-speed engines of the open crosshead type, scavenge pumps are driven off the extended crankshaft, or by rocking levers. Four-cycle engines are also built by the M.A.N. Co.

In the low-speed, two-stroke-cycle engines constructed by Messrs. Krupp, of Kiel, the general design is similar to the Carels type, except for some slight modification in the reversing gear, whilst for high-speed engines employed in submarines enclosed engines are constructed. These are made up to 1,000 h.p. and have a scavenge pump at each end and an air compressor in the centre. A section through a Krupp-Diesel slow-speed engine of 1,150 b.h.p. is shown in fig. 57.

One of the most interesting of the large Diesel engines that has been developed during the past few years is that of the F.I.A.T. Company of Turin. This is of the two-cycle type, and it is of especial interest in that after experience with two-cycle motors with valve scavenging the newer types are provided with ports in the cylinder walls for the admission of the scavenging air. Auxiliary ports are also fitted to allow extra air to enter after the main scavenging ports are closed and these are controlled by means of relatively small valves.

Six-cylinder marine Diesel engines of this design have been built in power up to 3,200 h.p. in six cylinders.

A development of the past year or so which seems likely to have a marked effect on the question of the manufacture of small internal combustion motors is the low powered type of Diesel marine engine built by the Polar Company of Stockholm. It is of the four-cycle non-reversible type running at about 550 r.p.m. and is made in 1, 3, 4, 6 and 8 cylinders, each cylinder having an output of 12½ h.p. It is so far as possible totally enclosed and the construction is perfectly standardised. A reverse gear of the ordinary type has to be employed with engines of this design, since they are not made reversible as are the larger sets.

THE KRUPP MARINE DIESEL ENGINE.
(1,150 b.h.p.)

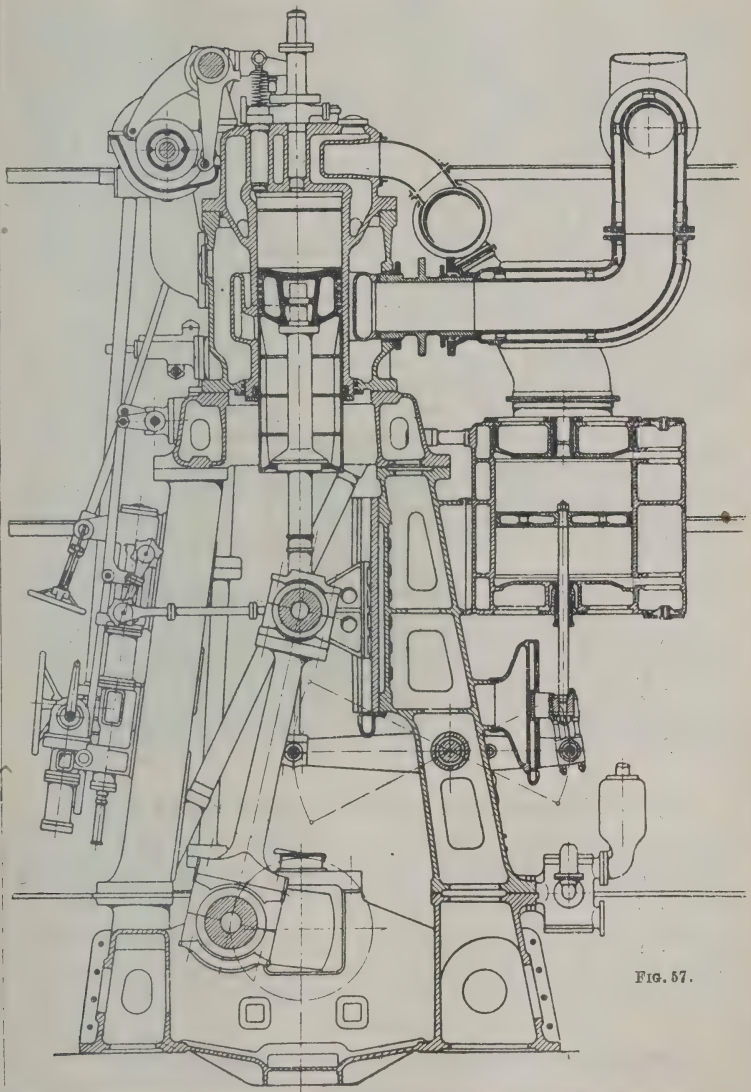

FIG. 57.

Diesel Engines for Submarines.

Practically all the European and American navies are now solely relying upon Diesel engines for the propulsion of submarines on the surface. These motors are of totally distinct type from those of the ordinary marine engine owing to the necessary high speed in order to reduce the weight sufficiently. They usually run at 400 to 500 r.p.m., and they are now constructed in powers up to 1,300 b.h.p. In the German and several other European Navies the Krupp two-cycle engine was employed, and also that of the M.A.N. Co., which is likewise of the two-cycle single-acting type. The former is a six-cylinder machine with two scavenge cylinders in the centre driven direct off the crankshaft, whilst in the latter the scavenge pumps are arranged directly beneath each working cylinder. The air pumps for air injection are also driven off the engine, so that it is practically self-contained. The weights of these motors are low, and usually somewhere in the neighbourhood of 50 to 60 lbs. per b.h.p. hour. For the British Navy the Vickers type is usually employed, which is a four-cycle twelve-cylinder motor of about 1,200 b.h.p. In this engine, solid injection of fuel is always adopted—thatis, the injection by mechanical means instead of compressed air. The advantage of this is that no air compressor is required, which is very desirable in a submarine. Although the engine as a Diesel engine is not quite so efficient as with air injection, the absence of air compressor renders the overall economy about the same as in other types of motors. It is doubtful, however, whether such heavy fuel may be satisfactorily employed as with the other engines, and Broxburne shale oil is generally used in these submarines. Two-cycle engines have also been designed for operation with mechanical injection.

Other types of Diesel engines are now used in British submarines, and one of the first of the two-cycle types to be employed for the purpose is the F.I.A.T., which was installed in the first submersible built by Scott's Shipbuilding and Engineering Co. In this engine the scavenge pumps are arranged beneath the working cylinders as with the M.A.N. engine previously mentioned, the pistons being stepped in the ordinary manner. Other types of two-stroke Diesel motors will be installed in British submarines, if they have not already been so fitted.

In order to keep the piston speed of submarine engines within the limits which it is not desirable to exceed (from 900 to 1,100 ft. per min.), it is usual to make the ratio of the stroke to the bore very much less than with the ordinary mercantile type of motor. Frequently the stroke is made equal to the diameter of the cylinders, and is very seldom more than 10 per cent. greater. In this way it is possible to construct Diesel for submarine purposes almost equal from the point of view of reliability to the slow-running types. High-speed engines of 1,300 h.p. have been constructed for installation to submarines, and others of over 2,500 b.h.p. in eight cylinders have been designed, and are possibly now being built for the same purpose.

A particularly important type of submarine Diesel engine is illustrated in fig. 58. This is a Sulzer motor as employed in several navies, and mainly follows along the lines of the slow speed mercantile Diesel motors built by the same firm and described in the preceding pages. The most notable feature is that port scavenging is employed and the method of introduction of an extra supply of scavenging air through valve controlled auxiliary ports is the same as in the larger sets. It had been thought that the high speed of rotation (350–500 r.p.m.) might render this system inefficient for submarine engines, but this does not appear to be the case. Motors of this design are being built in powers up to 4,000 b.h.p. per engine.

In their latest submarine motors the F.I.A.T. Company have also adopted the port scavenging arrangement, and engines of 1,300 h.p. in eight cylinders built according to this principle have already been installed in Italian submarines.

Output, Dimensions, and Weights of Diesel Marine Engines.

The design of Diesel engines in regard to the main dimensions of cylinders, etc., is not yet on a very definite or exact basis, mainly owing to the variations of mean effective pressure in the cylinders, and the uncertainty regarding the best speed of revolution. The output of a cylinder varies with the diameter, the stroke, the mean effective pressure, and the speed of revolutions. In general terms it may be expressed as follows:

B.H.P. $= KD^2 LNn$, where K = a constant; D = diameter of cylinder L = stroke of piston; N = revolutions per min.; n = number of cylinders.

Taking the dimensions of the cylinders in inches it is found that for four-cycle engines the value of K varies between ·00007 and ·00009, a good average figure being

$$K = \cdot 00008.$$

For two-cycle engines the value is between ·000125 and ·000155, the average being

$$K = \cdot 00014.$$

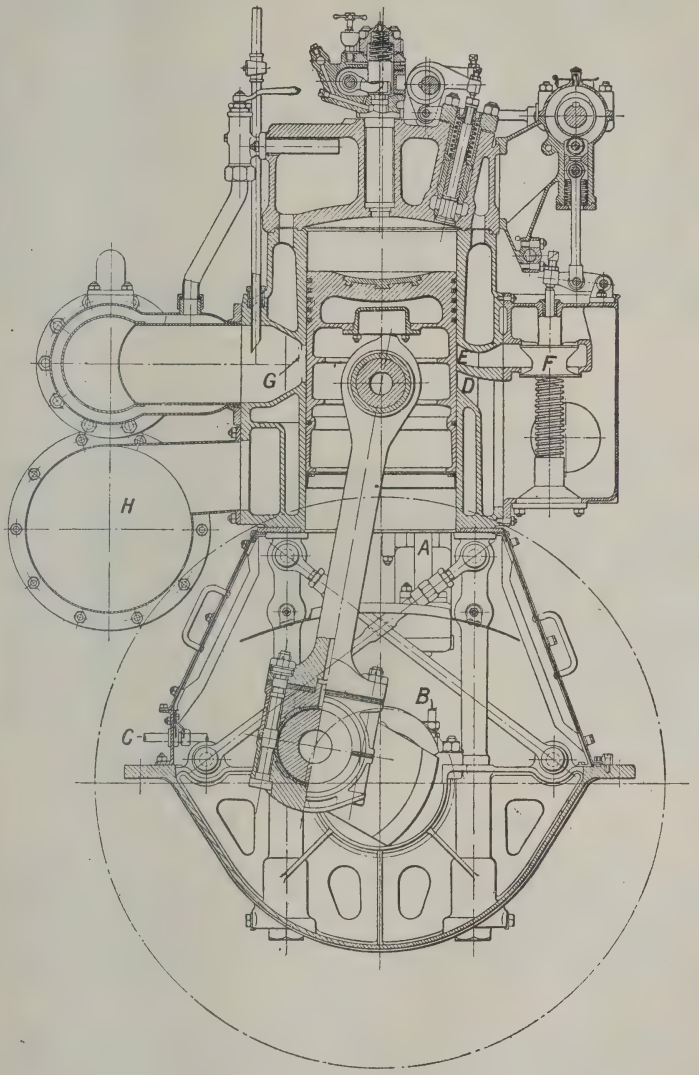

FIG. 58.—SULZER SUBMARINE DIESEL ENGINE.

As the mean effective pressure varies between 70 and 105 lbs. per square inch, and is sometimes higher, it is evident that cylinder dimensions are no absolute criterion of the exact output of a Diesel engine at a constant speed of revolution.

The piston speed in two- and four-cycle engines is approximately the same, namely, about 3 metres per sec., or 580 ft. per minute, with the ordinary slow-speed marine motors. It does not often vary between wider limits than 550 and 650 ft. per min., except in high-speed engine of the type employed in submarines, when it may be as much as 1,100 ft. per minute.

The ratio of stroke to bore is a matter of wide variation, and in some cases is as low as 1·3 and others as high as 1·8. This latter figure is common in most two-cycle motors with value scavenging, whilst 1·3 to 1·45 is more usual with port scavenging engines. Some types of four-cycle motors have a ratio of 1·4 and others 1·8.

The weight of Diesel marine engines varies as a rule between 200–300 lbs. per b.h.p., but is reduced to 60–70 lbs. per b.h.p. in submarine motors. Four-cycle engines are heavier than two-cycle, but the difference is not very marked, except in special cases, average figures being 300 lbs. in the first case and 250 lbs. in the second. This includes air compressors, scavenge pumps (in two-cycle motors) and various bilge, oil, and circulating pumps driven direct off the engine.

Power of Diesel Marine Engines.

The following table gives details of the dimensions and powers of some of the types of Diesel marine engines as now built :—

Engine.	B.H.P.	Diam.	Stroke.	R.p.m.	No. of Cyl.
Sulzer	850	18·5	26·8	160	4
Polar	800	15·7	21·25	165	6
Burmeister & Wain	1,100	20·5	28·5	140	8

Diesel Marine Engines in Service.

Motor ships have now been in operation for some considerable time, and it is possible to see in what manner the chief defects have developed. On the whole the four-cycle engines have proved most satisfactory, probably owing to the fact that more experience has been gained with this type of motor previously for land work. In the two-cycle engines one of the chief difficulties encountered has been the cracking of cylinder covers which has occurred with many engines. Cast steel, which was employed in some instances, has now been abandoned entirely in favour of cast iron, and with a proper mixture it is probable that the cracking of covers will in future be avoided. Air compressors have in some instances given rise to difficulty, whilst in the four-cycle motors, as might have been anticipated, the exhaust valves have required special attention.

The 1919 report of *Lloyd's Register of Shipping* devotes considerable attention to the development of the Diesel oil engine. Several vessels of considerable size fitted with Diesel engines were built during the war to the Society's class by Messrs. Harland & Wolff and by Messrs. Burmeister & Wain, of Copenhagen. The largest Diesel engines which have been fitted in any merchant vessel are the twin screw engines made by Messrs. Harland & Wolff, of Glasgow, for the motor vessel 'Glenapp' of 7,374 tons gross, which was built in 1918 by Messrs. Barclay, Curle & Co. Ltd.

The following table of typical vessels illustrates the advance which has taken place in the construction of Diesel engines :—

Name.	Tons.	Twin or Single Screw.	Date of Build.	Cylinders.		Stroke.
				No.	Diam.	
Vulcanus	1,179	Single	1910	6	$15\frac{3}{4}$	$23\frac{5}{8}$
Selandia	4,950	Twin	1912	16	$20\frac{7}{8}$	$28\frac{3}{4}$
Juno	2,345	Single	1912	6	22	$39\frac{3}{8}$
Siam	5,296	Twin	1913	16	$23\frac{1}{2}$	$31\frac{1}{2}$
Fiona	5,219	,,	1914	12	$29\frac{1}{2}$	$43\frac{5}{16}$
Panama	5,239	,,	1915	12	$24\frac{13}{16}$	$37\frac{13}{16}$
Glenamoy	7,269	,,	1916	12	$26\frac{3}{4}$	$39\frac{3}{8}$
Glenauy	5,075	,,	1917	12	$24\frac{13}{16}$	$35\frac{1}{2}$
Glenapp	7,374	,,	1918	16	$29\frac{1}{2}$	$43\frac{5}{16}$

There are now 69 vessels in service fitted with Diesel engines, which have been constructed in accordance with the Society's rules.

Oil Fuel for Diesel Engines.

(See also FUELS Section, page 1807.)

The fuel most commonly used in Diesel engines is that known as the residual oil, which is obtained by the process of distilling the crude oil when the lighter spirits are carried over, and the residual remains. Some crude oils are, however, directly used in Diesel motors, and in particular Texas oil, which does not contain sufficient proportion of petrol and other lighter oils to warrant its distillation. The only oil fuel which is unsuitable for employment is that from an asphaltum base, and it is for this reason that Mexican fuel oil is not as a rule employed for these motors without special treatment. Besides Texas oil, that from the Californian, Persian, Trinidad, Galician, Roumanian, and Russian oilfields is satisfactory for use in Diesel motors. Tar oil, which is obtained from the distillation of tar, is also very largely utilised in Germany, where the duties on imported oils are excessive, and often render the employment of Diesel engines unprofitable. Tar oil has a higher specific gravity than the petroleum fuel (usually in the neighbourhood of unity or slightly over), and has a lower calorific value, so that the consumption of an engine using this fuel is greater than when running on the ordinary oil. It is very viscous and, therefore, often requires heating, whilst some slight modifications have usually to be made in the fuel injection arrangements in order that an engine should run quite satisfactorily on tar oil. The usual method is to allow the injection of a small quantity of a lighter fuel oil before the main body of the tar oil passes into the cylinders through the pulveriser. It is claimed, however, that some motors run without any modification whatever, but this should not be taken as a general statement.

For information relating to Diesel engines for land installations, see page 1667.

LLOYD'S RULES FOR MARINE INTERNAL-COMBUSTION ENGINES. *See page* 1698.

Metals for Propellers.

A properly designed bronze screw will give a very marked increase of speed (as much as *half a knot*) as compared with an iron or steel propeller, this being due to reduced scantlings, smoother surfaces, etc. Whilst the efficiency of a bronze screw continues unimpaired, that of an iron or steel propeller diminishes, through the pitting and corroding of its surface. In the case of solid screws the reduction in weight as compared with a cast-iron screw ranges from 20 to 25 per cent.

Nearly all vessels of any size or pretension are now fitted with bronze propellers. The metal has a tensile breaking strength of about 32 tons per square inch with about 20 per cent. elongation, and a transverse strength of over 7,500 lbs. per square inch. All warships as well as many merchant steamers are fitted with bronze propellers. Cast-steel propellers cost about twice as much, and bronze propellers about five times as much, as those of cast iron.

The *Bull's Metal Company* have with great success combined the study of Bronze Propeller designs with that of material, manufacture, and finish, large numbers of ordinary Bronze Propellers having been replaced with Bull's Metal propellers, giving, it is stated, a very material increase in speed on a reduced consumption of coal.

The *Delta Metal Co. Ltd.*, supply their special corrosion-resisting 'Delta' propeller bronze for casting propellers and propeller blades.

(See also Section XXXVII, METALLURGY.)

Propeller Design.

As this is largely based upon experimental data it is impossible to give any reliable formula for designing propellers. The most generally recognised authorities on the subject are Froude in this country and Taylor in America, the results of whose experiments have been published in the form of series of curves in the Transactions of the Institution of Naval Architects (of Britain) for 1892 and 1908 (I) and of the Society of Naval Architects and Marine Engineers (of America) for the year 1904. To these volumes therefore we refer the reader.

Metals for Marine Engines.

Delta Bronze Nos. I. and IV. alloys (see Index), Phosphor bronze, and Phosphor white lining metal No. II. are especially suitable for various parts of marine engines; the latter metal (phosphor white) has a higher fusing point than good Babbitt metal, thus allowing a bearing to heat without causing the metal to melt, a matter of some importance at sea.

Delta Bronze No. IV., a malleable bronze of great strength and tenacity, is specially adapted to replace steel in cases where a material of the highest corrosion-resisting qualities is desired. For this reason it is employed on a very large scale in the form of forgings or extruded or rolled rods, etc., for air and circulating pump rods, shafts, plungers, spindles, thrust block bolts and other parts of marine engines. For particulars of corrosion-tests, see page 252.

Bull's Metal Propellers

Combine the strength and toughness of mild steel with the resistance to corrosion of gun metal. Their adoption means a considerable increase in speed or saving in coal consumption. See our Catalogue.

Bull's Metal Bars & Forgings

Possess the mechanical properties of mild nickel steel with extreme resistance to wear and corrosion. See our Catalogue.

F. 2059

Phosphor-bronze sheet is superior to copper in withstanding the action of sea-water. In a comparative experiment made at Blankenberghe, lasting over a period of six months, between the best English copper and phosphor bronze, the following results were arrived at : the loss in weight due to the oxidising action of the sea-water averaged for copper 3·058 per cent., while that of the phosphor bronze was only 1·158 per cent.

For lining bearings, crank-pin bushes, and other parts, exclusive of crosshead bushes, the following alloy has been found to give good results after extended experience in hard ocean steaming :—12 parts tin, 1 part copper, 1 part antimony, mixed in the following way : 6 parts tin alloyed with 1 part of antimony, and 6 parts tin with 1 of copper, and the two mixed together. For lining crosshead brasses the following harder alloy has been found to give good results : 85 per cent. tin, 5 per cent. copper, and 10 per cent. antimony.

The *Eyre Smelting Co. Ltd.*, who have made a special study of bearing metals for marine engines, supply a particular alloy of white metal which is stated to give good results in the big end bearings of Diesel engines. For the small end bearings the company supply a mixture of phosphor bronze, which is largely used in this country and on the Continent.

Painting Ships' Bottoms.

Ordinary oil paints are not suitable for this purpose, particularly because the drying of each coat of oil paint takes a longer time than owners can afford to allow vessels to remain in dock ; besides, these paints possess little or no power to prevent fouling. The practice, therefore, is to use what are termed ' compositions,' which are usually applied in two coats.

The composition paints have to be used in combination. The anti-corrosive, as a preservative and insulating coating, should be applied when the bottom is well scraped and dried. The anti-fouling composition contains powerful poisons and can be applied almost immediately after the primary coating, and the vessel can be floated as soon as the painting is completed, although it is desirable to allow the compositions a few hours to harden before the vessel enters the water.

It is very important to remove all rust or scale on the plates, as when such is not done corrosion is likely to continue beneath the surface and will eventually throw off any paint that can be applied. The ingredients in the best compositions are very expensive and are consequently not used to any extent in the manufacture of the cheaper brands.

The careful *stirring* up of these compositions is an essential point too often overlooked. The more valuable ingredients are heavy, and tend to form a sediment at the bottom of the drums, which requires to be carefully worked up. Much also depends upon careful painting—a thing which is unfortunately very difficult to arrange for in many of the dry docks owing to hurried and inefficient work.

Concrete Vessels.

A concrete weighing but 110 lbs. per cub. ft. and having a crushing strength after 28 days of 4,000 lbs. per sq. in. has been employed in the construction of reinforced concrete vessels of large tonnage, in America, for the United States Government. The aggregate itself, although light and cellular in structure, is not porous. The lighter quality will actually float on water, and as a test the United States Shipping Board authorities kept an amount of aggregate floating in water for some months, and it was demonstrated that the absorption was very small.

The aggregate is made from clay, calcined in kilns in a similar manner to that employed in the manufacture of bricks, the fundamental difference being that the heat (about 2,000° F.) is applied in a comparatively short time of 30 hours. This relatively sudden application of heat causes the material to swell, forming a clinker. The clay may be pressed into bricks and partially dried and stacked in kilns in the ordinary manner, care being taken to provide sufficient room around the bricks for expansion during burning. The size of the brick adopted in the United States is $8\frac{1}{2}$ ins. by $4\frac{1}{2}$ ins. by $2\frac{3}{4}$ ins. During burning, the bricks run together and form a solid mass of clinker, which is allowed to cool for about 3 days, in order to ensure a high degree of toughness. The cooling of the material is then completed by water, which causes the mass to split into pieces suitable for handling, and it is also found that this greatly facilitates the unloading of the kilns. The material may also be calcined in cement rotary kilns, the clay in this case being pressed into lumps of suitable size.

After burning, the product is crushed to the desired size. During the operation a proportion of the lightest aggregate is reduced to dust. This, however, is used to take the place of the sand or crushed stone in ordinary concrete, the constituent parts being carefully selected and graded. Light pneumatic hammers are used to vibrate the shuttering during ramming, materially assisting the flow of the concrete around the steel reinforcement, and producing a dense and impermeable material.

A number of reinforced light concrete oil tankers and cargo steamers of 7,500 tons deadweight have been under construction in various parts of the United States. These vessels are 434 ft. long. (*W. L. Scott, ' Engineering.'*)

When wood is used as a reinforcing material for concrete it should be impregnated with magnesium chloride, and the wood must be so placed that any change in the cross-sectional area does not affect the durability of the structure. If the latter precaution is overlooked the concrete may crack. Small strips of wood are better than larger ones, and rushes appear to be excellent for the purpose, especially for thin-walled structures such as ships.

(Beton u. Eisen.)

LLOYD'S RULES FOR FERRO-CONCRETE VESSELS.

No definite rules have as yet been formulated, but in regard to the quality and testing of steel to be used for reinforcements these are the same as given in Section 3 of the Rules of the Society, for Steel Ships. The cement should comply with the requirements of a recognised standard specification for Portland cement or the equivalent thereto. In the matter of the preparation of the concrete, the proportions of the cement, sand, and aggregate have been left to the individual constructors to submit their proposals for the consideration of the Committee, as these depend to some extent on the local facilities for obtaining sand and gravel, the quality of which varies in different districts.

In the design of vessels to be built of ferro-concrete, it is considered that concrete is incapable of withstanding any of the main tensional stresses, and the steel reinforcements embedded in the concrete must therefore be of sufficient strength to take up all the tensional stresses produced in the structure due to strain from longitudinal bending.

LLOYD'S TENTATIVE REGULATIONS FOR THE APPLICATION OF ELECTRIC ARC WELDING TO SHIP CONSTRUCTION.

(Abstract.)

Before welding, the surfaces to be joined must be fitted close to each other.

All butt and edge connections are to be lapped or strapped.

With lapped connections the breadths of overlaps of butts and seams and the profiles of the welds are to be in accordance with the following table :—

Thickness of plate. Inches.	Width of overlap seam and butt. Inches.	Throat thickness. Inches.
·40 and under	$2\frac{1}{4}$	·28
·60	$2\frac{1}{2}$	·38
·80	$2\frac{3}{4}$	·48
1·00	3	·50

Intermediate values may be obtained by direct interpolation, and for thicknesses below ·40 the throat thickness is to be about 70 per cent. of the thickness of the plate.

(Contributed by Alwyne Meade, A.M.Inst.C.E., author of 'Modern Gasworks Practice.')

Parliamentary.

The public supply of gas in this country is governed largely by local Acts, but in general by the Gasworks Clauses Acts of 1847 and 1871, the Sale of Gas Act of 1859, and the Gas and Water Works Facilities Acts of 1870 and 1873, and most recently by the Gas Regulation Act (1920). London companies are, in addition, under the regulations of the Metropolitan Gas Act (1860). Under the Public Health Act of 1875, the local authority may become its own gas supplier, or may purchase an existing undertaking by agreement. Thus gasworks are controlled by—

(*a*) Statutory companies.
(*b*) Non-statutory companies.
(*c*) Local authorities.

The supply of gas in Scotland is, for the most part, in the hands of the local authorities. In England local authorities predominate as owners in the counties of Yorkshire and Lancashire, and in the North generally, but in the Home and Southern counties private ownership is the general rule. In addition to the Acts named above, the supply of gas in Scotland is governed by the Gas Acts of 1864 and the Burghs Gas Supply Acts of 1876 and 1893.

The obligations of the gas undertakings in the way of standards of quality were somewhat modified by an order made by the Minister of Munitions in June, 1918, as to the manufacture and production of gas, compliance with which order by the gas undertaking protected the undertaking from any forfeiture for failing to comply with its statutory obligations with regard to the illuminating power or the calorific power of the gas supplied, provided that in any event gas of a lower calorific power than 450 B.Th.U. gross was not supplied to the consumers.

In July, 1918, a measure—The Statutory Undertakings (Temporary Increase of Charges) Bill—was introduced and passed. The Bill, although it fell short of its objective, was designed to provide relief from the provisions of the Sliding Scale, provisions which had shown themselves to be particularly inequitable during abnormal conditions such as resulted from the European War. In effect, the Bill enabled any statutory undertaking adversely affected by circumstances arising out of the war to make application to the Board of Trade for permission to modify its charges to an extent not more than sufficient to enable it to pay a dividend on its ordinary stock or shares at three-quarters of the standard rate or one-half of the pre-war rate, whichever might be the lower. The decision was made applicable not only to gas undertakings but to other public utility services, namely, electricity, water, and tramways.

It may be said that a new era in the supply of gas was marked by the introduction of The Gas Regulation Bill. The commodity is no longer sold on a basis of cubic feet, but in terms of 'Therms.' In other words, the consumer now pays for the useful energy only, i.e. British Thermal Units; accordingly, the incombustible constituents in gas have no longer any commercial value. The standard 'Therm' is equivalent to 100,000 B.Th.U. Thus, if 10,000 cubic feet of gas are registered on the consumer's meter, and the 'declared' or normal calorific power of the gas is 500 B.Th.U. per cubic foot, then the number of B.Th.U. consumed is 5,000,000, or 50 Therms.

The main provisions of the Act are as follows:—

(*a*) The obligation to charge consumers on the heat unit basis.

(*b*) The adjustment of the 'standard' or 'maximum' price (on the heat-unit basis) to meet the additional expenses of manufacture and distribution arising from post-war conditions.

(*c*) Powers are given to the Board of Trade to limit the proportion of inert constituents in the gas, if thought fit; but the committee recently appointed to examine the question of incombustibles recommended that no limit should yet be imposed.

(*d*) There is an obligation to supply gas at 2 ins. water pressure in mains or services of 2 ins. diameter and upwards.

One of the most noteworthy provisions of the Act is the latitude which is given to gas undertakings in connection with the quality of gas supplied. The old standard of illuminating power has completely given way to calorific power, and the producer is permitted a free choice in the type of gas he distributes. He must, however, declare at what calorific power he is prepared to supply, consumers' appliances must be adjusted by him to consume the 'declared' variety of gas to the best advantage, and, in order to preclude excessive fluctuations in quality, certain penalties are imposed when the heating value falls below a prescribed limit. As regards the machinery for carrying on the Act, powers are given to the Board of Trade to grant facilities which in the past have entailed formal application to Parliament.

A non-statutory company operates as the result of established practice, or under the goodwill of the local authority. Its position is in many respects similar to that of a statutory company, but before opening roads for the laying of mains permission must be obtained from the district or county authority.

Consumption per Head of Population.

In the larger towns the average consumption of gas per head of population varies from 5,500 to 10,000 cub. ft. per annum. In smaller towns it ranges between 3,000 and 7,500 cub. ft. Gas-works statistics are, however, generally based on the consumption per consumer, which figure, for consumers through ordinary meters, approximates to 42,000 cub. ft. per annum, and 15,000 cub. ft. for those taking the gas through 'slot' meters. In addition, there will be an appreciable consumption for public lighting, and about 5 per cent. of the whole output will be written off as 'unaccounted for.' In straggling districts with long lengths of mains the latter figure may reach so much as 10 per cent. Taking the country as a whole, the average consumption per consumer at the present time works out at almost exactly 30,000 cubic feet (say 150 therms) per annum.

Capital Expenditure.

This item varies considerably in accordance with the size of the installation and the current price of labour and materials. In pre-war times, however, a concern promoted for the erection of a modern works with the accompanying distribution plant found it possible to complete the scheme for 600*l.* per million cubic feet sold per annum. For smaller country works, the outlay was very much greater, varying from 750*l.* to 1,000*l.* per million cubic feet, or even more. The following figures show the approximate capital outlay in 1919 (neglecting floating capital and nominal additions) in the case of representative companies:—

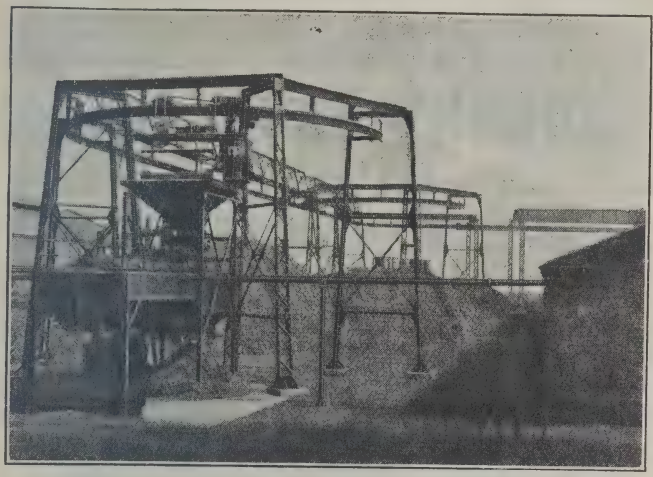
	Per million cubic feet. sold per annum.
Gaslight & Coke Company	495*l.*
Brighton	437*l.*
Derby	358*l.*
Birmingham (Corporation)	262*l.*
Manchester (Corporation)	583*l.*

It is a somewhat surprising fact that at the present day the expenditure on the district mains, etc., is generally rather greater than that laid out in the erection of the works. Of the total outlay approximately 55 per cent. will be expended on the district, 38 per cent. on the works, and the remainder on Parliamentary, promotion, and engineers' expenses.

General Rules relating to Capacity of the Apparatus, etc.

LAND

The area of land required for the erection of the works will amount to at least 2½ acres per million cubic feet of gas per maximum diem.



(NOTE.—The make of gas per maximum diem is calculated by dividing the total annual production by the factor of 240.)

RETORT HOUSE.

Dependent upon the size of the unit, i.e. the number of retorts set in each arch or section. The make per retort per 24 hours for different types of units is given in the following table:—

STOP-ENDED OR 'SINGLE' RETORTS.

	Cub. ft. per diem.
Length 9 to 10 ft., section 15 ins. round	3,000 to 4,000
,, 10 ft., section 16 ins. round	4,000 to 5,500
,, 10 ft., section 21 ins. by 15 ins. dee	7,000 to 8,500
,, 10 ft., section 22 ins. by 16 ins. dee

F. 2065

'Through' Retorts.

	Cub. ft. per diem.
Length 20 ft., section 24 ins. by 16 ins. dee	18,000 to 20,000
„ 20 ft., section 22 ins. by 18 ins. oval	18,000 to 21,000

A later development is the short 'through' retort, 12 to 16 ft. in length.

Vertical Retorts.

	Cub. ft. per diem.
Woodall-Duckham type	30,000 to 80,000
Glover-West type	25,000 „ 50,000
Intermittent type	12,000 „ 20,000
Glasgow type	31,500 „ 37,500
Chamber ovens	100,000 „ 120,000

The gas yield from vertical retorts is extremely flexible, very much depending upon the proportion of steam admitted.

(Note.—It is usual on gasworks to speak, not of the make per retort, but of the 'make per mouthpiece' per diem. As a 'through' retort has two mouthpieces—one each end—the make on this basis is half the retort make.)

Coal Storage.

In the present day, owing to uncertainty of delivery and such causes, it is advisable for gasworks to keep in hand much larger stocks than were thought necessary some years ago. No undertaking can now afford to risk three weeks' storage, although this is a usual and sufficient allowance for that kept under cover. When ground area is available large stocks may be arranged for out in the open. The calculation of the stock of coal in hand may be performed by assuming that one ton of average gas coal occupies from 42 to 43 cub. ft. For the convenience of dealing with stocks of other materials used on gasworks the following figures are given :—

One ton of coke occupies	85 cub. ft. (average).
„ „ broken coal occupies	40 „
„ „ cannel coal occupies	35 to 45 cub. ft. (varies considerably).
„ „ anthracite coal occupies	35 to 39 „
„ „ breeze occupies	60 to 65 „
„ „ lime occupies	42 „
„ „ oxide of iron (Dutch)	45 „
„ „ ditto (prepared)	41 „
„ „ sulphate of ammonia	47 to 48 „
„ „ ashes	50 „ (about).
„ „ Portland cement	23 to 26 „
„ „ loose earth	28 to 30 „

Condensers.

Water condensers are now largely used in preference to atmospheric types. Many of the latter kind are, however, still in use, and are not without their recommendations. Rules for condenser capacity vary to some considerable extent, and there is by no means agreement on the subject. The following are given as representing the average practice :—

Atmospheric condensers.—Allow 5 sq. ft. of atmospheric condensing surface per 1,000 cub. ft. of gas made per diem.

Water condensers.—Allow 3 sq. ft. of surface per 1,000 cub. ft. per diem.

In using the first of these two rules it must be borne in mind that the figure arrived at includes (in addition to the areas exposed by the actual condenser) the area of all piping between the outlet of the hydraulic main and the inlet of the condenser. In making calculations the actual surface to be considered is that with which the gas is in contact. Thus, when the gas travels inside a tube the interior surface must be taken, and when outside the exterior surface is considered.

Water condensers are of two distinct types :—

(*a*) Multitubular condensers.
(*b*) Water-tube condensers.

In the first type the gas passes through the tubes, which are surrounded by a water jacket. In the second type the water is within the tubes and the gas around them. As to which type is chosen depends entirely upon the conditions of working. When any deposit is likely to take place it is preferable to have this within the tubes which may be readily cleaned. Thus, when muddy water alone is available there should be no hesitation about adopting the water-tube type. On the other hand, when the gas dealt with is likely to be particularly dirty or to contain a large quantity of heavy tar vesicles the multitubular type is to be preferred. Condensers for carburetted water-gas are invariably of the water-tube type. As regards general dimensions the height of the apparatus should be from two to five times the diameter; 3-in. tubes are preferable for the larger condensers, but 2-in. pipes will suffice for those of smaller design. Th

ratio of the length of the tube to its diameter should be within the limits of 80 to 1, otherwise the tube loses in structural stability. In the direction of the number of tubes to be employed a good basis to work upon is that of arranging the tubes so that they occupy about 18 per cent. of the total area of the tube-plate. For water-gas condensers this may be increased to 25 per cent.

EXHAUSTERS.

In a works of from 4 to 6 million cub. ft. capacity per annum the saving to be effected by the installation of exhausters is problematical, after consideration has been given to interest on capital and running costs. Over six millions capacity the advantages of the machine are unquestionable. In the smaller works (from 15 to 20 million cub. ft. per annum) driving is nearly always carried out by means of a gas engine, the same engine providing power for operating tar, liquor, and other pumps. The effective hourly capacity of an exhauster is guaranteed by the makers. For the capacity of a four-blade machine, however, the following formula may be taken; it is not to be recommended when dealing with very large or very small exhausters:—

$$Q = 65D^2LN;$$

where Q = cub. ft. passed by the exhauster per hour; D = inside diameter of outer drum in ft.; L = length of drum in ft.; N = number of revolutions per minute.

This gives the gross capacity. To arrive at the nett capacity, about 20 per cent. must be deducted (for 'slip') from the figure obtained.

On the larger works it is usual to maintain a vacuum of about 4 ins. of water at the exhauster inlet. At the outlet, the pressure to be overcome varies in accordance with the resistance offered by the apparatus following and the quantity of gas passing at the time. As a general rule the total back-pressure may vary between 8 and 10 ins. on a small country works to as much as 50 ins. of water on the largest plants, but under average conditions the following pressures will approximate to those found at the different portions of the apparatus:—

Retorts	Level gauge.
Hydraulic main	½ in. to 1 in. vacuum.
Exhauster inlet	4 ins. vacuum.
,, outlet	30 ins. pressure.
Tar extractor, outlet	26 ins. ,,
Washers, outlet	24 ins. ,,
Scrubbers, outlet	22 ins. ,,
Purifiers, outlet	9 ins. ,,
Station meter, outlet	8·5 ins. ,,
Holder, inlet and outlet	8·5 ins. ,,

It will be seen from the above that the forcing of the gas through the dry purification material and the raising of the holder bell account for by far the greatest portion of the work against back-pressure which the exhauster is called upon to perform.

RUNNING SPEED.

The speed at which the exhauster operates should be gauged, not by a consideration of the revolutions performed per minute, but by the peripheral speed of the tips of the blades. This speed should be approximately constant for all sizes of exhausters, and should lie within the limits of 650 to 850 ft. per minute.

LUBRICATION.

This is a point requiring the most careful attention. Much depends upon the type of lubricant made use of, the best being a mixture of refined creosote and a mineral oil. These should be admixed in the proportion of one part of creosote to three parts of mineral oil. A vegetable oil should not be used, as this will tend to thicken the tar inside the drum.

In modern practice there is a tendency for the ordinary rotary blade type of machine to give way to the newer high speed turbo-exhauster working on the fan principle and providing large clearances. An advantage attached to this type of machine is that it has some considerable volumetric capacity per unit of floor-space occupied. The construction consists of an outer case provided internally with two or more impellers which rotate on a common axis, but in distinct cells. The gas is passed from cell to cell in series until it is discharged from the machine at the requisite pressure, the pressure obtained being dependent upon the size and speed of the impellers.

WASHERS AND SCRUBBERS

WASHERS.

The capacity of the wet purification plant depends very largely upon the type of apparatus employed, whether mechanical or merely static. Mechanical washer-scrubbers are now largely used, while of the static washers the well-known Livesey type has few rivals.

Rules for Capacity.—For washers of the Livesey and similar types allow one-seventh to one-fifth of a cubic foot capacity per 1,000 cub. ft. of gas passed per maximum diem.

For mechanical washer-scrubbers an allowance of one-half to three-quarters of a cubic foot capacity per 1,000 cub. ft. of gas per diem may be made.

Scrubbers.

Some works are provided with scrubbers of the tower type only, and have no separate washing vessels. In such cases the size of the scrubbers and their number may be based on the following rule :—

Allow 10 cub. ft. of capacity per 1,000 cub. ft. of gas dealt with per maximum diem. When the scrubbers are operated in conjunction with mechanical washer-scrubbers the above allowance may be reduced to from 5 to 6 cub. ft. When Livesey and such washers are employed prior to the scrubbers, the latter should have a capacity based on 6 cub. ft. of volume per 1,000 cub. ft. of gas per diem.

Washing and scrubbing capacity is greatly dependent upon the manner in which condensation is carried out. Extremely effective condensation will be the means towards reducing the usual wet purification allowances by nearly 50 per cent.

Horse-Power Required to Drive Washer-Scrubbers.

The following figures refer to the power necessary for the modern vertical type of machine. The horizontal machines of similar capacity will usually require one or two horse-power less :—

500,000 cub. ft. capacity per diem	4 H.P.
1,000,000 ,, ,, ,,	5 H.P.
2,000,000 ,, ,, ,,	7 H.P.
3,000,000 ,, ,, ,,	10 H.P.

It is advisable to allow a small margin (about 20 per cent.) above these figures for emergencies.

If the power employed is electricity, and this is obtainable for a halfpenny per unit, the cost of driving amounts to about 0·033*d.* per 1,000 cub. ft.

The ratio of the height to the diameter of tower scrubbers varies between 2½ and 5 to 1. In exceptional instances, however, it may be so much as 7 to 1, particularly in the case of scrubbers of small capacity. When the diameter becomes greater than 30 ft. the flat cast-iron top is inclined to sag. In such cases it may be found advisable to provide a domed top having a rise equivalent to one-sixth of the diameter, and made from steel.

As regards the material employed for packing, Livesey has given the following figures relating to the area of wetted surface exposed to the gas :—

	Sq. ft. per cub. ft. of Scrubber Capacity.
Coke	8½
Drain pipes, 3 ins. diameter	17
,, 2 ins. diameter	21
Boards on edge	31

Boards on edge, although expensive in the first instance, are to be preferred to any other type of packing. They conform to no hard and fast rule as regards size, but the following will afford satisfactory results :—

6-in. boards, ¼ in. thick, laid ⅜ in. apart.
11-in. boards, ½ in. thick, laid ½ in. to ¾ in. apart.

Water Required.

The amount of water required to effect wet purification depends very largely on the type of apparatus, but very variable results are found. As an average it may be taken that the water admitted to the final scrubber will vary between 10 and 13 gallons per ton of coal carbonised. At Salisbury Works it was found that with a modern form of vertical washer-scrubber the whole of the ammonia could be removed by admitting only 3¾ gallons of water per ton of coal carbonised.

DRY PURIFICATION PLANT.

Capacity of the dry purifiers depends upon the extent to which purification is carried. Nowadays it is customary to remove sulphuretted hydrogen alone, but if lime purification (for the removal of carbon disulphide) is resorted to it is advisable to employ rather larger vessels. It is always as well, however, that the vessels should be too large rather than too small, for the first cost increases but slowly as compared with the capacity, and purification charges undergo considerable reduction as the unit capacity becomes greater. For oxide boxes the following rule may be taken :—

For a set of four purifiers allow *for each box* an area of 0·5 sq. ft. per 1,000 cub. ft. of gas to be dealt with per maximum day. If lime is to be used this figure should be increased to 0·6 sq. ft., or 0·65 to 0·7 if no catch boxes are available.

Hunt's rule for the total amount of purification space required, i.e. the combined area of all boxes, says that 20 to 30 sq. ft. per ton of coal carbonised per maximum day should be allowed.

As regards the purifying capacity of oxide of iron it may be taken that one ton will purify about two million cubic feet of gas before it is finally spent.

Purifiers are invariably square or rectangular in shape and are constructed from cast-iron plates bolted together. In one or two isolated instances reinforced concrete vessels have lately been experimented with.

As regards the necessary thickness of the cast-iron plates the following figures may be taken as indicative of the general practice :—

Purifiers up to 10 ft. square	$\frac{5}{8}$ in. plates.
,, ,, 20 ,, ,, ...	$\frac{11}{16}$ in. ,,
,, above 20 ,, ,, ...	$\frac{3}{4}$ in. ,,

The flanges are usually cast $\frac{1}{16}$ to $\frac{1}{8}$ in. thicker than the body. The smallest vessels are usually 3 ft. deep, while the largest sizes vary from 6 to 8 ft. in depth. The following rule is suggested for ascertaining the required depth :—

$$\text{Depth in feet} = \sqrt[4]{\text{Total superficial area} \times 1{\cdot}1}.$$

The depth as given may be taken to the nearest foot. For smaller purifiers, i.e. up to 300 sq. ft. in area, multiply by 1·3 instead of 1·1.

PURIFIER CONNECTIONS.

The diameter of the connecting mains is most readily and accurately computed from the following formula :—

$$\text{Diameter of pipe in ins.} = \sqrt{\text{area of each box in sq. ft.}}$$

For small purifiers (up to 60 sq. ft. area) the result can be taken as it stands, but for medium size boxes deduct 16 per cent., and for large vessels 25 per cent.

CONSTRUCTIONAL NOTES.

From the point of view of economy water-lute purifiers should be so constructed that the lute is portion of the side plate itself and not a distinct unit. This method of construction facilitates erection and is less costly in the first place. The depth of the lute is usually half the depth of the side plate, but the depth of water obtainable must in all events be sufficient to withstand the greatest pressure which is likely to prevail within the box. The covers of purifiers are invariably made from wrought iron or steel plates, usually about $\frac{1}{4}$ in. in thickness. They are either flat or slightly curved, but in either case some form of trussing or stiffening is necessary, and strong curbs should be provided when the vessel is of any size. In modern purifiers the water-lute principle is largely abandoned, and dry-luted covers are provided. These possess many advantages over the older method, chiefly in the direction of initial outlay, whilst they combine greater durability with increased safety. Moreover, owing to the lighter construction of the covers the lifting apparatus may be less cumbersome and costly. A gastight joint between cover and box is usually ensured by inserting a strip of rubber or tallowed hemp between the parallel flanges, the two flanges being afterwards pulled together by means of special fasteners or ordinary bolts.

For carburetted water gas purifiers the capacity allowed should be rather greater than is the case with purifiers used in connection with coal gas. A satisfactory allowance is 0·8 sq. ft. per 1,000 cub. ft. of water gas per maximum day.

STORAGE CAPACITY.

The holder capacity necessary is somewhat dependent upon whether or not the works is provided with a water gas plant. If such a plant is available the storage allowed for need not exceed 18 hours maximum make, but if there is no water gas to fall back upon provision should be made for 21 to 24 hours maximum production. In years gone by it was customary to provide considerably greater storage chiefly on account of the heavy fluctuations in output. The levelling up of the hourly load-curve has, however, had a marked effect in the direction of diminishing the quantity of gas kept in hand.

PROPORTIONS OF GASHOLDERS.

Single lift height = 0·3 to 0·4 of diameter.
Multiple lift height = 0·6 to 1·0 of diameter.

In computing the capacity of a holder the volume enclosed by the crown is neglected, as the gas contained therein is not available for distribution. Accordingly

$$\text{Capacity in cub. ft.} = \cdot 7854 \times \text{diameter in ft.}^2 \times \text{height in ft.}$$

With multiple lift holders the capacity of each lift should be estimated separately by applying the above formula to each section.

DEPTH OF LIFTS.

Each lift will be approximately of equal depth.

RISE OF CROWN.

The greater the rise the stronger will be the crown. The dome should conform to a segment of a sphere. Normally, the rise will range between $\frac{1}{5}$th to $\frac{1}{10}$th of the diameter, but when trussing is employed it may be less than when the plain crown only is used.

The cubic capacity of the crown space may be found from the following :—

$$\text{Volume in cub. ft.} = \cdot 5236\text{R}\left(\text{R}^2 + \frac{3\text{D}^2}{4}\right)$$

where

R = rise of crown in ft.;
D = diameter of top lift in ft.

The depth of each lift should never be less than one-seventh of its diameter, otherwise locking or tilting may occur. In general, the proportion varies between one-fourth to one-fifth of the diameter.

The crown sheeting of gasholders varies from 14 gauge to 10 gauge (about $\frac{5}{64}$ in. to $\frac{1}{4}$ in.), but much depends upon the size of the holder.

The side sheeting varies from 12 gauge to 10 gauge, but curb or cup and grip rows are thicker, $\frac{1}{4}$ in. to $\frac{3}{8}$ in. Top lift sheets are usually thicker than those of succeeding lifts, often about 8 gauge.

The thinner sheets of the bell are generally riveted up cold with $\frac{1}{4}$ in. rivets at a pitch of 1 in. to $1\frac{1}{8}$ in. All rivets above $\frac{1}{2}$ in. must be driven hot.

GASHOLDER TANKS.

Steel tanks have many advantages over the masonry variety, and cast-iron as a material for this purpose may now be looked upon as obsolete.

The thickness of plate required may be calculated as follows :—

$$\text{T} = \frac{\text{PD}}{2fe},$$

where

T = thickness of the plate in ins.;
D = diameter of the tank in ins.;
f = allowable working stress (usually $5\frac{1}{2}$ tons per sq. in.);
e = the efficiency of the vertical riveted seams. This will range up to 90 per cent. for large holders. For small holders it will vary between 75 and 85 per cent.;
P = the pressure due to the water in lbs. per sq. in.

The latter may readily be found from the following :—

$$\text{P} = \text{WD},$$

where

W = the weight of a cub. ft. of water = 62·4 lbs.;
D = depth below the surface of the section under consideration.

As regards the apportionment of the cost of gasholders, the following figures represent normal conditions :—

	Per Cent. of Total Outlay.
Bell, complete	35 to 45
Guide framing	18 to 23
Tank (steel)	35 to 45

Single lift holders (up to about 50,000 cub. ft.) cost in pre-war days from 25*l.* to 28*l.* per 1,000 cub. ft. If of the spiral type the outlay would be reduced by 25 per cent. Two lift holders (about 250,000 cub. ft. capacity) ranged from 16*l.* to 20*l.*; or, if spirally guided, about 10*l.* per 1,000 cub. ft. capacity. Holders varying from 2 to 3 million cub. ft. capacity cost from 9*l.* to 12*l.* per 1,000 cub. ft. The large 12-million holder at the East Greenwich Works cost five guineas per 1,000 cub. ft. capacity, whilst a $10\frac{1}{2}$-million holder at Manchester worked out at 5*l.* per 1,000 cub. ft.

CALCULATION OF PRESSURE THROWN.

The pressure thrown is dependent upon the weight of the floating portion and its diameter. It may be found as follows:—

$$\text{Maximum pressure (ins. of water)} = \frac{549W}{D^2},$$

where

W = weight of bell and water in lutes, in tons;
D = diameter of holder in ft.

When dealing with a multiple lift holder take the mean diameter.

Size of Works Mains.

No hard and fast rules are adhered to, but the following will form a guide as to the average conditions:—

Size of Works.	Suitable Size for Mains. Ins Diam.
3 to 4 million cub. ft. per annum.	5
6 to 10 ,, ,,	6
15 to 25 ,, ,,	8
30 to 45 ,, ,,	10
55 to 90 ,, ,,	12
100 to 150 ,, ,,	15
200 to 300 ,, ,,	18
350 to 450 ,, ,,	20 to 21
500 to 600 ,, ,,	24
600 to 900 ,, ,,	30

Composition of Various Gases.

Per Cent. by Volume.	Coal Gas.	Carburetted Water Gas.	'Blue' Water Gas.	Mond Gas.	Suction Gas.	Dowson Gas.
Hydrogen	49·0	35·0	52·0	26·0	16·0	20·0
Carbon Monoxide	9·0	32·0	38·0	15·0	34·0	24·0
Carbon Dioxide	2·5	4·5	4·5	12·0	3·0	6·0
Methane	27·0	13·0	1·0	3·0	nil	1·0
Heavy Hydrocarbons	4·0	10·0	nil	nil	nil	nil
Nitrogen	8·5	5·5	4·5	44·0	47·0	49·0
Candle Power	14·0	18·0	nil	nil	nil	nil
Calorific Power, B.Th.U. gross	550	580	300	165	160	155

Composition of Coal and Coke.

Per Cent.	Anthracite Coal.	Average Gas Coal.	Average Gas Coke.
Carbon	94·0	80·0	88·0
Hydrogen	2·5	5·5	0·2
Oxygen	0·25	8·8	traces to 3·0 (varies considerably)
Nitrogen	0·5	1·5	2·0
Sulphur	0·5	0·8	1·0
Ash	2·25	3·4	5·8
Calorific Power, B.Th.U.	15,500 per lb.	14,800 per lb.	13,500 per lb.
Volatile Matter	8 per cent.	30 per cent.	1 per cent.

Products of Distillation.

One ton of average gas coal will yield (approximately) the following products —

Gas (unstripped)	13,000 cub. ft. of 13½ to 14 candle-power.
Coke	13 to 14 cwts., including breeze.
Breeze	1 cwt.
Tar	9 to 11 gallons.
Ammoniacal liquor	32 to 40 gallons at 8 ozs.
Sulphate of ammonia	24 to 28 lbs.
Sulphur	5 to 7 lbs.
Cyanogen (HCN)	4 lbs.
Virgin liquor	10 to 12 gallons.

The yield of gas as given above is the normal obtained when benzol recovery is not practised.

(The sulphate of ammonia is obtained from the ammoniacal liquor, and not in addition to it. The virgin liquor is included in the figure given for total yield of ammoniacal liquor. The figure given for sulphur is that which may be recovered during purification of the gas, and does not include the quantity remaining behind in the coke.)

The approximate distribution of the elements of the original coal, and the manner in which each exists after the process of carbonisation, is illustrated in the following table :—

One ton of coal, consisting of :—	Lbs.
Carbon, 1,792 lbs., distributed as—	
Coke	1,385
Breeze	107
In gas, as CO and CO_2	30
In gas, as hydrocarbons	130
In tar	122
As scurf, cyanide, etc.	18
Hydrogen, 123 lbs., distributed—	
In gas and tar	98·5
As ammonia	1·0
As water	18·5
In coke	5
Oxygen, 197 lbs., distributed—	
In gas, as CO, CO_2, and combined in tar	49
As water	148
Nitrogen, 34 lbs., distributed—	
In gas (free)	11·8
In coke	14·1
In tar (combined)	1·0
As ammonia	5·8
As cyanogen (total HCN 4 lbs.)	1·3
Sulphur, 18 lbs., distributed—	
As gaseous impurities and in liquor	6
In coke	12
Ash, remaining in coke and breeze	76
Total	2,240

Amount of Coke Used as Fuel.

The quantity of coke used for heating the retort benches varies in accordance with the system of firing adopted. There are three types of firing now in common use, namely :—

(*a*) Direct-fired settings.
(*b*) Semi-gaseous settings.
(*c*) Gaseous-fired settings.

In addition, some works employ external producers, in which the producer gas is generated in a producer of special design situated away from the retorts, and forming a central source from which all the settings are supplied.

The following shows the amount used :—

	Per cent. of the original weight of coal carbonised.
Direct-fired settings	28
Generator settings	15 to 18
Regenerator settings	11 to 14
Vertical retorts :—	
(*a*) Intermittent types	16
(*b*) Continuous types	11½
Outside producers	13 to 16

With modern systems it should be possible actually to sell 10 cwts. of coke per ton of coal. See also ' Coke as Boiler Fuel,' page 1778.

Composition of the Producer Gas.

The following is the average composition under good conditions :—

	Per cent. by volume.
Carbon monoxide	25
Carbon dioxide	5
Hydrogen	6
Methane	1
Nitrogen	63

(Oxygen should be absent, for its presence indicates an excess of primary air.)

The analysis of the waste gases emitted from the retort setting should approximate to the following —

	Per cent. by volume.
Carbon monoxide	19
Oxygen	0·4
Nitrogen	80·6

(The presence of carbon monoxide in the waste gases is indicative of a deficiency of secondary air, and is wasteful in firing. The oxygen, if above 0·5 per cent., denotes an excess of secondary air.)

Gasworks Temperatures.

	F.°
Retorts	1800 to 2100
Ascension pipes	200 to 300
Foul main (inlet)	140
Condensers (inlet)	125
„ (outlet)	75 to 85
Washers and scrubbers (outlet)	60
Purifiers (inlet)	60
„ (outlet)	65
Holders	60

The modern combustion chamber temperature rarely, if ever, exceeds 2800 F.°. The prevailing temperature of the fuel-bed is in the neighbourhood of 1800 to 1900 F.°

Before the introduction of the regenerative system, one of the chief causes of the loss of heat arose from the escape of the waste gases of the producer at unnecessarily high temperatures. In such cases the normal temperature at which the gases are allowed to leave the settings is in the neighbourhood of 1700 to 1800 F.°, but by the transference of the sensible heat from these gases to the inflowing secondary air the temperature of the waste gases has, in the modern regenerator, been reduced to 600–800 F.° before their escape is permitted. In the ordinary way, the secondary air approaches a temperature of 1800 F°. before combustion.

Grate and Chimney Area.

The grate area of the retort bench producer must in all cases be ample, so as to ensure a steady travel for the air passing through the fuel. When the ordinary horizontal fire-bar grate is employed the recognised modern rule for grate area is as follows :

Allow one-tenth square foot of grate area for every lineal foot of retort in the setting. Thus, for a through setting of ten 20-ft. retorts, this gives a total grate area of 20 sq. ft. Another, but less common rule, is that which gives the allowance as 1 sq. ft. of area for every 8 lbs. of coke consumed by the furnace per hour. As the actual consumption of coke (which is shot into the producer hot) is somewhat difficult to compute, the rule is not readily applied.

The ordinary horizontal form of bar grate is now rapidly giving way to the sloping form of grate. The original sloping arrangement consisted of a number of flat plates placed progressively in the manner of a stairway, cooling being effected by a small stream of water which was permitted to drop from step to step. The latest development is the Grille grate, which is composed of a number of independent components set together so as to form an interlocking grille. The grate is made entirely from special cast iron, and embraces a series of hanger bars, which are hung from specially shaped cross-bars. When in the working position each hanger is automatically locked, so that it cannot be displaced during the process of cleaning the fire, while at the same time, should it be necessary to remove any one of the hangers, this may readily be done by applying a slight forward movement to the lower end. The grate is employed in conjunction with a supply of steam, and the formation of clinker is practically avoided, the inert matter coming down in the form of a fine dust.

The rule given above for grate area does not apply when grates of the sloping type are employed, for, owing to the more favourable conditions of the base of the fuel bed, the circulation of primary air is uninterrupted by layers of dead matter. With the Grille type of grate the following rule may be employed :—Allow 0·6 sq. ft. of sloping superficial area per 10 linea ft. of retort in the setting.

Flue and chimney area is calculated by allowing 1½ sq. ins. of area per lineal foot of retort in all those settings which depend upon the flues and chimney under question. Thus, if a retort bench consists of eight settings, each containing ten 20-ft. retorts, the area required would be 16½ sq. ft.

In large retort houses the height of the chimneys varies from 50 to 70 ft. The chief considerations to bear in mind are the heights of adjoining buildings, also the avoidance of down-draughts and the effect of shifting winds. It is not advisable to connect a chimney to a greater number of retort beds than ten, for above this number its dimensions become unwieldy. Circular chimneys, except for vertical retort installations, are now almost things of the past. The rectangular chimney with an external batter is most commonly employed. The batter usually varies between the limits of 1 in 36 to 1 in 40. Retort house chimneys are usually braced for their entire height ; the general methods being to run angle-iron up each corner, the angles being held in position by tie bands placed at intervals of about six feet. An inspection door should be left at the base of the shaft for cleaning purposes. As regards material of construction, stock bricks may be employed for the external courses, but a lining of fire bricks in the interior is essential. Very frequently the whole chimney is constructed from fire bricks, in which case no lining is, of course, necessary. The volume of gas drawn up a chimney increases in proportion to the square root of its height ; thus any increase in height produces only a comparatively small change in this respect. On the Continent it is occasionally found that a separate chimney is installed for each retort setting, but the idea is confined almost wholly to stop-ended settings. The construction of retort bench shafts should be such that the cross sectional area, in spite of the batter, is constant throughout the whole height. This may readily be arranged for by reducing the thickness of the brickwork from the bottom upwards.

Proportions of Horizontal Retort Benches.

The following normal dimensions are given as exemplifying the usual proportions of various types of retort houses and benches :—

(*a*) Single retort bench, 10-ft. retorts :—

	ft.	ins.
Width of bench	12	6
At back of bench	1	6
In front of bench	18	0
Total width inside house	32	0

The height of the retort house to the eaves would be 20 ft., and the height of the retort bench from ground level 11 ft.

(*b*) Through retort bench, hand charging and discharging—

	ft.	ins.
Width of bench	20	0
Each side of bench, 20 ft.	40	0
Total width of house	60	0

The height of the retort house to eaves, if house of the stage type, would be about 35 ft. ; if of the subway type 8 to 10 ft. less. The height of the retort bench from base of producers to top of brickwork about 20 ft., if retorts set in three tiers.

(*c*) Through bench, mechanical charging and discharging—

	ft.	ins.
Width of bench	20	0
Charging side of bench	23	0
Discharging side	17	0
Total width of house	60	0

The height of the bench from base of producers to top of brickwork would be about 25 ft. if retorts are set in five tiers. The height of the house (stage type) to eaves would be about 40 ft. if continuous coal hoppers overhead were included. As an approximate rule for ascertaining the height of the bench from charging floor to top of brickwork, allow 29 ins. for each tier of retorts. The width of the main setting arch will be, for two rows of retorts, from 7 ft. 9 ins. to 8 ft. 9 ins.; for three rows of retorts, 8 ft. 6 ins. to 9 ft.

RETORTS.

VERTICAL RETORTS.

Modern vertical retorts are of three types, namely, (*a*) continuous; (*b*) intermittent; (*c*) continuous-intermittent. The best known examples of the continuous type are the Woodall-Duckham and Glover-West systems.

Woodall-Duckham System.

Length of 5½ ton retorts is 25 ft. The shape of the retorts is rectangular tapered, their dimensions at the top being 4 ft. 3 ins. by 7 ins., and at the bottom 5 ft. 3 ins. by 18½ ins. Each retort will carbonise from 4½ to 5½ tons of coal per diem, and it is usual for two or four of them to be erected in one unit. The coke is extracted by a revolving rake device which makes one revolution in from 50 to 70 minutes, and the speed of extraction of the coke regulates the speed of inflow of coal at the top of the retort. The coke, after extraction, drops into a receiving hopper which is emptied about every three hours. The power required to drive the mechanical portion amounts to approximately 1·8 b.h.p. per ton of coal per maximum day.

Glover-West System.

In this case the retorts are elliptical in shape, having a taper towards the bottom. The length of the 9-ton retorts is 21 ft., and their dimensions at the top are 33 ins. by 10 ins., and at the bottom 39 ins. by 18 ins. Usually eight retorts are set in each unit, each retort being capable of carbonising from 3½ to 4½ tons of coal per diem. The extractor takes the form of a vertical spiral, and requires about 3 b.h.p. for its operation.

Intermittent (Dessau) System.

In this system the retorts are operated on the same principle as horizontal retorts, that is, they receive a definite charge which is entirely withdrawn and replaced by a fresh charge of coal at definite intervals. The length of the retorts is either 4 or 5 metres, and the 5-metre types are capable of carbonising about 22½ cwts. of coal per diem. The shape of the retorts is oblong with rounded corners, and their dimensions at the top are 21 ins. by 8½ ins., whereas at the base they are 27 ins. by 14 ins.

Recently the principle of steaming has been applied to the continuous systems of vertical retorts with extremely promising results. Blue water gas is thus generated *in situ*, and besides increasing the yield of gas per ton of coal carbonised, some noticeable augmentation of the liquor and tar yield has resulted. With Wigan Arley coal Mr. John West, M.Inst.C.E., has obtained the following results :—

	Cub. ft. of gas per ton of coal.	Calorific Value B.Th.U. (gross).	Total Units per ton.
Without steaming	12,834	572	7,353,883
With steaming	23,016	453	10,439,756

In a few instances, where gasworks are situated in a neighbourhood in which there is likely to be a demand for foundry coke, special chamber ovens have been introduced for carbonisation purposes. A notable instance is the Birmingham Corporation Gasworks, where a large battery of Koppers' ovens is in use. These ovens, laid horizontally, are 35 ft. in length, and have a rectangular tapered cross section. Their height is 8 ft. 10 ins., width at narrow end 18 ins. and at wide end 19½ ins. Each is capable of dealing with from 8 to 10 tons of coal per diem, and of yielding from 100,000 to 120,000 cub. ft. of gas. The distillation period continues for from 24 to 30 hours, and at Birmingham they are fired by means of external producers of the Mond type.

Fireclays as used on Gasworks.

(See Section IX., p. 427.)

Retort Bench Fittings.

The following may be taken as giving the approximate size of ascension pipes necessary with horizontal retorts :

Works making under 10 million cub. ft. per annum . . . 5-in. pipes.
" " between 10 and 200 million cub. ft. per annum 6-in. "
" " above 200 million cub. ft. per annum . . 7-in. "

The above refer to retorts having an ascension pipe at both ends. If a single pipe is used it should not be less than 8 ins. in diameter.

Joints for Ascension Pipes.

These must on no account be made with lead. Rust joints are to be preferred to any others, although they may entail no little labour when having to be cut out. To prepare the material for these joints, cast-iron borings should be damped down with gas liquor; the mixture is then rammed well down into the joint space. When the bench is at work the heat soon hardens off the joint. If borings cannot be obtained, a serviceable joint may be made from the following :

Ewell brick dust . . . . 1 part.
Slaked lime . . . . . 2 parts.

This is rammed into the joint dry, no moistening being necessary.

For the joints between the cast-iron mouthpiece and the fireclay retort the following may be used :—1 part of cast-iron borings to 2½ parts of fireclay. This mixture is then damped down with a solution of sal ammoniac. The amount of sal ammoniac required is about 1 lb. to every cwt. of the fireclay and borings. Ammoniacal liquor may be used in lieu of the sal ammoniac, but the latter is to be preferred, as a more complete rusting action is thereby set up.

Hydraulic Mains.

These are now of two types, i.e. :

(*a*) Distinct mains, one to every retort bench, on either or both sides.
(*b*) Continuous mains, one uninterrupted main extending over a number of settings.

The latter type have their advantages as regards initial cost, but distinct mains are otherwise to be preferred owing to the greater ease with which they are adjusted. In addition, by their use a single setting may be readily shut down and isolated.

The gas take-off from the hydraulics should be arranged from the cover of the box, rather than from the side, as is so frequently found.

Foul Main.

The size of the foul main must depend upon the combined areas of all pipes leading into it. Generally speaking, the following sizes are those prevailing, and which may be safely applied

Capacity of Bench per 24 hours.	Size of Foul Main.	
	If one.	If two.
30,000 to 100,000 cub. ft.	6 ins. to 9 ins. . . .	—
200,000 to 500,000 cub. ft.	12 ins. to 15 ins. . . .	—
1 million to 1¾ million cub. ft.	18 ins.	14 ins.
2 million to 3 million cub. ft.	24 ins.	18 ins.

Another rule is that which states that the foul main (if it delivers all the gas) should be 125 per cent. of the area of the main works connections.

The modern practice is to construct the foul main from lap-welded steel plates or solid drawn tubes in lieu of cast-iron pipes. When steel is used, however, some form of expansion joint should be introduced, for the main is liable to undergo some considerable expansion when the settings are fired up from cold. With the cast-iron main, the lead joints at the spigots will be sufficient to cope with any change of length, and flange joints should therefore be avoided unless some form of expansion joint is inserted.

Tar and Liquor Removal.

The method employed for removing the tar and liquor condensed out of the gas in the hydraulic main is of extreme importance, for if an efficient principle is not employed endless trouble results in the shape of pitched-up hydraulics, stopped ascension pipes and tar mains, and considerable loss of ammonia. The tar-tower system has been regarded as one of the best methods and is a considerable improvement on the older systems. The objection to the tar-tower, however, is that it is not automatic in action, requiring periodical 'running-off,' during which process there is every possibility of temporarily unsealing the dip-pipes. The latest method, which eliminates the drawbacks of the tar-tower, is the 'Reflux' system, which is entirely automatic and may be left for weeks at a time with no attention whatever. The system separates tar and liquor while hot, and by means of a compressed gas installation it effects the continuous circulation of hot liquor in the hydraulics, which presents many advantages from the point of view of practical working.

Retort House Governors.

The retort house governor is a more or less essential auxiliary of the modern retort house. It differs from the station governor in that, whilst the latter is employed with the object of reducing pressure, the retort house governor is interposed for the purpose of reducing the intensity of vacuum created by the exhauster. Thus the governor ensures a constant vacuum in the hydraulic main, whatever the volume of gas coming away from the coal charges may be. The intensity of vacuum required is obtained by loading the bell on similar lines to those employed with the station governor. The best place for the governor is on the top of the retort bench, as close up to the end of each section of the foul main as possible, for it is not so sensitive when interposed at the inlet or outlet of the condenser as is occasionally found. By-passes should be fitted to the governor, for it will require cleaning out about every four months.

COMPARATIVE COST OF OPERATING RETORTS BY HAND AND MACHINERY.
(*Pre-war prices.*)

	Per Ton of Coal Handled.
Hand charging and discharging	2*s.* 6*d.* to 3*s.*
'Manual' machines	1*s.* 10*d.* to 2*s.* 2*d.*
Power machines (older types)	1*s.* 3*d.*
Projector and pusher	1*s.* to 1*s.* 2*d.*
Discharging chargers	10*d.* to 1*s.*
Inclined retorts	1*s.* 2*d.*
Vertical retorts (both types)	4*d.* to 6*d.*
Chamber ovens	1½*d.* to 3*d.*

Gasworks Conveyors and Elevators.

The formula given below may be taken as giving a useful guide as to the capacity of bucket conveyors:

$$\text{Capacity} = \frac{S \times B \times W}{96{,}768 \times P} \text{ tons per hour,}$$

where

B = capacity of buckets in cub. ins.;
S = speed of conveyor in ft. per minute;
W = weight per cub. ft. of substance carried (see page 2065);
P = pitch of buckets in ft.

The horse-power required to operate elevators and conveyors may be readily arrived at by adopting a coefficient of friction in accordance with the conditions under which the machine is working.

Let
M = the weight of material carried in lbs.
W = the weight of the moving parts in lbs.
K = the coefficient of friction.
S = the speed of the conveyor or elevator in ft. per minute.

Then, for

(*a*) Vertical elevator

$$\text{H.P.} = \frac{M \times S}{33{,}000} + \frac{K \times S(M+W)}{33{,}000};$$

(*b*) Inclined elevator:

Let α° = the angle of inclination with the horizontal.

Then

$$\text{H.P.} = \frac{M \times S \times \sin\alpha^\circ}{33{,}000} + \frac{K \times S(MW)\cos\alpha^\circ}{33{,}000};$$

(*c*) Horizontal conveyor:

$$\text{H.P.} = \frac{K \times S(M+W)}{33{,}000}.$$

As regards the value of K, the following figures may be taken:

0·15 for metal sliding on metal;
0·07 to 0·8 „ „ (well lubricated)
0·25 for wood sliding on wood.

Purification of Coal Gas.

The purification of coal gas is carried out in two stages, namely, by means of wet purification in the washers and scrubbers and afterwards in the dry purifiers. During the wet purification of the gas the alkaline ammonia is made use of for removing a portion of the acidic impurities, sulphuretted hydrogen and carbon dioxide. The two last-named are, therefore, absorbed with the formation of certain salts, which are themselves soluble in water. The resultant solution

consists of water containing a certain proportion of these salts, and is known as ammoniacal liquor. In crude coal gas the ammonia content is usually in the neighbourhood of 1·5 per cent. by volume, and of this amount from about one-third to one-half will have been deposited prior to the gas reaching the wet purification plant. Hunt has given the following figures for the distribution of ammonia :

	Per cent. of total.
Ammonia removed by condensation	42·7
,, ,, first scrubber	43·3
,, ,, second scrubber	14·0

When gas containing carbon dioxide and sulphuretted hydrogen comes in contact with a solution of ammonia both acid and normal salts are formed. Thus we have :

(*a*) $2NH_3+H_2O+CO_2=(NH_4)_2, CO_3$ (normal) (*c*) $2NH_4OH+SH_2=(NH_4)_2S$ (normal) $+2H_2O$
(*b*) $NH_3+H_2O+CO_2=NH_4, HCO_3$ (acid) (*d*) $NH_4OH+SH_2=NH_4, HS$ (acid) $+H_2O$

Composition of Gas Liquor.

The ammonia present in gas liquor is combined in two distinct ways. In the first place it is present as easily decomposible compounds, such as carbonates and sulphides, and secondly, as more stable compounds which will only undergo decomposition by heating in the presence of a caustic alkali. In general, the final mixture of gas liquor obtained consists of from 75 to 80 per cent. of the more unstable salts, i.e. 'free' ammonia, whereas the remaining 20 to 25 per cent. is made up of the more stable salts, i.e. 'fixed' ammonia. The possible constituents of gas liquor are enumerated below, although it must be borne in mind that any one sample of liquor will seldom contain all of the compounds given. In fact, some of those included are only met with on rare occasions.

Water, containing in solution:

Ammonium carbonate ,, bicarbonate ,, carbamate ,, sulphide ,, hydrosulphide ,, cyanide ,, polysulphide	'Free' ammonia.
Ammonium chloride ,, sulphocyanide ,, sulphite ,, thiosulphate ,, sulphate ,, ferrocyanide ,, acetate	'Fixed ammonia.

Also phenols, amines, and other nitrogenous bodies.

The amount of ammonia in gas liquor is in reality quite small, and varies between 1·5 and 2 per cent. In general, it will be apportioned as follows :

	Per cent.
'Free' ammonia	1·2 to 1·6
'Fixed' ammonia	0·3 to 0·4

The following figures relate to sulphuretted hydrogen and carbon dioxide :

	Per cent.
Carbon dioxide in gas liquor	1·3 to 2
Sulphuretted hydrogen	0·1 to 0·6

The distribution of the total ammonia in gas liquor varies, of course, to some considerable extent. The following table, however, refers to the average solution :

	Per cent. of total ammonia.
Ammonium sulphides	6
,, carbonates	74
,, chloride	15
,, sulphocyanide	1·75
,, thiosulphate, sulphite, etc.	3
,, sulphate	0·25

The most effective manner of operating the washing and scrubbing plant is to ensure that the gas on first entering the apparatus is treated with the strongest liquor available. In each succeeding vessel the washing liquor employed becomes gradually weaker and weaker until, in the final scrubber, clean water should be employed. Where circumstances permit, it is preferable that the first washer should be operated with the liquor from the hydraulic main, for in this way both CO_2 and SH_2 may be considerably reduced.

The amount of water which must be added for the purpose of wet purification seems to vary to some considerable extent in accordance with the conditions prevailing. The writer has

found with Durham coal that the ammonia may be completely removed in ordinary coke-filled tower scrubbers by adding from 10 to 13 gallons per ton of coal carbonised. When mechanical washer-scrubbers are in use the quantity of water required will be considerably less, probably no more than 4 gallons per ton of coal.

Mr. Thos. Glover states that the liquor distributed per sq. ft. of cross sectional area of the scrubber should be 0·145 gallons per minute. This is less the quantity of clean water added to the final scrubber.

Ammonia Lost.

The quantity of ammonia lost in the direction of that permitted to go forward from the final scrubber may be conveniently calculated as so many gallons of 10 oz. liquor.

$$\text{Quantity of 10-oz. liquor lost per week (in gallons)} = \frac{\text{Total grains of ammonia passing forward from scrubber per week.}}{1{,}522}$$

Impurities in the Gas at various stages.

(The last three named above may all be removed, or partially removed, by the employment of special processes, but in the majority of gasworks such processes are not resorted to.)

Removal of Sulphuretted Hydrogen.

Sulphuretted hydrogen is now almost universally removed by means of oxide of iron in one of its forms. Natural ferric oxide (bog-ore) is still largely employed for the purpose, although in recent years various artificial preparations have found a good deal of favour, chiefly owing to their lower cost. The natural bog-ore is chiefly obtained from deposits in Holland, Belgium, and Ireland. In the dried state its composition varies between the following limits :

	Per cent.
Hydrated ferric oxide (Fe_2O_3, H_2O)	60 to 65
Organic matter	15 „ 25
Silica	3 „ 6
Alumina	1

The active material in bog-ore and artificial preparations is not actually the iron oxide, but the oxide plus a certain quantity of water of combination, i.e. a hydrated ferric oxide. In addition to this moisture the material as used should contain a further quantity of water, usually from 20 to 30 per cent. The artificial oxides are employed with a similar degree of moisture. The made-up or artificial material, if of good quality, is usually rather more active than the natural product, owing to a rather higher content of ferric hydrate, which may reach so much as 70 to 75 per cent.

Reactions during the Removal of Sulphuretted Hydrogen.

The absorption of SH_2 by the active oxide occurs in two distinct ways :

(*a*) $Fe_2O_3, H_2O + 3H_2S = Fe_2S_3 + 4H_2O$.
(*b*) $Fe_2O_3, H_2O + 3H_2S = 2FeS + S + 4H_2O$.

In the first instance ferric sulphide is formed, whilst secondly the result is ferrous sulphide and some free sulphur.

When spent and inactive the material is removed from the purifier and subjected to the process of revivification, or exposure to the air, when the sulphides are oxidised to oxides and the material is ready for further use. The following are the revivification reactions :

$$(a)\ 2Fe_2S_3 + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 3S_2.$$
$$(b)\ 4FeS + 3O_2 + 2H_2O = 2Fe_2O_3, H_2O + 2S_2.$$

Oxide is generally laid in the purifiers on grids to a depth of from 8 to 10 ins. In some works, however, it is still customary to employ deep layers of as much as 30 ins. This is particularly the case in those purifiers in which hurdle grids are made use of.

A space of at least two inches should be left between the top of one layer and the base of the sieves or grids of the layer immediately above. Oxide as it becomes fouled increases in bulk, hence this precaution. Partial revivification *in situ* is nearly always arranged for in present-day systems. This is effected by admitting a small measured quantity of air to the purifiers along with the gas. The air may be taken from a small compressor and forced into the box, or may be injected by means of steam. In other cases it is sucked in with the gas through a pipe attached to the main on the inlet side of the exhausters. When air is admitted at some point prior to the washers and scrubbers it should not be overlooked that undesirable reactions may be set up in the wet purification plant.

It is generally understood that the material in any one purifier cannot simultaneously extract sulphuretted hydrogen and undergo revivification. The assumption is not entirely accurate, but the process of suphiding takes place at a very much more rapid rate than does the oxidation effect.

If the capacity of the purification plant is not ample the full effect of the admitted air will not be realised. For the most effective results a slight excess of air above that theoretically required (as determined from the SH_2 present) should be admitted.

When air is admitted to a purifier a rise in temperature of about 5 degrees Fahr. will usually be found as the gas passes from inlet to outlet. The air acts, of course, as a diluent, and therefore a careful check must be kept on the quantity admitted with the gas. As regards the effect of the air in this direction the following may be quoted :

Audonin and Berard found that 1 per cent of air reduces illuminating power by 6 per cent.

	Per cent.
2 per cent. of air reduces illuminating power by . .	11
3 " " " " . .	18
4 " " " " . .	26

Würtz has stated that

3 per cent. of air causes 15·69 per cent. loss in light.
5 " " 24·0 " "

Dr. W. B. Davidson, in more recent experiments, has found the following results :

			Per cent.
1 per cent. of oxygen		reduces candle power by .	8
1 "	"	" calorific power by .	1
1 "	nitrogen	" candle power by .	2·8
1 "	"	" calorific power by .	1
1 "	carbon dioxide	" candle power by .	3·5

Lime Purification.

Prior to the year 1905 lime purification for the removal of carbon dioxide and sulphur compounds other than sulphuretted hydrogen was in almost universal use. To-day, purification by this method is met with only in isolated instances.

Lime in the slaked condition is an active absorbent of sulphuretted hydrogen and carbon dioxide, and—after special treatment—is capable of removing carbon disulphide. The following reactions occur during the process of purifying by means of lime :

(*a*) Removal of carbon dioxide—

$$Ca(OH)_2 + CO_2 = CaCO_2 + H_2O.$$

(*b*) Removal of sulphuretted hydrogen—

$$Ca(OH_2 + 2SH_2 = Ca(SH)_2 + 2H_2O.$$

(*c*) Removal of CS_2.

It must be borne in mind that slaked lime in itself has no action upon carbon disulphide. The active medium which accounts for the removal of the CS_2 is now generally supposed to be calcium hydroxyhydrosulphide. This is prepared by sulphiding the slaked lime, in other words by admitting gas containing sulphuretted hydrogen to the vessels which are destined to

remove the CS_2. Carbon disulphide certainly cannot be absorbed according to the following equation, which has been so often set down as illustrating the reaction :

$$CaS + CS_2 = CaCS_3.$$

Veley has laid down the following theory as to the actual reactions which occur :

(1) Calcium hydrosulphide is formed in the first place—

$$Ca(OH)_2 + 2H_2S = Ca(SH)_2 + 2H_2O.$$

(2) By the addition of water or oxygen the hydrosulphide is converted into hydroxyhydrosulphide—

$$(a)\ Ca(SH)_2 + H_2O = CaOH,SH + SH_2$$

or

$$(b)\ 2Ca(SH)_2 + O_2 = 2CaOH,SH + 2S.$$

(3) The carbon disulphide and hydroxyhydrosulphide then react as follows :

$$(a)\ 2CaOH,SH + CS_2 = SH_2 + Ca(OH)_2,CaCS_3$$

or

$$(b)\ 3CaOH,SH + CS_2 + H_2O = 2SH_2 + Ca(OH)_2,CaCS_3.$$

When gas is manufactured and is to be freed from the whole of its impurities it is usual to instal a system in which oxide of iron and lime are used in conjunction. Many methods of operating for this purpose are employed, but one of the most common systems is that generally known as the 'Beckton' method. It consists in the main of four sets of purifiers operated in rotation :

First Set, Lime.—These remove the whole of the CO_2 and some SH_2, which is afterwards displaced by CO_2. Some CS_2 is also absorbed.

Second Set, Oxide.—These remove the whole of the SH_2, including any which may be displaced from the lime in the previous set.

Third Set, Lime.—This lime has been previously 'sulphided' and removes the bulk of the CS_2. It will not remove the whole of this impurity.

Fourth Set, Oxide.—These vessels remove any SH_2 which is disengaged from the third set.

Cost of Purifiers.

It is difficult to give any reliable figure, based on each 1,000 cub. ft. capacity, for the cost of purifiers, for everything is dependent upon the size of the vessel. The larger the box, the lower the cost per unit of capacity. As regards the distribution of the cost, the following is illustrative of normal conditions with a medium size installation :

	Per cent. of total expenditure.
Purifying boxes	50
Covers (dry lute)	15
Lifting apparatus	4 to 6
Grids	6 to 10
Connections and valves	20 to 30

Castings for the boxes, in normal times, cost from 10*l.* to 11*l.* per ton. The covers cost from 17*l.* to 19*l.* per ton. As regards valves, it is usual to base these per inch of diameter. The following figures are approximate pre-war costs :

	Per inch of diameter.
Ordinary rack and pinion valve	1*l.*
Centre valves	9*l.*
Weck's valves, and such types	10*l.* 10*s.*

Removal of CS_2 by Hot Purification.

Owing to the uncertainty and expense of lime purification for the removal of sulphur compounds other methods of effecting the same end have recently been introduced. The most important of these is the Carpenter-Evans system of hot purification, which is now in everyday use at some works. The principle of the process consists in converting the CS_2 into sulphuretted hydrogen, and then removing the latter by means of ordinary oxide of iron purification. The gas, after being purified from SH_2 in the usual way, is passed into special chambers containing a catalyst heated to a temperature of about 800°F. The CS_2 is thereby decomposed according to the following reaction :

$$CS_2 + 2H_2 = 2H_2S + C.$$

The catalytic agent employed consists of fireclay balls about 1 in. in diameter impregnated with nickel reduced from the chloride. The free carbon resulting from the reaction is left behind in the catalysing apparatus, and after about thirty days' run it is necessary to remove it. This is

carried out by the process known as 'aeration.' Air is pumped through the catalyser tubes at a definite rate, thus burning out the carbon and disposing of it as carbon dioxide. The aeration process on the larger plants usually occupies about one week, after which the apparatus is again ready for work. When starting and stopping special precautions have to be taken to ensure immunity from explosion. The effect of the process on the general composition of the gas seems to be but slight; as an instance the following figures, given by Dr. Carpenter, are quoted:

Analysis of Gas.	Before Treatment.	After Treatment.
CO_2, per cent. by volume	1·44	1·45
Heavy hydrocarbons	3·55	3·63
Oxygen	0·33	0·06
Carbon monoxide	8·16	8·03
Methane	26·85	27·26
Hydrogen	54·19	54·25
Nitrogen	5·48	5·32
Illuminating power	14·70	14·70
Calorific power (Gross, B.Th.U.)	590·0	594·40

The present-day cost of operating the Carpenter-Evans system of purification is shown in the following table:—

	Pence per 1,000 cubic feet.
Fuel (coke @ 42*s.* 6*d.* per ton)	0·2550
Conveying coke and cleaning producer	0·0240
Power	0·0129
Labour and chemical supervision	0·1180
Repairs and maintenance	0·1649
Capital charges	0·1967
Total	0·7715*d.*

Purification by means of Charcoal.

Mr. W. Gordon Adam has recently introduced a method for removing carbon disulphide and thiophen by passing the gas, after washing and scrubbing, through animal or wood charcoal in a granulated state. The impurities (including naphthalene) are afterwards removed from the charcoal in an unchanged condition by the application of heat, a temperature of about 300° C. being sufficient. After this treatment the charcoal is ready for further use, and is employed in a purifying vessel of ordinary construction. The prevention of ethylene absorption is effected by curtailing the quantity of charcoal used—in other words, by increasing the space-velocity above that at which ethylene is extracted.

Removal of Naphthalene.

During recent years it has become usual to employ special naphthalene solvents, to the action of which the gas is subjected before travelling to the district mains. Paraffin, water-gas, tar, and anthracene oil have all proved effective, particularly the latter. In general the gas will contain, if no special treatment is accorded it, from 6 to 12 grains of naphthalene as it leaves the works. Butterfield has pointed out that a million cubic feet of gas cooled from 68° to 50°F. may deposit about 14 lbs. of naphthalene. The introduction of carburetted water gas has to a certain extent lessened the naphthalene evil, although its effect in this direction is somewhat erratic. As regards the methods of washing with solvents, the most ready plan to adopt is that of treating the gas in a Livesey or mechanical washer just prior to its entering the holders.

Carburation with the aid of solvents was introduced by Botley, who injected, by means of a special spray, about 4 gallons of thoroughly atomised paraffin oil per million cubic feet of gas. Botley found that petroleum oil was more suitable for the purpose than spirits such as benzol. Leather made use of a creosote oil for washing the gas, but owing to the 'stripping' properties of this oil he took the precaution to pre-benzolise it first. The practice of Ferguson Bell is somewhat uncommon. The gas whilst in a warm state is washed with warm tar, and at the outlet of the wet purification plant it is further treated with a naphtha oil.

Recovery of Cyanogen on Gasworks.

Cyanogen is a subsidiary by-product which is only recovered on the largest of works. The maximum amount which can be obtained from a ton of coal is about 1½ lbs. of hydrocyanic acid, or about 10,000 grains. The processes now employed recover the hydrocyanic acid either as ammonium sulphocyanide or as sodium ferrocyanide (prussiate of soda). The most readily

applied method is that operating on the polysulphide principle. In this system the gas, prior to washing and scrubbing, is passed through a special vessel (of the nature of a small purifier) containing a layer of spent oxide of iron about 2 ft. in depth. Above the oxide material sprays are arranged around the box, and the oxide is periodically sprayed with water or weak cyanide liquor. The gas, containing hydrocyanic acid, passes upwards through the layer of oxide and comes in contact with the polysulphide solution trickling through the mass. The hydrocyanic acid combines with the ammonium polysulphide and yields ammonium sulphocyanide according to the following equation :

$$(NH_4)_2S_2+HCN=NH_4SCN+NH_4SH.$$

The spent oxide used in the process should contain about 50 per cent. of sulphur, and it is a surprising fact that although sulphur is required for the completion of the reaction the spent oxide, when removed from the vessel after working for about three months, shows little or no loss in sulphur, while occasionally some slight increase may be found. Accordingly, the process would be of a continuous nature were it not for the fact that the physical nature of the oxide gives rise, after a time, to excessive back-pressure, when the only remedy is the substitution of a fresh layer. Figures obtained in practice show that one ton of spent oxide is capable of removing the cyanide evolved from 350 tons of coal.

The Recovery of Crude Benzol.

While the 'stripping' of gas for the recovery of the aromatic series of hydrocarbons has been carried out in the case of coal gas produced on coke-oven works for some years, the practice has only recently been introduced in gasworks, primarily as a means of meeting the demand for certain essential war products. The coal gas, either in the semi-crude state (i.e. after the wet purification plant) or when completely purified, is subjected to washing with a solvent which absorbs the benzene hydrocarbons but which has no effect on the remainder of the constituents. The solvent employed consists usually of a coal-tar distillate known as 'green oil,' although other substances, such as creosote, blast-furnace oil, or crude petroleum, may also be employed. The oil, after having been in contact with the gas, is said to be benzolised, when it may contain up to 5 per cent. of benzene hydrocarbons, according to the extent to which 'stripping' is carried. The benzolised oil is then passed through a series of vessels comprising the distilling plant in which the benzene hydrocarbons, with some light naphthas and a small proportion of naphthalene, are driven off and separated from the wash-oil. The benzene vapours thus obtained are condensed and collected as a crude spirit, while the wash-oil, having been 'debenzolised,' is cooled and once more employed for treating the gas. In general, it is customary to recover from normal coal gas from 1½ to 2½ gallons per ton of coal carbonised, depending upon the amount of aromatic hydrocarbons contained in the original gas and the proportion of these which it is deemed advisable to extract. The crude spirit will vary in composition, but in general about 65 to 70 per cent. will distill over up to 120° C., and 80 per cent. up to 160° C. The portion which distills over will consist of about 80 per cent. of benzol and 15 per cent. of toluol, the remainder being xylol. The amount of wash-oil employed for extraction per ton of coal carbonised undergoes considerable variation in accordance with the taste of the responsible engineer. It may be said, however, that it should never be less than 60 gallons per ton of coal, while it may be so much as 100 gallons. Water in the wash-oil is strongly to be guarded against, and should never exceed 1 per cent. by volume if effective results are to be obtained. Temperatures play an important rôle in the process, and it may be said that the scrubber should never exceed about 70° F., and as regards the temperature of the debenzolised oil a good rule to observe is that of maintaining the oil about 5° F. above the temperature of the gas. Now that the demand for explosives has ceased many gas undertakings have discontinued the recovery of benzol.

Tar Distillation.

(Contributed by Harold Moore, M.Sc., A.I.C., F.C.S.)

The yield of coal tar depends very largely upon the volatile content of the coal; but, in addition, it is considerably affected by the design of the retort. Retorts in which heating is conducted gradually, and which ensure the rapid removal of the volatile products from the heat zone, yield the largest quantities of tar. The nature of the tar depends, to a slight extent, upon the type of coal used, but is much more seriously affected by the carbonising conditions. A rapid rise in temperature, with a high maximum temperature, tends to produce tar high in specific gravity, high in viscosity, rich in free carbon, and mainly consisting of aromatic hydrocarbons. Gradual heating, low maximum temperature, and rapid removal of the volatile products result in brown mobile tars, comparatively devoid of free carbon and rich in aliphatic hydrocarbons.

Horizontal retorts subject the coal to a very rapid heating with a high maximum temperature, whilst the volatile products have to pass along the heated retort walls, whereby they undergo cracking. The result is a viscous tar, rich in free carbon. Horizontal retort tars frequently

contain over 20 per cent. They possess a specific gravity of about 1·2. In continuous vertical retorts the coal is slowly passed from the cool zone into a hotter zone, undergoing gradual heating, whilst the volatiles are removed from the cooler end of the retort, and, therefore, are not so liable to undergo cracking. The resulting tar possesses a specific gravity of about 1·08, and about 1 to 5 per cent. of free carbon. Inclined retorts give products of intermediate composition; whilst coke ovens yield tars of very varied composition, depending upon the design of the ovens.

Special processes for the low-temperature carbonisation of coal, such as the Coalite and Premier Tarless systems, yield brown low-gravity tars in which free carbon is almost entirely absent. Gas works and coke ovens supply nearly all the tar produced in this country. Tar produced in gas works is accompanied by ammoniacal liquor, and requires settling out previously to distillation. The tar in distillation is usually divided into the following fractions in English distilleries:—

	Temperature.	Approx. Yield.
1. Crude naphtha	Up to 110° C.	3 per cent.
2. Light oil	110° to 200° C.	7 ,,
3. Crude carbolic oil	200° to 240° C.	7 ,,
4. Creosote oil	240° to 270° C.	15 ,,
5. Anthracene oil	270° to finish	10 ,,
6. Residuum of pitch	—	58 ,,

The finishing-point of the distillation is decided by the quality of pitch desired. The yields of the above products vary, of course, with the nature of the tars, horizontal retort tars yielding a residue of about 65 per cent. of pitch, whilst vertical retort tars give only about 50 per cent. of pitch. The benzene and toluene are mostly present in the crude naphtha fraction, the yield of benzene being about 2 gallons to the ton of tar. They are separated by distillation combined with washing with dilute alkali, which removes phenols, cresols, and other acidic bodies, followed by washing with dilute acid, which removes pyridine, quinoline, and other basic substances, and are finally refined by treatment with strong sulphuric acid, which removes certain sulphur-containing compounds and a portion of the unsaturated hydrocarbons originally present in the tar. Similar processes of refining are adopted for other fractions, though the strong acid treatment is usually applied only to the benzene, toluene, and solvent naphtha-containing fractions. The most common grades of these three distillates are sold under the names of 90*s.* benzol, 90*s.* toluol, and 90*s.* xylol. The 90*s.* benzol distils 90 per cent. of its volume at 100° C. by the tar distillers' retort test; 90*s.* toluol yields 90 per cent. at 120° C. by the same test; whilst 90*s.* solvent yields 90 per cent. at 160° C. The solvent fraction consists mainly of the three isomeric xylols. Naphthalene and anthracene are removed from the higher boiling fractions (naphthalene mainly from the carbolic oil fraction, anthracene from anthracene oil) by cooling and decantation, or by cooling and filtration.

The limiting temperatures of the fractions are liable to alteration, depending upon market conditions, whilst the distillation is frequently stopped at an earlier stage than that indicated in the above table, in order to yield a soft residue known as treated or refined tar, which is used for tar spraying on the roads. A soft finished residue is also frequently sold as pitch-creosote mixture, and used for the fuel market.

Benzol is mainly used for motor fuel, together with a considerable quantity of the toluol, though smaller amounts are employed in the synthetic chemical industry. Carbolic acid (phenol) and cresylic acid (cresols), obtained by alkali washing, both find their main market for the manufacture of disinfectants. Creosote oil is used for timber preservation and as fuel. The use of creosote as fuel is somewhat intermittent, depending upon the price of petroleum. Pitch is mainly used for road repairing, but also for many other purposes, a considerable amount being consumed for electric insulation.

WATER GAS.

Manufacture of Water Gas.

Water gas as now employed as an auxiliary to coal gas in gasworks is nearly always of the carburetted type, although in some instances the unenriched, or 'blue,' gas is admixed when the quality of the coal gas is above that normally manufactured. The composition of these two gases has already been given on pp. 1844, 2072. The reactions occurring in the generator of the water gas plant are as follows:

$$(a)\ C + 2H_2O = CO_2 + 2H_2.$$
$$(b)\ C + H_2O = CO + H_2.$$

The carbon dioxide produced in the lower portion of the fuel bed according to equation (*a*) is then reduced to carbon monoxide on passing through the remainder of the fuel bed :

$$(c)\ CO_2 + C = 2CO.$$

The extent to which the reaction (*b*) takes place depends largely upon the temperature prevailing in the lower part of the fuel bed.

As the above reactions are of an endothermic nature the heat of the fuel bed is gradually absorbed, accordingly this is replaced at intervals by the process of blowing. The reaction occurring during the 'blow' is of an exothermic nature, being simply as follows :

$$C + O_2 = CO_2.$$

All practical water gas plants are now operated on the intermittent principle of providing for short periods of a gasmaking 'run' and a 'blow.' In the more common carburetting plants the 'run' continues for 5 or 6 minutes, and is followed by a 'blow' extending for 3 or 4 minutes. In certain forms of plant intended entirely for the production of 'blue' gas the blowing period is generally of much shorter duration, lasting for about 70 to 90 seconds. The primary object of the 'blow' is to convert the coke direct into CO_2, thereby liberating the maximum quantity of heat, but this condition is never attained in practice, some CO being always present. This CO, in the enriching plants, is made use of for heating up the subsequent apparatus in which enriching takes place. In some of the later forms of 'blue' plants (in which no enriching vessels are required) the CO is employed for the purpose of raising the steam required during the 'run.' The average composition of the 'blow' gases issuing from the top of the generator is as follows :

Carbon monoxide	. . . .	17	per cent. by volume.
Carbon dioxide	. . . .	10	" " "
Nitrogen	. . . .	73	" " "

Traces of hydrogen, methane and sulphuretted hydrogen may also be found. The CO is at a maximum, and the CO_2 at a minimum, during the first minute of the 'blow,' and as the period proceeds the CO undergoes reduction while the CO_2 increases in quantity.

As regards temperatures the generator should, at the commencement of the 'run,' be worked up to 2,000F.° By the time that the 'run' is completed the temperature will have dropped by from 300° to 500°. Owing to this fact the quality of the water gas undergoes gradual deterioration from the commencement of the 'run' onwards ; thus at the end of the first minute of the 'run' the CO_2 content will only amount to some 2 per cent., whilst at the end of the fifth minute it may amount to from 7 to 8 per cent. The temperature of the carburettor and superheater varies in accordance with the type and quantity of oil in use at the time. Under normal conditions the following will apply :

Carburettor	1350 to 1400 F.°
Superheater	1400 to 1450 F.°

For the manufacture of carburetted water gas the materials required are given below :

Coke . .	35 to 41 lbs. per 1,000 cub. ft. of gas ;
Oil . . .	about 2½ gallons per 1,000 cub. ft. of 18 candle gas ;
Steam . .	27 to 30 lbs. per 1,000 cub. ft. of gas.

The cost of carburetted water gas is mainly influenced by the current value of the enriching oil utilised. To-day, blue water gas is a far more common and important product, so that many plants formerly utilised for producing carburetted gas are now employed for the production of blue gas only. The present-day cost of manufacturing blue gas is given below :—

BLUE WATER GAS: COST OF MANUFACTURE.

	Per 1,000 cubic feet. *d.*
Coke, for generator	9·0
Coke, for steam	3·0
Water, for steam	0·125
Wages	3·50
Maintenance	2·50
Purification	0·45
Establishment charges	1·00
Total	19·575*d.*
Cost per therm	6·5*d.*

MODERN GASWORKS PRACTICE

BY

ALWYNE MEADE, Assoc.M.Inst.C.E.

Engineer of the Wapping Works of the Commercial Gas Company. Formerly Lecturer in Gas Engineering and Allied Subjects to the London County Council and at the Regent Street Polytechnic.

SOON after the publication of the first edition some four years ago, 'Modern Gasworks Practice' established itself as the recognised standard reference book of the gas industry, not only in this country, but in America and on the Continent.

The first edition was rapidly exhausted and a new edition has been eagerly awaited for a long time. During the last four years the technique of gasworks methods has undergone nothing less than an upheaval, and it was necessary to await some semblance of quiescence in gasworks development before putting into permanent form new principles which might prove of but ephemeral interest. **So great have the developments been that it has been necessary completely to revise the greater part of the work and to increase its bulk by 50 per cent.**

The new edition, which contains nearly 900 pages and 500 illustrations, represents the most up-to-date and comprehensive treatise on the important subject with which it deals; and notwithstanding the fact that gasworks officials must to-day combine the qualifications of engineer, scientist, and administrator with a specialised knowledge of their primary subject, they will find every phase dealt with fully, clearly, and accurately in 'Modern Gasworks Practice.'

BENN BROTHERS LTD.,

'The Gas World' Offices, 8 Bouverie Street, London, E.C. 4.

F. 2085

The impurities in water gas consist of carbon disulphide and sulphuretted hydrogen, which are present in the following quantities :

	Grains per 1,000 cub. ft.
Sulphuretted hydrogen	110 to 120
Carbon disulphide	10 to 15

As regards water gas tar, S. Carter has given the following analysis :

Specific gravity	1·0665
	Per cent.
Benzol	1·11
Naphtha	2·33
Creosote oil	21·35
Naphthalene	4·09
Anthracene oil	15·91
Pitch	56·70

The Complete Gasification of Coal.

Now that the choice of the quality of gas to be distributed rests with the gas engineer instead of being stipulated by Parliament, some considerable impetus has been given to the process known as the complete gasification of coal. By this is meant the treatment of the coal under such conditions that no solid residue other than ash remains. Complete gasification may, of course, be carried out in two ways, namely, by treating the coal in two stages for the production, firstly, of straight coal gas, and secondly, of blue water gas in distinct plants, the two gases being subsequently mixed either in the crude or purified state. The alternative is to employ plant of special design in which the above two processes are carried out simultaneously.

From the standpoint of gas production, the two methods may be contrasted as follows :—

A. Dual Process.

1 ton of coal yields—		B.Th.U.
13,000 cubic feet of straight coal gas @ 520 B.Th.U. and 11 cwts. surplus coke.	=	6,760,000
11 cwts. coke yields :—		
20,500 cubic feet of blue gas @ 300 B.Th.U.	=	6,150,000
Total yield in gaseous form from 1 ton of coal.	=	12,910,000

B. Single Process.

1 ton of coal yields—		B.Th.U.
50,000 cubic feet of mixed gas @ 370 B.Th.U.	=	18,500,000

The composition of the gas obtained from the modern single-stage complete gasification plant is as follows :

	Per Cent.
Hydrogen	51·0
Carbon monoxide	30·0
Methane	8·0
Unsaturated hydrocarbons	1·4
Carbon dioxide	4·6
Nitrogen	5·0
Oxygen	trace
Yield per ton of coal (cubic feet)	50,000
Calculated calorific power (gross)	370
Therms per ton of coal	185

SULPHATE OF AMMONIA.

Average commercial salt contains :

Ammonia	from 24½ to 25½ per cent.
Equal to	
Nitrogen	20·2 to 20·8 per cent.
Free acid	0·4 per cent.
Moisture	2 to 3 per cent.

Materials required for the manufacture of 1 ton of sulphate of ammonia :

Liquor, approximately	3,400 gallons of 8 oz. strength.
Acid ,,	18 cwts. at 80 per cent. strength
Lime ,,	3 cwts.

The sulphate of ammonia recovered per ton of coal varies in this country between 24 and 28 lbs.

Equation for formation:

$$2NH_3 + H_2SO_4 = (NH_4)_2SO_4.$$

Gallons of liquor × ounce strength × 0·0823 = lbs. of sulphate.

CONCENTRATED LIQUOR.

The exigencies of the war were responsible for a new gasworks product in the form of concentrated and purified ammoniacal liquor. This product contains about 25 per cent. of ammonia, while the sulphuretted hydrogen is reduced to 0·5 per cent. by volume. The concentrated liquor is prepared by passing the ordinary liquor from the storage well through a desulphurising column in which the carbon dioxide and sulphuretted hydrogen are removed, the purified liquor being afterwards concentrated in a special still. With the war ended the majority of these plants have been shut down.

USEFUL MEMORANDA.

1 in. of mercury = 0·490 lbs. per sq. in.
1 in. of water = 0·0361 ,, ,,
1 lb. per sq. in. = 27·7 ins. of water.

A British Thermal Unit is the amount of heat required to raise 1 lb. of pure water 1° Fahr.; correctly, from 39·1° Fahr. to 40·1° Fahr.

A Calorie is the amount of heat required to raise 1 kilogramme of water 1° Cent.; correctly, from 0° to 1° Cent.

NOTE.—The above is the *large* calorie, which is the unit employed on gasworks.

1 British Thermal Unit = 0·252 calories.
1 Calorie = 3·968 B.Th.U.

CALORIFIC POWER OF VARIOUS SUBSTANCES.

	B.Th.U. per lb.		B.Th.U. per lb.
Coke-oven coke	14,436	Petrol, specific gravity 0·684	20,923
Peat, 5 per cent. water	9,900	Shale oil	18,217
Wood, pine	9,153	Blast-furnace oil	16,080
,, oak	8,316	Heavy tar oil	16,050
Petroleum, American	19,627	Coal gas tar	15,500
,, Texas	19,242	Alcohol, absolute	12,931
,, Russian	19,440		(*Lewes.*)

At normal temperature and pressure 32 cub. ft. of coal gas (14 candle power) weigh approximately 1 lb.

1 cub. ft. of coal gas (14 candle power) at N.T.P. weighs ·03125 lb.
1 ,, blue water gas ,, ,, ·0376 lb.

GASWORKS TERMS.

A barrel of tar	25 gallons	A fodder of lead	19½ cwts.
A butt of liquor	108 ,,	A hundred of deals	120 in number
(Usually 8 oz. strength)		A load of lime	32 bushels
A bushel of coal	80 lbs.	(A bushel = 70 lbs.)	
A bushel of coke	45 lbs.	A long thousand of slates	1,200 in number
A chaldron of coal	25½ cwts.	A seam of glass	120 lbs.
(Varies according to locality)		A short ton (American)	2,000 lbs.
A chaldron of coke	12½ cwts.	A tonne (French)	2,204·6 lbs.
(Varies according to locality)		A ton of freight	40 cub. ft.
A cord of wood	128 cub. ft.	A truckload of bricks	About 3,300 in number

Light Obtained from Various Burners.

Burner.	Candles per cubic foot per Hour.	Cost per Candle per Hour with Gas at 5*s.* per 1,000 cubic feet.
		d.
Flat Flame } Old-fashioned types . . .	2·0	·03
Argand } Old-fashioned types . . .	3·3	·019
Regenerative } Old-fashioned types . . .	10·0	·006
Incandescent (O Burner)	15·0	·004
,, Inverted	20·0	·003
,, Keith's High-pressure Inverted .	60·0	·0009

For high-pressure lighting the cost of compressing the gas only amounts to from 2½ per cent. to 4 per cent. of the total cost of the gas consumed, which is very small when it is compared with the extra light obtained.

With a water-driven compressor, from 250 to 300 gals. water are required per 1,000 cubic feet gas compressed to, say, 9 ins. pressure; with a gas-driven plant, 12·4 to 13·4 cubic feet per 1,000 cubic feet compressed to same pressure.

Compressing coal gas reduces the illuminating value until, with a pressure of 200 lbs. per sq. in., the loss is 16 per cent.

(See also ' LIGHTING, Section XXXV., Part III, p. 2137.)

Incandescent Burners.

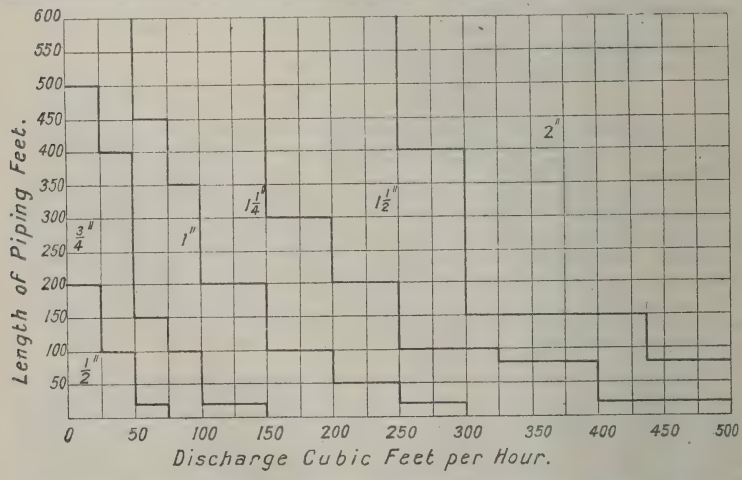
The Bunsen burners used for incandescent lighting should give a flame with a green inner cone and not a violet one, so as to show that the proportion of air used for primary combustion is as large as possible. This ensures an intense heat in the flame, which intensity adds greatly to the light emitted by the burner. This intensity of flame is obtained in the high pressure systems, which are now becoming so general for street and shop lighting, by increasing the pressure of this gas to about 2 lbs. per sq. in., and when this is used with an inverted mantle of a much longer shape than the ordinary low pressure ones, the rush of gas at this high pressure at the nipple causes the full quantity of air required for combustion to be drawn in at the base of the burner mixing tube and so give a flame of the highest intensity. This flame only gives off the same heat per cubic ft. of gas as an ordinary Bunsen burner, but the heat is concentrated and the flame is much smaller. If the quantity of air induced by the current of gas into the mixing tube is 2½ times that of the gas there will be a lilac inner cone, and the hottest part of the flame will be about 2,800°F., and the mantle will then show about 20 candles per cubic ft. of gas consumed. If 3½ times of air are induced, a green inner cone will be noticed, and then the flame will be about 3,000°F., and 30 candle power per cubic ft. of gas obtained.

Products of combustion must be conveyed away and not allowed to enter at the primary air hole of the Bunsen burner. The air used there should contain the full proportion of oxygen to ensure proper combustion. Mantles must fit the flame, or, inversely, the flame must fit the mantle, as then it will be in the hottest part of the flame which is at the outside where the C in the gas is combining with the O_2 of the air to form CO_2 with the evolution of the heat. As the flame is hollow, if the mantle is smaller than the flame it will be in the cooler region of the flame where the gas is not being fully burned. Upright burners give their greatest light horizontally, inverted burners downwards. Shades for gas lights should be at 45° with the horizontal, not 60° or 70° as usually adopted, when very little light is reflected.

The best effects are obtained with burners which permit of the adjustment of both air and gas. These burners should be adjusted from time to time. The burner should be thoroughly cleaned out each time a mantle is fixed.

Incandescent Mantles.

Mantles are made from cotton, ramie, or artificial silk knitted into a 'stocking' or hose about 2 ins. in diameter. This stocking is thoroughly washed and dried. Then it is saturated with a solution of nitrate of thorium and 1 per cent. of nitrate of cerium. After the stocking has been washed and dried, it is either cut to proper size and impregnated with the thorium solution, or is first impregnated and then cut to the required lengths. The impregnated stockings, after being cut and dried, are sewed at one end with asbestos thread so as to form a head provided with a loop, which serves to hold the mantle in process of manufacturing and when in use on the burner. Then the impregnated stocking is hung on a wire by the asbestos loop, and heated in a gas flame of the Bunsen type. This is done in order to burn out the thread. The next process is called the shaping. The mantle now consists only of ashes of thorium (oxide of thorium), and is carefully held over a high pressure Bunsen flame, and gradually given the right shape, at the same time being hardened. As soon as the mantle is shaped and hardened it is practically completed, but in order to protect it from breakage it is 'dipped' in a stiffening solution. There are many forms of 'dip,' but the one most used is made of soluble cotton (gun cotton) dissolved in good alcohol and acetone. To this mixture castor oil and shellac are added.



Gas versus Electricity.

The inverted incandescent gas lamp requires 47 B.Th.U. per candle-power hour obtained. The one-watt electric lamp requires 54 B.Th.U., and the ½-watt lamp 31 B.Th.U. A considerable proportion of gas burners consist of the upright type, which are less efficient, requiring 82 B.Th.U. per candle-power hour. The average may be taken at 64 B.Th.U. per candle-power hour. High-pressure incandescent burners reduced the heat consumption to 23 B.Th.U. per candle-power hour and flame arcs in electric lighting use only 15 B.Th.U. At about 75 per cent. of full load a gas engine of the ordinary type would deliver to the consumer as actual or brake horse-power 11 per cent. of the heat used at the gasworks, while an electric motor would deliver, also as brake horse-power, only 6·8 per cent. of the heat used at the electricity generating station. The efficiency of the gas power production and distribution was thus over 1·6 times that of the electricity system.

(Sir Dugald Clerk.)

Gas Piping.

In the following diagram the point of intersection of consumption in cub. ft. per hour and length of pipe falls into an area indicating size of pipe for the work.

The diagram shows the size of pipe for the conveyance of a given quantity of gas. It is based on a fall of pressure between the extreme ends of the pipe of $\frac{3}{10}$-inch water gauge, and for

ordinary low-pressure gas supply it would not be desirable to have a drop greater than this. The diagram does not provide for piping smaller than ¼ in. because generally sizes smaller than this are only used for the branches to pendants or other apparatus consuming less than 25 cub. ft. per hour. Up to 10 cub. ft. per hour ¼ in. pipe is sufficient and for 10 to 25 cub. ft. ⅜ in.

Flow of Gas in Mains.

Pole's Formula.

Let Q = the discharge of gas in cub. ft. per hour.
d = the diameter of pipe in inches.
p = pressure of gas in inches of water.
s = specific gravity of gas, air being 1.
l = length of pipe in yards.

Then

$$Q = 1350d^2\sqrt{\frac{p\,d}{s\,l}}\,;\quad d = \sqrt[5]{\frac{Q^2 s\,l}{(1350)^2 P}}\,;\quad p = \frac{Q^2 s\,l}{(1350)^2 d^5}\,;\quad l = \frac{(1350)^2 d^5 p}{Q^2 s}$$

Unwin's Formula for High Pressure Gas Mains.

Let D = diameter of pipe in ft.
S = specific gravity of gas (air being 1).
L = Length of pipe in ft.
P_1 = initial pressure in lbs. per sq. inch absolute.
P_2 = final pressure in lbs. per sq. inch absolute.
C = coefficient of friction $= 0{\cdot}0044\left(1+\frac{1}{7D}\right)$
U_1 = initial velocity of gas in feet per second.
U_2 = final velocity of gas in feet per second.
W = area of pipe in sq. ft.
Q = discharge in cub. ft. per hour.

Then

$$Q = 1{,}323{,}250\sqrt{\frac{P_1^2 - P_2^2}{P_1^2}\cdot\frac{P_1^2}{P_2^2}\cdot\frac{D^5}{CSL}}\,;\quad U_1 = 468\sqrt{\frac{D}{CSL}\cdot\frac{P_1^2 - P_2^2}{P_1^2}}\,;\quad U_2 = \frac{P_1}{P_2}U_1.$$

Table of Constants for Friction in Gas Mains.

Diameter of Main in Ins.	Diameter of Main in Ft. = D.	Area of Main in Sq. Ft. = W.	Value of C = Coefficient of Friction $= 0{\cdot}0044\left(1+\frac{1}{7D}\right)$

(Professor Unwin.)

Gas Pressures.

Generally, gas pressures (in a factory, for example) are sufficiently constant for the correct working of gas-consuming apparatus, but occasionally owing to piping being of insufficient size a variation in the consumption will cause a variation of pressure. The best remedy is to relay or supplement the piping in the building, but, as a temporary measure, governors can be installed on any apparatus which needs a fairly constant supply of gas. The Stott, Peebles, Tilley, Sugg, and Williams governors are typical of this appliance. They maintain a constant pressure on their outlet regardless of wide variation at the inlet.

Gas Meters.

Size of Meter.	Normal Capacity.	Safe Maximum Capacity.
Lights.	Cub. ft. per hour.	Cub. ft. per hour.
5	30	60
10	60	100
20	120	200
30	180	300
50	300	450
60	360	480
80	480	600
100	600	750
150	900	1,100
200	1,200	1,500
250	1,500	1,900
300	1,800	2,300
400	2,400	3,000
500	3,000	3,700
600	3,600	4,500
800	4,400	6,000
1,000	5,000	7,500

It is desirable that the normal capacity should not be exceeded for continuous working, as there will be some risk of the meter breaking down and the supply of gas temporarily stopped. If additional gas-consuming apparatus is installed a larger meter should, if necessary, be used.

GAS TESTS AS PRESCRIBED BY THE METROPOLITAN GAS REFEREES.

As gas is now sold on the 'Therm' basis, the determination of calorific power is the most important of the official tests. Illuminating power, however, is frequently required as a matter of interest rather than importance, and for this reason the test is given below.

(1) *Illuminating Power.*

Although calorific power is taking the place of illuminating power as a standard of quality, the latter test is still carried out in many instances.

This test is made by a photometric comparison between (*a*) a standard Argand burner called the Metropolitan Argand Burner No. 2, of which a part section drawing is given in fig. 1; (*b*) a standard flat-flame wing burner $\left(\text{Bray's } \frac{G}{L} \text{ 5 ft. } \frac{15}{10}\right)$ having a slit 0·028 in. wide, and a 10-candle power standard lamp burning a mixture of pentane and air. The standard lamp is shown in fig. 2. A is a receptacle subdivided by seven alternate partitions which do not extend the full width of the chamber; so that air, drawn in through the cock S_1, by means of which the supply is regulated, is caused to traverse the surface of the liquid, with which the chamber is filled to about two-thirds of its height, eight times. The mixture of gas and air passes through the cock S_2 to a burner B, consisting of a steatite ring pierced with thirty holes between 1·5 and 1·25 mm. in diameter. The flame is viewed through a mica window in G. Careful adjustments are made to regulate the height of the flame and the concentricity of the chimney D.

The pentane for the lamp is prepared and tested in the following manner:—Light American petroleum, such as is used for making air-gas, is rectified by three successive distillations, at 55° C., 50°, and 45°. The distillate is shaken up from time to time, during two periods of not less than three hours each, with one-tenth its bulk of (1) strong sulphuric acid, (2) solution of caustic soda. After this it is again distilled, and that portion which comes over between the temperatures of 25° and 40° is collected. This consists chiefly of pentane, with small quantities of other homologues the presence of which does not affect the light of the lamp.

The density of the liquid pentane at 15° C. should lie between 0·6235 and 0·626 compared with water of maximum density.

Any admixture with pentane of hydrocarbons having a higher photogenic value, such as benzene or amylene, must be avoided. The presence of these may be detected by the following test:—Pour into a stoppered 4-oz. bottle of white glass 10 c.c. of dilute nitric acid, specific gravity 1·32; add 1 c.c. of a dilute solution of potassium permanganate (1 gr. in 200 c.c.). Pour into the bottle 50 c.c. of the sample of pentane, and shake strongly during five successive periods of 20 seconds. If there is an admixture of as much as ½ per cent. of amylene or benzene, the pink colour will disappear.

The photometric comparison is made by producing equality in the illumination of a white paper screen by shifting the test burner nearer to or further from the screen; the result, after applying barometric and temperature corrections, is expressed to the nearest hundredth of a candle.

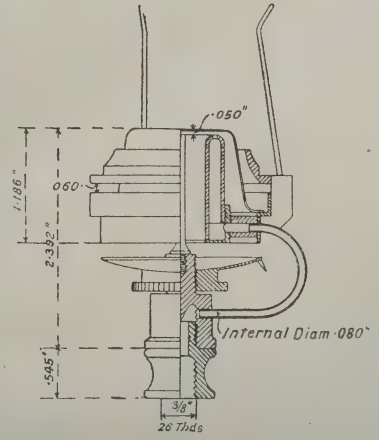

FIG. 1.

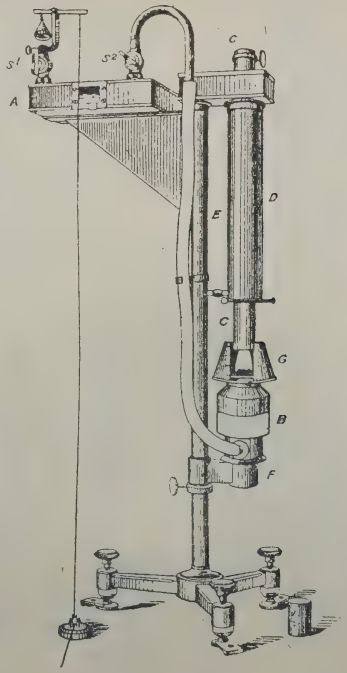

FIG. 2

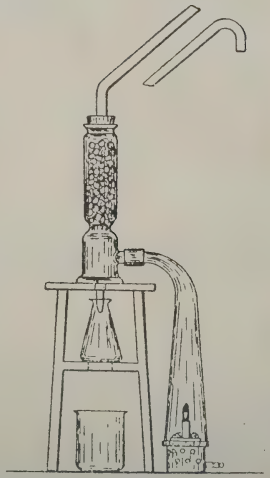

FIG. 3.

(2) *Test for Sulphuretted Hydrogen.*

The gas is passed through a glass vessel in which are suspended strips of bibulous paper moistened with a solution of 6·5 grams acetate of lead crystals in 100 c.c. water. The gas having been turned into the vessel long enough to sweep out the air, is ignited at the issuing orifice, and when it has burned for three minutes one of the slips is compared with a slip similarly moistened but not exposed to the gas. The gas is taken as exhibiting a trace of H_2S if the exposed is unmistakably darker than the unexposed slip.

(3) *Tests for other Sulphur Compounds.*

Ten cubic feet of gas is burned in a Bunsen burner at the rate of ·5 cubic foot of gas per hour. The stem of the burner is surrounded with about 2 ounces of sesquicarbonate of ammonia, and the combined products of combustion and volatilisation are collected by means of a trumpet

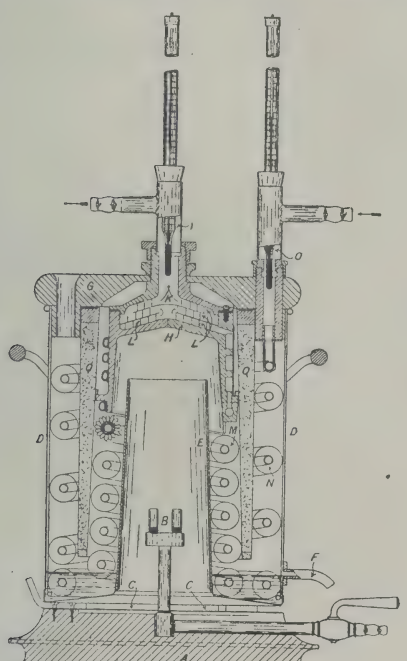

FIG. 4.

glass fitted over the burner and salt, an air-way being provided for the burner in the stand upon which it is placed (see fig. 3). The products are condensed as far as possible in the upper glass vessel, which, to aid the condensation, is filled with a number of glass balls about 15 mm. in diameter. The distillate, collected in a beaker placed beneath the bottom orifice of the condenser as shown, is poured, together with the washings of the trumpet and condenser, into a measure glass. A sample $\left(\frac{1}{n}\text{th part}\right)$ of the liquid is treated with hydrochloric acid in a covered beaker until there is an excess of acid, and then raised to boiling point; an excess of a barium

chloride solution is added, and the boiling continued for five minutes. After standing for a time, barium sulphate settles; the latter is filtered off and washed with hot distilled water, in order to remove all traces of ammonium and barium chlorides. (A sample of the washings is tested for this in a test tube with silver nitrate, the washing being continued until no cloudiness is produced by the nitrate.) The filter paper with the barium sulphate is heated in a weighed platinum crucible until the paper is removed. When cool the crucible is placed in a desiccator over strong sulphuric acid and again weighed. The number of grains of barium sulphate thus obtained, multiplied by $\frac{11n}{8}$ (n being the quantity of liquid under test as above), gives the grains of sulphur per 100 cub. ft. of gas. This figure is corrected for barometric and temperature variations as in the case of the illuminating power test.

(4) *Tests for Calorific Power.*

These are carried out by observations taken by means of the special calorimeter illustrated in fig. 4, in which water flowing at a calibrated rate is heated by a double burner consuming the gas at a rate of $\frac{1}{10}$ cub. ft. per minute. The calorimeter having been set up, the burners lighted, and the water flow adjusted, the heating is allowed to proceed for not less than half an hour. Four readings of the inlet thermometer and fifteen readings of the outlet thermometer are taken at periodic intervals, during which the discharged water is collected in a measuring vessel and the operation timed by means of a chronograph. The temperature of the air about the apparatus, the gas in the meter, and the effluent gas are also observed. The mean of the four readings of the inlet temperature is subtracted from the mean of the fifteen readings of the outlet temperature, and the difference is multiplied by 3 and by the number of litres of water collected. The product is divided by a tabular number.* The difference in degrees Centigrade of the temperature of the effluent gas and of the surrounding air divided by 6 is added to the result previously found if the effluent gas is the warmer of the two, or subtracted if the effluent gas is the cooler. The result is the gross calorific power of the gas in calories per cubic foot (c).

In addition to the foregoing, the amount of condensed water resulting from the combustion of the gas is measured. For this purpose the condensation water is led into a flask not less than 20 minutes after the calorimeter has been set up. The amount collected in not less than 30 minutes is measured, the time of collection being accurately noted on the chronograph. The number of cubic centimetres collected is multiplied by the number of seconds and by the number 1·86 (a). The number of seconds during which the condensed water is collected is multiplied by the tabular number (b). The first product (a) divided by the second (b) and subtracted from the gross calorific power (c) gives the net calorific power in calories per cubic foot. The gross and net calorific power in British thermal units is obtained by multiplying the corresponding numbers of calories by 3·968.

The meters used for these tests are of the 'wet' type, having a calibrated capacity of $\frac{1}{5}$ cubic foot per revolution of the drum. The drum carries an index-hand moving over a dial divided into 100 divisions, and the meters are provided with a thermometer for measuring the normal gas temperature.

ACETYLENE.

(Contributed by the late Professor Vivian B. Lewes, F.C.S., F.I.C.) Revised by Charles Bingham, C.E.

Acetylene, which is a gaseous compound of hydrogen and carbon, represented by the formula C_2H_2, is a colourless gas with a density of 0·92. As ordinarily prepared, it has a strong and very penetrating odour, but when purified from minute traces of other gases, invariably present with it in its crude state, has a not unpleasant ethereal odour. It can be converted into a liquid at a pressure of 21·53 atmospheres, at a temperature of 0° C., and liquefies under ordinary atmospheric pressure when cooled to a temperature of −82° C. The critical point of the gas is 37° C., and at this temperature the pressure has to be raised to 68 atmospheres for its liquefaction.

Acetylene is readily soluble in water, which at normal temperature and pressure takes up about its own volume of the gas; its solubility in other liquids is given in the following table:

100 Volumes of		Volumes of Acetylene.	100 Volumes of		Volumes of Acetylene.
Brine	absorb	5	Fusel oil	absorb	100
Water	,,	110	Benzene	,,	400
Alcohol	,,	600	Chloroform	,,	400
Paraffin	,,	150	Acetic acid	,,	600
Carbon disulphide	,,	100	Acetone	,,	2,500

* The tabular number depends upon the barometer reading and the normal temperature of the gas passing through the meter.

Many years ago experiments were carried out in this country with alcohol and petrol, which were enriched with acetylene, owing to the property possessed by these liquids of absorbing far more acetylene than their own volume. The object at that time was not so much to get a richer fuel, as to obtain easier starting of the single and two-cylinder cars then in general use. The results obtained with these enriched fuels (for which various patents were obtained in this country) were apparently quite satisfactory, but with the coming of the 4-cylinder and 6-cylinder cars, starting was rendered much easier, and the use of the enriched fuels disappeared.

Lately the high price of petrol has caused the use of acetylene for enriching liquid hydrocarbons to be taken up again, and in one country at least, alcohol enriched with acetylene is being pushed with considerable vigour.

Extended researches by Bistrow and Liebreich upon the toxic properties of acetylene show that it acts upon the blood in much the same way as carbon monoxide, but exhaustive experiments show that it is less poisonous than ordinary coal gas.

Acetylene forms compounds of an explosive character with copper and silver, and at first this was thought to be a great drawback to its general use ; but experience has shown that these fears were unfounded, and that brass gas fittings, when gas-tight, can be used with perfect safety.

When heated to a temperature slightly below its decomposing point, acetylene rapidly polymerises into a large number of other more complex hydrocarbons, amongst which have been identified benzene, toluene, naphthalene, anthracene, indene, diphenyl, fluorene, pyrene, and chrysene. When heated to a temperature of 780° C. it decomposes into carbon and hydrogen with the evolution of so much heat that the carbon is rendered incandescent and emits light, this being due to the fact that acetylene is one of the few bodies the formation of which is attended with the disappearance of heat ; it is for this reason termed an ' endothermic ' compound.

Experiments carried out lately by the French Acetylene Office have shown that, whereas, as stated above, polymerisation only takes place at a comparatively high temperature when the gas itself is heated in the way customary in the laboratory, it commences at a far lower temperature in the generating chamber of a commercial acetylene apparatus, when calcium carbide is brought into contact with water.

Polymerisation has been shown to start in the carbide chamber at as low a temperature as 135° C., or at not much above the boiling-point of water, while the heat liberated by the polymerisation itself sets up additional polymerisation.

These experiments are of the utmost importance, particularly as regards oxy-acetylene welding.

There are numerous acetylene generators in this country, in which the temperature in the generating chamber considerably exceeds 135° C., chiefly owing to the fact that the quantity of water fed to the carbide is not sufficient to carry off the very considerable amount of heat liberated when the carbide is decomposed to form acetylene.

The result in such cases is that a portion of the acetylene is polymerised—i.e. converted into gases, such as hydrogen, methane, etc., and even into tarry products. These other gases and tar have very little or no value for welding purposes, and on many occasions have even led to the welding being most unsatisfactory, although the expenditure in carbide, oxygen, and labour may have been far higher than it should have been.

In contact with air acetylene inflames at a temperature of 480° C. and burns with a flame which, when properly spread out so as to obtain a large quantity of oxygen, emits more light than any other gaseous compound of carbon and hydrogen.

Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.	Gas.	Candle hours per 5 cub. ft.	Carcel hours per cub. metre.
Methane	5·2	3·5	Propane	56·2	40·0
Paris gas	13·3	9·6	Ethylene	70·0	49·0
London gas	16	11·5	Butylene	123·0	86·0
Ethane	35·7	25·0	Acetylene	240·0	168·0

Professor Clowes has shown that acetylene has a wider range of explosibility when mixed with air than any other combustible gas, the limits in percentages being as follows :

	Per cent.		Per cent.		Per cent.
Acetylene	3 to 82	Carbon monoxide	13 to 75	Methane	5 to 13
Hydrogen	5 to 72	Ethylene	4 to 22		

Acetylene is made commercially by acting upon a compound known as calcium carbide (CaC_2) with water, when acetylene gas is liberated and calcium hydrate (slaked lime, $Ca(HO_2)$) is formed.

Calcium carbide is made by fusing together very pure coke (or high-carbon anthracite coal) and very pure lime by the intense heat of the electric furnace. No other way of heating the mixture to the required temperature has yet been discovered, although many attempts have been made, for instance by the use of the oxy-acetylene blowpipe.

Acetylene generators, in which the interaction of the calcium carbide and water to generate the gas takes place, may be either automatic or non-automatic. In the former class, devices are used to stop the generation of the gas automatically, by cutting off the supply of water or the supply of carbide, thus doing away with the need of a large store-holder for the gas, whilst in the non-automatic class the action is allowed to continue until all the carbide is decomposed, the gas being stored in a holder from which it is used as required.

In making acetylene, water may be brought in contact with the carbide either by adding it to the carbide, or by adding the carbide to water.

The overwhelming majority of acetylene generators in practically all countries are now constructed on the water-to-carbide system.

Of late years the automatic type of apparatus for the generation of acetylene has almost entirely superseded the non-automatic type, owing to the very large quantity of acetylene now being required for the oxy-acetylene welding process.

Experience has shown that automatic generators can be constructed with a high factor of efficiency, while the capital outlay per unit of gas generated is considerably less than in the case of non-automatic apparatus.

Owing also to the much smaller space occupied by the automatic type, it has also been found much more convenient for private use.

The oxy-acetylene blowpipe has been most successfully used for a considerable time for case-hardening various parts of machinery, and in particular the gear-wheels and other parts of motor cars. Lately a most important development has taken place in this direction, the blowpipe having come into the most extensive use, not only for cutting and repairing rails, but for applying an exceedingly hard surface, to a depth reaching even the high figure of ¼ inch and more, to the entire rail system of electric tramways.

The improvement shown in the wearing properties of rails is shown by the following figures :

	Wear of rails in 12 months.		No. of cars
	Untreated.	Treated.	carried.
Bristol	0·045	0·0157	300,000
Liverpool . . .	0·030	0·0125	200,000

The rails are hardened *in situ*, without otherwise interfering with the track in any way.

Acetylene as obtained from ordinary generators contains a certain amount of impurities. The use of the acetylene blowpipe for welding high-class steels has shown more and more clearly the necessity for removing these impurities from the gas, a purification which can easily be effected by the use of such purifying materials as catalysol, heratol, etc.

One pound of commercial calcium carbide, when acted upon by water, yields on an average about 4·5 cub. ft. of the gas.

Before the war the price of carbide was about 12*l.* 10*s.* per ton, packages included. The price is now about 20*l.* in the United Kingdom, while it is still higher in many of the countries producing it, notably in Italy and France.

Dissolved Acetylene.

By an Order in Council issued in 1897 the compression of acetylene was made illegal, but further orders were issued in 1901 and 1912 exempting the process now known as 'dissolved acetylene.' This is acetylene thoroughly purified and washed, and compressed into steel cylinders previously filled with a porous mass and having a fixed quantity of acetone added. Acetone is a liquid hydrocarbon, having the property of absorbing 25 times its own volume of acetylene at atmospheric pressure and 15° C.

For each additional atmosphere of pressure, the same proportion of gas is absorbed, but an allowance has, of course, to be made not only for the volume occupied by the porous filling of the cylinder, but, in addition, in order to allow for expansion, so that it is customary to charge these cylinders with only 43 per cent. of acetone.

A cylinder will therefore in actual practice contain about 100 times its own volume at 10 atmospheres pressure and about 150 times at 15 atmospheres pressure.

In order to show the enormous capacity for storing light obtained in this manner, it may be mentioned that the standard oil-gas cylinder in use on railways has a capacity of 14 cub. ft. at atmospheric pressure. As the oil-gas is usually compressed to 12 atmospheres, this gives a gas volume of 168 cub. ft., which, if filled with oil-gas, will supply eight burners using 2 ft. per hour and burning eight hours per day, for about a day and a half. If this cylinder were filled with porous material and acetone in the manner described above, and charged with acetylene at 15 atmospheres, its capacity would be 2,100 cub. ft., or sufficient to supply eight acetylene burners of 1 cub. ft. each (giving a most brilliant light), for about thirty-three days (basing on eight hours' lighting per day), before the cylinders would require to be re-charged.

The possibility of obtaining acetylene in compressed form opens up a very wide field for the expansion of its utility.

The tests carried out by the Home Office Authorities before issuing the exemption order of 1901 were exhaustive, and furnished satisfactory proof of the safety attending the process of manufacture and the use of the cylinders.

Storage of Dissolved Acetylene.

Acetylene dissolved in acetone and stored, under a pressure not exceeding 225 lbs. per sq. in., in a vessel filled as completely as possible with some porous substance such as charcoal, is not deemed an explosive, and can therefore be manufactured, stored, and used without risk of infringing the Explosives Act.

(See also 1919 Order in Council, ' Dissolved Acetylene.')

Porous Material.—Various types of filling are in use and appear to give satisfaction. In this country the Kapok filling, patented by *Allen-Liversidge, Ltd.*, is chiefly in use. The porosity of the material should not exceed 80 per cent. The material should completely fill the receptacle, and should contain no pockets or cavities.

The Solvent.—Acetone is the most suitable commercial solvent, but substitutes for acetone could be permitted. The solvent should not completely fill the porosity of the material under any rise of temperature likely to be met with in practice.

Pressure Allowed.—The pressure can be 225 lbs., provided the cylinders used are of the solid drawn type, the pressure to be measured at 60° F. This increased pressure is only allowed for acetylene welded cylinders above 100 cubic feet in capacity if the construction of the cylinders is such that the strength at the top and bottom joints is not solely dependent on the strength of the welds at these points. This concession to acetylene-welded cylinders is made to expire after a limited period.

The Cylinders.—The cylinders should be made of mild steel containing not more than 0·25 per cent. of carbon and not more than 0·05 per cent. each of phosphorus and sulphur. The test pressure should be four times the working pressure, and should be maintained for not less than fifteen minutes. The use of oxy-acetylene welded cylinders should be discontinued as soon as possible, and, in the meantime, the ends of such cylinders should be made additionally strong by spinning them over. All cylinders should be annealed, but the use of fusible plugs, at present compulsory on acetylene cylinders, should be discontinued, as they are apt to become loose and, further, in the event of fire occurring, may actually lead to the fire being augmented.

It is not considered necessary to impose any conditions as regards the retesting of acetylene cylinders beyond requiring them to be thoroughly examined visually at intervals. The form of retesting to which oxygen and other cylinders are subjected cannot readily be applied to acetylene cylinders with their content of porous material and solvent.

Acetylene Lighting.

For the illumination of buildings, towns, and large areas by acetylene, generators of some suitable type are in general use.

Dissolved acetylene is used successfully from an economical and efficient point of view for many purposes where a constant supply of acetylene is required, and is particularly adaptable where space available for the apparatus is strictly limited.

In the matter of motor vehicle lighting it has been very extensively adopted. A cylinder containing acetylene absorbed in acetone under pressure and of convenient size is attached to the footboard or other suitable position on the car. Such a cylinder contains a sufficient supply of acetylene to meet the requirements for the lighting of the necessary lamps. The time for which the supply is available is variable according to the rate of consumption; the pressure of gas in the cylinder is reduced by an automatic governor or regulating valve, and the supply in the service pipes is maintained at a constant pressure to the lamps.

The standard automobile cylinders contain 20 cub. ft. and 40 cub. ft. of dissolved acetylene, and by the exchange system originated by the manufacturers it is possible for users to obtain refills at practically all important garages throughout the country.

Larger vehicles, such as motor omnibuses, mail vans, motor lorries, etc., may be equipped with outfits of larger capacity to meet the requirements of any particular case.

Another recent departure is the manufacture and circulation of cylinders containing dissolved acetylene of such capacity to meet the demands of motor cyclists. These cylinders are

standardised and contain 5 and 10 cub. ft of acetylene and, as with the standard cylinders for automobile work, they may be exchanged throughout the country.

For buoy and coast lighting dissolved acetylene has many advantages. The purity of the gas in this form, which is assured before compressing, gives the light increased brilliance and greater penetrating power, hence a shorter light period can be employed than with any other illuminant. Various special apparatus are in use, in which flashes of long or short duration are obtained by automatic means, the light being extinguished between the flashes instead of obscured (a small bypass burner remaining alight), thus economising gas. In some cases a flash of as short duration as one-tenth of a second is obtained, with perfect accuracy and flame. By means of this economical consumption and the great storage capacity of a comparatively small cylinder, a gas supply for periods as long as 12 months can be easily carried on a buoy, no attention being required until the gas is exhausted, when the cylinder is disconnected and replaced by a full one. The cylinders may be arranged in the form of a battery where larger consumption is involved.

Owing to the smallness of space required for acetylene in this form it is particularly adaptable for lighting railway coaches, yachts, and small craft. The effect of atmospheric temperature on the gas in this form is almost negligible, and other advantages are obtained by reason of the purity of gas and the elimination of handling carbide, water, waste and residue, and by the fact that the gas in this form can be stored indefinitely without deterioration.

The applications of this form of acetylene are ever increasing, and it has been recently applied with success to cinematographs, searchlight, signalling and projection work, where a small and compact plant consistent with efficiency is required.

The most recent application for illuminating purposes is that of its adoption for portable hand-lamps for mining and other similar purposes.

Lately acetylene buoys have commenced to displace other forms of coast-lighting to a very considerable extent. Such buoys take a very large charge of calcium carbide, usually one to two tons. They are entirely automatic, require practically no attention, and as they run for six to twelve months before requiring recharging, they form an exceedingly economical means of coast and harbour-lighting. Another great advantage is the fact that the light can be recognised at a much greater distance than that of the oil, or oil-gas, buoys previously used.

PETROL AIR GAS.

(Contributed by E. Scott-Snell, A.M.S.E.)

Petrol gas is made by impregnating air with the vapour of petroleum spirit, this mixture being sent through pipes in the usual way for combustion with incandescent mantles. The essential features of an apparatus for producing this gas are an air compressor, a carburettor—in which the air and petrol are brought into contact—and a gas-holder from which the pipe service is fed. In automatic apparatus, i.e. machines in which gas is made according to the demand, the holder is also used as a governor for controlling the supply of air and petrol to the carburettor. The relative proportions of air to petrol are very important: in fact, upon the relation of these ingredients, and the constancy of this relation under varying load and climatic conditions, the success or failure of any apparatus must depend. As a mantle is used for light-giving, a flame is required at the burner which shall give the highest possible temperature, i.e. the amount of air mixed with the petrol vapour must be such as to completely combust it. With the more volatile spirit, mainly hexane (C_6H_{14}), used for making this gas, complete combustion is assured when approximately two volumes of vapour are mixed with 98 volumes of air. This is calculated from the typical equation $2\ C_6H_{14}+19O_2=12\ CO_2+14H_2O$ representing the combustion of the chief constituent of light spirit. At present, opinion seems to be divided as to the advisability of sending such a mixture—which from its composition is obviously an explosive one in a confined space such as a gas-holder—through the system. It is found, however, that when the percentage of vapour in the mixture exceeds 4½ per cent., e.g., a 5 per cent. or 6 per cent. mixture, the gas is incombustible without the addition of further air, and in the better class machines advantage is taken of this fact to make a slightly richer gas than 4½ per cent., diluting it with the extra air required for complete combustion by the aid of Bunsen burners.

The air-compressing apparatus of a petrol gas machine may be actuated by any motive power, but as the work of forcing the gas through the pipes is comparatively light, nothing more powerful than a hot-air motor or wound-up weights is usually required. In a good apparatus, the relative amounts of air and petrol are mechanically measured before passing to the carburettor, so that constancy of mixture is obtained under all conditions of temperature within wide limits. When other means are adopted, such as leading the air across a bath of petrol, selective evaporation takes place, producing erratic results, the make of gas varying with every change of temperature. In fact, attempts to make apparatus of this sort automatic almost inevitably end in failure.

Petrol gas is probably one of the safest lighting mediums known, by reason of the small compass over which mixtures of petrol vapour and air are explosive (1½ per cent. to 4½ per cent., c.f. acetylene 3·3 per cent. to 52·3 per cent., coal-gas 7·9 per cent. to 19·1 per cent.) and the fact that over 90 per cent. of the escaping gas from any leak is air. It is also non-asphyxiating.

The gas varies in calorific value according to the proportions of the mixture and the spirit used, but a 6 per cent. mixture from 0·680 sp. gr. petrol has a gross calorific value of nearly 300 B.T.U.'s per cubic foot. Although this is a comparatively low figure, cooking and heating can be efficiently performed with suitably proportioned burners.

One gallon of light spirit gives 5,000 candle-power hours (Lewes). With petrol at 1*s.* a gallon this is equivalent to 2·4*d.* per 1,000 candle-power hours. The Government tax of 3*d.* per gallon is remitted when petrol is used for purposes other than propelling road vehicles.

Petrol gas can be stored almost indefinitely over water, but since a small 'Bijou' mantle requires anything from 4 to 12 cub. ft. per hour (according to whether a 6 per cent. or 2 per cent. mixture is used) the storage of any reasonable quantity of the gas entails the use of very large holders. Hence the advantage of the weight-driven type of automatic generator.

Attempts are being made to effect economy by using the less volatile petrols of 0·720 to 0·760 sp. gr. for lighting purposes, such as are in general use for motor cars. The physical characteristics of these spirits, however, are such that they do not lend themselves readily to cold carburation, for either considerable quantities will pass through the carburettor unvapourised, or if heat is used to evaporate them, heavy condensation is unavoidable in the pipe service, which must necessarily be very carefully laid to provide for it.

An explosive (or 'weak') mixture in the pipes and holder is unavoidable if heavy spirits are used, since they are not sufficiently volatile to allow of the use of a 'rich' mixture. See also Scott-Snell on 'Petrol Air Gas,' Soc. of Eng. Journal and Trans., March 1911; Illuminating Engineer's Soc. Journal and Trans., February 1913.

Heating Value and Candle-Power of Petrol-Air Gas.

According to *The Snercold Engineering Co.*, as the result of tests of a variety of different brands and grades of petrol, the fair average heating value of a gallon of petrol is 143,500 B.Th.U., and the maximum candle-power hours that can be obtained under the best conditions is 6,025. The following table shows different mixtures in percentages of petrol vapour used; for calculation purposes the heating value has been taken as 143,000 B.Th.U., and the candle-power hours as 6,000 per gallon.

TABLE SHOWING VARIOUS MIXTURES OF PETROL-AIR GAS.

Mixture Percentage of Petrol Vapour.	Gallons per 1,000 Cubic Feet of Gas.	Heating Value B.Th.U. per Cubic Foot.	Cubic Feet of Gas to the Gallon.	Candle-power Hours per Cubic Foot.
6	2·184	312	458·3	13·104
5½	2·0	286	500	12·0
5	1·82	260	555	10·92
4½	1·638	234	612	9·828
4	1·4638	208	687·5	8·7828
3½	1·274¼	182	785·7	7·644
3	1·092	156	916·6	6·552
2½	0·91	130	1100	5·46
2	0·728	104	1375	4·368
1½	0·546	78	1833·2	3·276

The heating value of coal-gas varies from 420–550 B.Th.U.'s per cubic foot according to the source of supply.

THE SNERCOLD PETROL-AIR GAS PLANT.

In this plant a 5½ per cent. mixture is generated. The carburettor will vaporise petrol in very cold weather without the application of warmth; in it, the temperature of evaporation falls as low as 49° of frost (– 17° F.), which is well below the lowest winter temperature in this country; for this reason condensation is impossible with the apparatus. The arrangement extracts the moisture from the air, which is carefully kept from contact with water, and thus the air on carburation is dry; hence it always absorbs the correct proportion of petrol, and a uniform gas is produced without possibility of variation. The air cannot obtain more than the predetermined quantity of petrol, while from the design of the carburettor it must take all that is supplied. When no gas is being consumed the apparatus is entirely inactive.

THE WELLS LIGHT.

FIG. 5.

Wells Light (*A. C. Wells & Co., Midland Road, St. Pancras, London, and Manchester*), fig. 5, is a portable light, up to 3,000 candle-power, produced from oil spray blown horizontally; the flame is quite unaffected by wind or rain. The arrangement is self-contained, and the containing vessel can easily be charged with oil and air during working, while accessibility of all parts for cleaning, combined with strength and simplicity, are features of the lamp.

The most useful sizes are as follows:

		Ins.	Ins.
No. 0, 500	candle-power; size of tank	13½	× 9
„ 1, 500 and 1,500	„ „ „ „	16	× 10½
„ 2, 1,500	„ „ „ „	24	× 15
„ 3, 2,500	„ „ „ „	24	× 18

The Wells Light has been adopted by more than 26 Governments, for military and naval purposes, and also by the principal Railway Companies in England and abroad.

(For 'LIGHTING,' see Section XXXV., Part III.)

HEATING.

(Revised by J. Roger Preston, Member of the Council of the Institution of Heating and Ventilating Engineers.)

General.

The unit of heat or British Thermal Unit (B.Th.U.) is the heat required to raise the temperature of 1 lb. of water 1° F.; the unit of surface is the square foot; the unit of pressure is the pound per square inch; the unit of temperature is the degree Fah. Air may be expressed in cubic feet or in pounds weight, and Table A shows how these are convertible.

TABLE A.

Air Temperatures.	12°	22°	32°	42°	52°	62°	72°
Relative Volume of dry air at given temperatures (Volume at 32° F. = 1) . . .	·960	·980	1·00	1·02	1·04	1·06	1·08
Weight per cubic foot in pounds	·0842	·0824	·0807	·0791	·0776	·0761	·0747

NOTE.—The volume of 1 lb. of dry air at 32° F. = 12·38 cub. ft. For any other of the above temperatures multiply by the relative volume.

The *unit loss of heat* for direct radiation may be taken as 1·8 heat units per square foot per hour per degree difference of temperature on the two sides of the surface, under normal conditions, viz.: in still dry air at a temperature of 60° F.

OPEN FIRE GRATES.

It would seem that the open fireplace is not the criminally wasteful contrivance that it is commonly supposed to be, and that the 'well' type of fireplace is open to criticism. 'The pleasant British practice of sitting round the open fire,' says the Fuel Research Board Report, 1918–19, 'is amply justified from the scientific point of view, when we know that so much as one-fifth of the total heat of the coal is immediately available for absorption by the sitters if they constitute themselves into a sufficiently close screen around the fire.' In addition to the directly measured radiant heat, the open fire, it seems, is to be credited with heat conducted, radiated, and convected from the fireplace, chimney, and walls to an extent which is such that all together some 60 to 70 per cent. of the heat of the coal is utilised in warming the room and the general fabric of the building.

The following hints as to the best method of altering ordinary house fire-grates, so that they will be more effective and economical, have been circulated by the Royal Institute of British Architects: 'Line your grates with fire-bricks. See that the fire-bricks are high enough to stand up above the fire. Take care that the back brick leans forward and is not more than 4 ins. from the front bars. Fill in the space at the back with fire-clay. See that your register is open not more than one-fourth of its full capacity. If you have no register, partially close the chimney opening with another fire-brick. Fill in the front space beneath the grate with a movable piece of metal. If you cannot do this, put a small fire-tile in the bottom of the grate.'

Heat Losses.

When a room is maintained at a higher temperature than the surrounding air, there is always a loss of heat through the windows, walls, air-change, etc. Modern practice demands that these losses shall be estimated as accurately as possible; a few of the most useful factors concerned are given below:—

Brick wall 12″ thick	. .	0·30	B.Th.U.'s loss per deg. diff. per sq. ft.
Brick wall 18″ thick	. .	0·24	" " "
Without plaster 12″ thick	.	0·34	" " "
Without plaster 18″ thick	.	0·26	" " "
Concrete wall 4″ thick	. .	0·53	" " "
Concrete wall 8″ thick	. .	0·40	" " "
Single window	. . .	1·06	" " " cub. ft.
Double window	. . .	0·76	" " "
Air	. . . . .	0·019	" " "

The following are some of the channels through which heat may be lost:—

Gases of high calorific value escaping the chimney unburnt.
Flue gases passing away at high temperatures.
By radiation and convection from uncovered pipes and fittings in Boiler House.
" " " " " " in Trenches.
" " " " " " in Basements.
" " " " " " on Roof.
Steam blowing away into atmosphere.
Condense water cooling in collecting well, etc.
Leakage from, and the cooling of air in, ducts where heated at intake.
Heated air passing away without doing any useful work.
Excessive heating of rooms.
Normal heating of rooms where not in use.
Leakage from air flues.

Reliable comparison of existing work can only be made after exhaustive tests, as owing to conditions varying so much, comparison can easily be misleading, a careful theoretical test balance would be more reliable than an incomplete one of existing conditions.

Care in design at every point to prevent waste, makes a very important whole in large buildings.

Economy.

The most economical system is that which wastes the least heat and costs the least in attendance and upkeep, providing the initial cost is reasonable.

Direct radiation plants are the most economical. Systems where the air is fully heated at the intake and distributed by ducts throughout the building will obviously have a rather high fuel consumption.

As a distributing medium, hot water comes the first, except where exhaust steam is available; there is not a great deal of difference between water and steam, providing that each is the best of its kind.

Cost of Heating.

The warming of the air costs much more than moving it; where it would take 1*d.* to move 1,000,000 cubic feet, it would cost 7½*d.* to heat it from 30° to 60° F.

Heating Systems.

The heating medium may be either water, steam, or gas. In the case of water and steam, these may be distributed in various ways, as follows:—

Water	Low pressure gravity circulation. Forced or induced circulation by accelerators. Various automatic induced. Gravity return.
Low-pressure steam.	Condense through traps (live-steam or exhaust-steam). Vacuum systems. Automatic vapour systems.

Heating by Hot Water.

Gravity Circulation.

For installations not exceeding, say, 5,000 sq. ft. of radiating surface, where upkeep and attention are serious items, this system is very suitable, and, if no exhaust steam is available, for economy it cannot be beaten.

Arrangements of Circulation.

The two-pipe method was at one time nearly universal. The single pipe has taken its place to a great extent, but a combination of the two is most general. The 'drop' system gives a very rapid circulation.

The following points require to be borne in mind :—Short circuits, dips and air-pockets, size and lengths of mains.

Size of Mains.

The first thing to decide is the maximum drop in temperature to be allowed between the flow and return; a small drop is desirable, but not always practicable, 20° may be taken as a standard. The following formula agrees very well with practice :—

$$U = \left[\left(16{\cdot}353 \frac{\left(H - \frac{S_1 H}{S_2} \right) 12D}{L} + 0{\cdot}00665 \right)^{\frac{1}{2}} - 0{\cdot}0816 \right] D^2 1224F.$$

where,

H = height of circulation in feet; S_1 = specific gravity of water in flow pipe; S_2 = specific gravity of water in return pipe; L = equivalent length of pipe in feet (bend, say, 12 diameters), D = diameter of pipe in inches; F = drop between flow and return in degrees; U = British Thermal Units per hour.

The rapidity of circulation in vertical pipes often increases at a greater rate than as the $\sqrt{H}$, owing to bubbles of steam forming.

The above formula gives B.Th.U.'s, but the curves on the following diagram, fig. 1, are in sq. ft. of radiation, calculated on an average of 160 B.Th.U.'s per ft. of radiating surface.

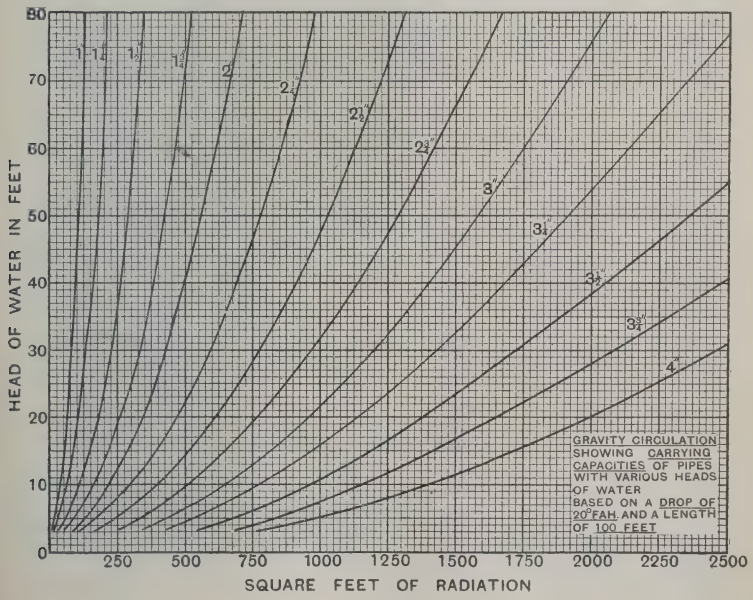

FIG. 1.

For short pipes, such as connections to radiators, a liberal allowance should be made to make up for velocity loss at entry and through connections; these have a considerable effect, so that apart from having a well-designed scheme, it is necessary to have an intelligent fitter.

TABLE OF FACTORS FOR DIFFERENT LENGTHS OF MAINS.

Length of Main. Ft.	Factor.
50	1·5000
100	1·0000
150	0·8125
200	0·7000
250	0·6125
300	0·5375
350	0·4875
400	0·4500
450	0·4375
500	0·3875

For different lengths of mains, multiply the heating surface from fig. 1 by the factor given.

CIRCULATION BY ACCELERATORS.

In large buildings where the radiation is extensive and at many different levels, pumps may be employed to circulate the water; this allows of smaller mains, owing to the higher velocities obtained. The piping may be arranged either on the one-pipe or two-pipe system. With the one-pipe, practically only the mains are under the influence of the pump, though there is a little pull on the branches, due to the loss of head on the main between the point where the flow is taken off and the return back.

The number of gallons of water required to supply the heat can be ascertained as follows:—

$$G = \frac{U}{10D}$$

where,

G = number of gallons per hour; U = heat loss in B.Th.U.'s; D = drop in temperature (F°) allowed between flow and return.

The size of mains depends upon their length, the number of gallons, and the maximum loss of head due to friction to be allowed. A fair velocity in the mains is from 200 to 600 ft. per min., according to the size and length, arranging for the total head not to exceed about 20 ft.; this is a point that should be carefully watched, as a contractor may cut down the size of mains to save initial cost, but, as a result, increasing the cost of upkeep.

The friction head and power required may be calculated in the usual manner for cold water.

There are several special types of accelerators on the market, though most centrifugal pumps are suitable, also drum or other pumps may be used if desired.

AUTOMATIC INDUCED CIRCULATION.

Where power is available, a simple accelerator is to be preferred; but there are conditions where an automatic arrangement is an advantage. These utilise the power of steam in some form, either by condensation, a partial vacuum being formed, which exerts a powerful pull on the water in the returns, or by the pressure being utilised to lift water from one tank to another at a higher level, the water returning through the circuits by gravity; a separate steam boiler is not always needed, steam being formed in connection with the water boiler.

Apart from the particular apparatus for producing the motive power, the heating system is the same as any other low-pressure system.

Low Pressure Steam Heating.

Gravity Return.

In this system the condense water finds its way back to the boiler by gravity. The steam may be distributed to the radiators by either the one or the two pipe systems.

In single pipe work the steam in the mains travels in the direction of the condense water, but in the risers and branches they meet (except in the drop system), and when starting the heat, noise is created. Where absence of noise is essential at all times, the two-pipe system is preferable; with this arrangement there are two pipes to each radiator, the condense pipes are carried down into a wet return or fitted with an automatic water-seal at the outlet to the radiator.

Size of Pipe.

The size of pipe to supply a given amount of heat at a given point depends upon the length, initial pressure, and the maximum loss of pressure to be allowed.

Taking the known formulæ for steam, and modifying the exponent and value of P, we get the following:—

$$U = \left(\frac{WPD^5}{L\left(1 + \frac{3 \cdot 6}{D}\right)} \right)^{\frac{1}{2}} 10^5$$

where,

U = British Thermal Units per hour; W = weight of a cubic foot of steam; P = loss of pressure in inches of water; D = diameter of pipe in inches; L = length of pipe in feet.

The results shown in Fig. 2 have been worked out for about 1·3 lb. initial gauge pressure and 3 ins. water gauge drop.

For one pipe work, multiply B.Th.U.'s by 0·5.

British Standard Heating Pipes.

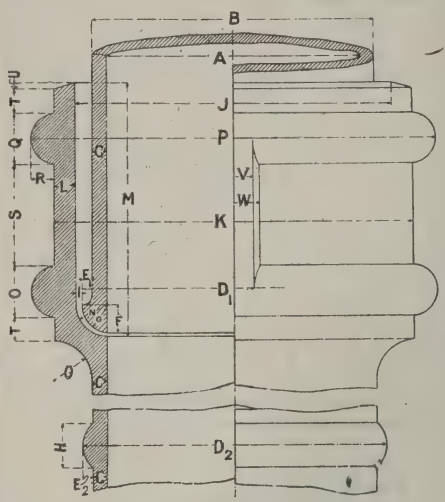

Fig. 3.

Fig. 4.

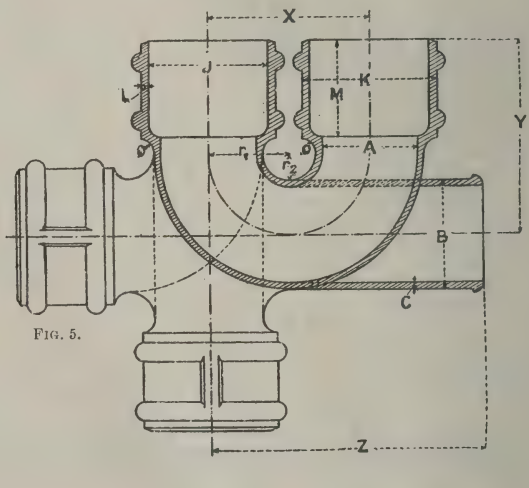

Fig. 5.

Vacuum System.

One of the objections to the ordinary gravity steam work is the difficulty of displacing the air in the radiators, and controlling the heat; this may be overcome by attaching a system of piping to the air valves connected to a small exhausting pump, which draws away the air and forms a partial vacuum; another way is to attach all the condense mains to a pump which will exhaust the air and draw away the condense water, this method is known as the 'Vacuum System.'

The piping is much the same as an ordinary gravity arrangement, except that the mains are rather smaller, and the condense pipes much smaller.

Owing to the thorough circulation of steam, the radiating surface as a high efficiency per sq. ft. per degree difference. It should be noted, however, that this does not materially affect the fuel efficiency.

The success of a vacuum system depends to a large extent on the proper working of the valves which are fixed on the radiators, or wherever condense water is likely to collect.

There are numberless different traps on the market, but a trap embodying the now well-known principle of the 'Laminated Strip' made up of two metals having different coefficients of expansion is very efficient. Some of the diaphragm traps are also good. The 'Trane' and 'Dunham' are typical examples of the foregoing respectively.

Heating by Exhaust Steam.

The use of exhaust steam for heating and other purposes such as drying, hot-water supplies, etc., is to be recommended wherever possible, as the adoption of this system enables the latent heat in the steam to be used, whereas this cannot possibly be used for the production of power, and the extension of this system would render many small and inefficient power plants at present in existence more efficient than any large condensing plant could possibly be.

For instance, the Technical Advisor to the Coal Controller states that the average thermal efficiency of steam-driven electric power plants at the present time is only 8½ per cent., whereas, if sufficient demand for heat can be found to enable the exhaust steam to be used for heating purposes, etc., the thermal efficiency of these plants might be increased to something like 60 per cent.

The exhaust steam can be either taken direct from the engines and conveyed without back pressure, for considerable distances, by the adoption of a modern vacuum system, or alternatively it can be used to heat water in calorifiers and the water pumped round to the various points where heat is required.

In many institutions, hotels, etc., it is found that there is practically no difference in the coal consumption whether the power is purchased from outside or generated on the premises, as there is a demand for heat all the year round which can be met by the exhaust steam from the power plant, so that the extension of this system to general domestic heating from the existing small power plants would enable these small power plants to run at a greater efficiency than any large condensing plant.

The utilisation of exhaust steam for heating when, as is too frequently the case, there is a back pressure on the engine—does not always result in economy. For assume that at a large works offices are to be warmed, requiring 800 sq. ft. of radiation, which offices are at such a distance from the main engine that a back pressure of 8 to 10 lbs. is required to force the circulation, the engine being 200 h.p. cutting off automatically at one-third of its stroke; the effect of the back pressure in this case would be to decrease the range of expansion to approximately one-half stroke, and presuming the initial pressure to be 80 lbs., and the consumption at one-third stroke to be 25·7 lbs. weight of steam per h.p. per hour, the consumption would be increased to 29 lbs. per h.p. hour, or a total for the 200 h.p., of 200 × 3·3 (the latter figure being the difference in the consumption without and with back pressure) = 660 lbs. of steam per hour. Now as the amount of radiation mentioned would require, at 8 to 10 lbs. pressure, less than 300 lbs. per hour, there is, so far from being an economy, a loss of over 360 lbs. of steam per hour as the result of using the exhaust steam under such conditions of back pressure. Only when it is used without back pressure will the full economy be derivable from the utilisation of exhaust steam for heating.

One square foot of radiation will give off about 250 heat units an hour. One pound of steam an hour will supply about 4 square feet of radiation. A rough-and-ready rule for finding the radiation that may be supplied by an engine is to multiply the horse-power of the engine by 131. When estimating on exhaust-steam heating, with non-condensing engines, the steam consumption for each indicated horse-power an hour will be about as follows :—

Engine.	Total.	Available for Heating.
Compound automatic	20 lbs.	18 lbs.
Simple Corliss	30 lbs.	27 lbs.
Simple throttling	40 lbs.	36 lbs.
Simple automatic, single valve	35 lbs.	31 lbs.

When exhaust steam is employed as the heating medium it is necessary to extract the grease by means of a separator, so placed as to intercept the grease before the steam enters the heating

main. It is also necessary to have an outlet to the atmosphere which should be closed by a valve weighted to open at a pressure of ½ lb. above the atmosphere, so as not to cause any back pressure. So low a pressure can, however, only be used for circulation when a vacuum return line is maintained, as in the vacuum system, for unless the air is first exhausted from the apparatus, a definite pressure is required to force it out through the air valves. With a vacuum return line no air valves are required on the radiation, and no foul air from the radiators is discharged into the rooms under any circumstances.

Plenum System.

'Plenum' is the name given to the system where the air is dealt with at the intake, tempered, washed, heated, and blown into the various rooms in such a quantity as to provide ventilation and make good the heat losses, the size of outlets being so proportioned as to allow of a slight pressure in the building, hence the name 'Plenum.'

The inlets may be from 8 to 10 ft. above the floor level, outlets at floor level on the same side of the room, the initial velocity of the air carrying it across the room, some of it cooling and gradually falling on the way—an extra outlet at ceiling level is advisable, especially if gas is the illuminant. Two ducts are necessary, one for hot and one for tempered or cold air.

Note.—Any system where the air is propelled into a building and maintained at a higher pressure than the atmosphere is a Plenum system, though the name is usually associated with downward methods of ventilation only.

Centrifugal fans are the most suitable, as the resistance of the heaters is considerable, apart rom the ducts.

There are several special makes, including the multivane types, for which a much higher efficiency is claimed.

For economy a fan should be chosen that will pass the amount of air just running at a suitable speed to overcome the resistance, as the power rises as the cube of the speed, while the output is only directly as the speed.

In steam heating, the temperature depends on the pressure of steam in accordance with the figures given in the following table :—

Table of the Properties of Saturated Steam.

Absolute Pressure per Square inch.	Tempera-tures.	Total Heat of One Pound of Steam from Water at 32 deg. F.	Latent Heat of One Pound of Steam from Water at 32 deg. F.	Weight of One Cubic Foot of Steam.	Volume of One Pound of Steam.	Pressure as shown by Gauge.

Boilers.

If plenty of draught is available, a boiler with a liberal amount of secondary flues and small grate area may be chosen: if the draught is small, one with less flue resistance would be more suitable. It should be of such a design as to allow of proper combustion in the fire-pot, free circulation in the waterways, the lighting, feeding, and ash doors to be well fitted, so as to stop an inrush of air at undesirable points; the general design to allow of clinkering and flue cleaning to be carried out with a minimum of trouble. The catalogue rating should give the number of B.Th.U.'s given off with a *six hours' firing interval*; *this should be taken from test, not based upon square feet of boiler heating surface, the value of which varies very much with different makes.* The *fuel efficiency* should be stated, and should *not be less than* 60 *per cent.* On testing a well-known sectional boiler, the highest efficiency was found to be at seven hours' firing interval (78 per cent. evaporative test), with a slight drop to four hours (due to loss from high flue temperature) and a quick drop to ten hours (due to incomplete combustion). While in power boilers combustion has received a deal of attention, heating boilers have been neglected in this respect.

Approximate Minimum Size of Boiler House for Different Sized Heating Installations.

Amount of Radiation in Feet Super.	Dimensions of Boiler House.*		
1,000 . . .	9 ft. long	5 ft. wide	7 ft. 6 ins. high
2,500 . . .	11 ft. ,,	6 ft. ,,	7 ft. 6 ins. ,,
5,000 . . .	13 ft. ,,	9 ft. ,,	8 ft. ,,
10,000 . . .	14 ft. ,,	13 ft. ,,	9 ft. ,,
20,000 . . .	18 ft. ,,	16 ft. 6 ins. ,,	10 ft. ,,
50,000 . . .	18 ft. ,,	32 ft. ,,	10 ft. ,,

* Exclusive of fuel space.

If hot water supply, boiler, etc., are required, extra space must be allowed.

Approximate Size of Chimney for Various Sized Installations.

Radiation in feet super. . . .	1,000	2,500	5,000	10,000	20,000	50,000
Size of chimney in inches . . .	9×9	14×9	14×14	21×18	24×24	36×36

Fuel.

The average calorific value per pound of fuel may be calculated at 12,000 B.Th.U., but of this it is only possible to obtain in the boiler an actual efficiency of 70 to 75 per cent. In other words, 8,000 B.Th.U. would represent the heat available from the boiler per pound of fuel burnt, the coal being of an average quality.

Size of Minimum Fuel Space Required for Various Sizes of Heating Installations on a Basis of One Month's Supply.

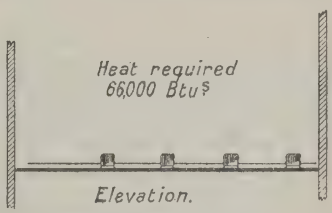
Radiation in feet super . . .	1,000	2,500	5,000	10,000	20,000	50,000
Fuel space in cubic feet . . .	500	1,000	2,000	3,800	7,600	19,000

Radiators.

Radiating Surface.

Vertical Loop Radiators are mostly used. Their efficiency varies with the design and size. They should be plain, smooth, and the loops so spaced as to allow of every part being easily cleaned.

Where it is permissible for the pipe supplying the radiators to be above the floor, the initial cost is considerably reduced, as will be seen from fig. 7; this is an important point often lost sight of in considering the cost of a heating installation.



Pipes below floor: cost £31.

FIG. 6.

Pipes above floor: cost £19 8s.

FIG. 7.

The above figures show the advantage of having the pipe above the floor where permissible

Note.—Prices fair competitive basis. (Jan. 1922.)

The amount of radiating surface will vary according to the class of surface and its temperature.

The relative efficiency may be put as follows:

Open pipe work	2 ins.	2·27	B.Th.U. per deg. steam.
" "	4 "	2·17	" "
Single column radiators	36 ins. high	1·75	" "
" "	24 " "	1·9	" "
Double column "	36 " "	1·66	" "
" "	24 " "	1·75	" "

The radiation from a surface is proportional to the difference of the fourth power of the absolute temperature, but a so-called radiator in practice also acts as a convector, the total heat given off per degree difference under normal conditions varying about as the 2·8 root of the difference in temperature between the skin of the radiator (5° less than the water) and the room.

The total heat loss from a room divided by the amount of heat given off from 1 sq. ft. of radiating surface will give the amount of radiation needed.

The following example shows how the amount of heat may vary:

Heat Loss from Room . . 100,000 *B.Th.U.'s.*

	Surface required in Sq. Ft.		
	Steam 210.	Water 185.	Water 160.
Open pipe work	293 (Min.)	376	505
Single column radiators 36 ins. high	380	487	660
" " 24 " "	350	450	605
Double column radiators 36 " "	400	513	690 (Max.)
" " 24 " "	380	487	660

Fig. 8 shows the variation needed for drop in temperature on a hot water circuit, each room being supposed to have exactly the same heat loss.

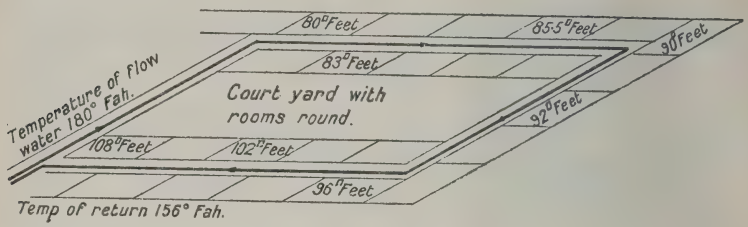


FIG. 8.

The above figure represents a number of rooms which are supplied with a hot water ring main, either forced or gravity circulation; each of the rooms are supposed *to have the same heat loss* (about 14,800 B.Th.U.'s); the figures show the amount of double col. radiation required, and shows the *increase in surface required* due to drop in temperature of the water in main. A total drop of 24 degrees is taken. The chief object of this diagram is to draw attention to a fact which is often given secondary consideration.

NOTE.—It is good practice if possible to arrange the circulations so that the hottest water is at the coldest side of building.

In indirect radiators, the B.Th.U.'s vary approximately as the square root of the velocity of air passing over the heated surfaces.

AMOUNT OF RADIATION SURFACE REQUIRED IN ROOMS OF AN AVERAGE HOUSE.

Type of Room.	Radiation in Feet Super. per 1,000 Cub. Ft. (To supplement domestic fires.)	Radiation in Feet Super. per 1,000 Cub. Ft. (Without fires in rooms.)
Corner room with large exposed wall and window surface	12	20
Less exposed room	9	15
Passage	—	20
Bedrooms	10	16

RADIATING SURFACE REQUIRED FOR DIFFERENT CLASSES OF BUILDINGS, AND COST OF HEATING.

Type of Building. (Taking the total cube.)	Average Heating Surface in Feet Super. per 1,000.	Approximate Cost of Heating per 1,000 Cubic Feet.
Churches	12	76 pence
Hospitals	20	170 ,,
Block of offices	15	135 ,,
Public buildings	12	108 ,,
Factories	7 to 10	51 ,,
Residences	12	108 ,,
Retail shops, etc.	8	70 ,,

The amounts given include the surface in mains for average work.

These costs, which are based upon present-day prices (January 1922), do not include builders' work, cutting away, making good, etc.

For country work add 10 per cent. to cover additional allowance to workmen, travelling, and incidental expenses.

APPROXIMATE HEATING SURFACE REQUIRED FOR HORTICULTURAL HEATING.

Type of House.	Approx. surface in feet super per 1,000 cubic feet.
Houses requiring to be kept at a temperature above 35° in order to prevent frost entering	16
Peach and similar Houses	27
Greenhouses	40
Tomatoes. Vines, etc.	60
Forcing Pits	130

TABLE OF RADIATION.

Height of Radiator in Ins.:		46	38	32	26	23	20	18
Type.	Length of One Section. Ins.	Heating Surface per Section in Ft. Super.						
Single column	3	—	3	2½	2	1⅔	—	—
Two columns	3	5	4	3½	2⅔	—	—	—
Three ,,	2¾	6	5	4¼	3½	—	—	2¼
Four ,,	3	—	8	6½	5	—	—	3

To find the space necessary for radiators, multiply the above figures by the number of sections required, adding 8 ins. in length for valve, elbow, union, and bushing.

WIDTH OF RADIATORS AT FEET.

	Ins.		Ins.
Single column	5½	Three columns	10½
Two columns	8⅔	Four ,,	11

The kind of metal, and the thickness of the latter, of which the radiator is made, has little effect upon the heat transmission, provided the radiator is painted.

Some recent experiments have proved that painting may affect the radiation as much as 28 per cent.

The white enamels give rather a better effect (103 %) than a plain unpainted surface (100 %). The ordinary white paints give about 100 %, the greens dropping to 96 %. Copper and aluminium bronzes are the worst, 72 %.

The *thickness of the coat* makes very little difference.

THE WESTINGHOUSE PATENT STEAM RADIATOR.

The Westinghouse Patent Radiator shown in fig. 9 was designed to overcome the disadvantages formerly attendant on the use of steam for heating purposes. Steam enters the radiator at A and passes through the opening in the valve seat B into a distribution pipe C, in the upper side of which a small hole is drilled opposite each column. It then passes up each column as shown by the arrows and into tube D. This tube contains another tube E of metal with a high coefficient of expansion, and when it reaches a temperature of about 210° F. or any lower temperature to which it is set, expands and closes the valve F, thus shutting off steam until the temperature is slightly reduced, when the valve again opens.

The temperature of the radiator can be varied as desired up to the maximum by moving the handle H which, owing to the screwed socket J, moves the tube E and valve F near to, or further from its seat B, and thus causes the valve to close at a lower or higher temperature as desired. The temperature of the radiator can never exceed 212° F., as the steam inlet is restricted by

the valve while the outlet is fully open to the return line, and the steam is therefore entirely condensed in the radiator, only water escaping to the return line. It will therefore be seen that the temperature of the radiator does not depend on the pressure of the steam supply, nor is it affected by the distance of the radiator from the source of supply.

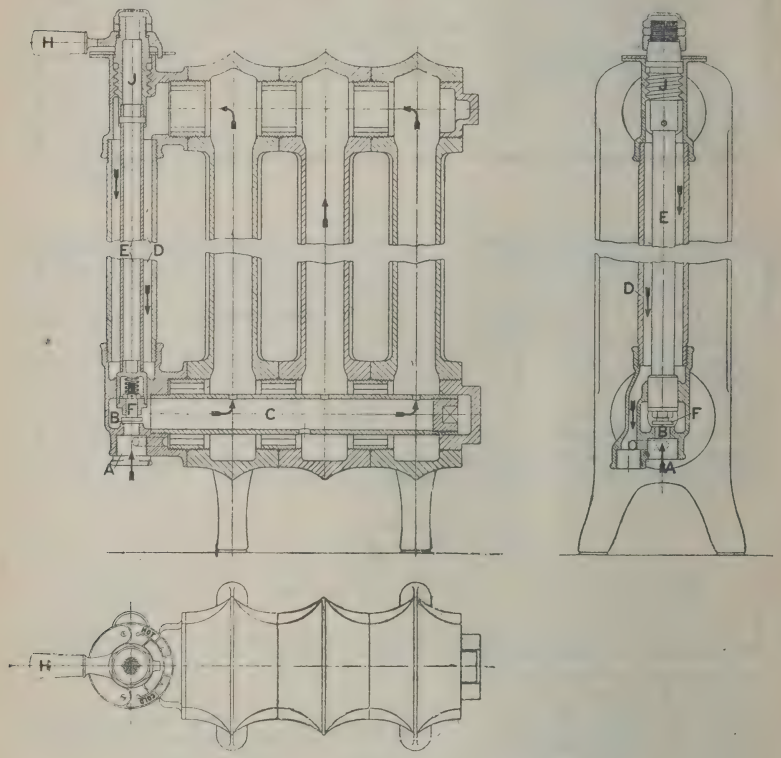

FIG. 9.—THE WESTINGHOUSE PATENT RADIATOR.

Temperature Regulation.

Complete automatic temperature regulation is conducive to health, comfort, and of its economy there is no doubt.

The temperature of each room should be regulated; this is accomplished in the principle system by means of compressed air acting on a diaphragm at the valves controlling the heat supply. Whatever it may be, either steam, water, or air, an instrument—sometimes a Thermostat—is hung in a suitable position in the room; it has a sensitive part made of metal (see p. 2378) or composition (according to make) which expands with heat and actuates the small valves controlling the compressed air.

Another method of temperature regulation is to have a system of 'telethermometers,' all leading to one central point where the engineer is stationed.

Contract Temperatures and their Equivalents.

(Direct Radiation.)

These, which are of considerable interest to architects and engineers, have been the subject of considerable controversy. Some years ago a Committee of the American Institute of Heating and Ventilating Engineers reported on the subject; in 1903 Mr. Walter Jones gave a paper before the English Institute. Professor Allen's paper on 'The Coefficient of Heat Transmission in Cast Iron Radiation,' June 1908, is one of the most modern.

The expression

$$\frac{t_3 - t_2}{t_2 - t} = \frac{t_3 - t_5}{t_5 - t_4}$$

is considerably in error, *even taking into consideration the different coefficients of transmission, extra losses due to increased air changes, etc.* In the discussion on Professor Allen's paper, Mr. C. B. Thompson said he had recently made some tests, but could not get more than 105° F. inside, with an outside temperature of 85° F. and surface that gave 70° inside when 0° outside.

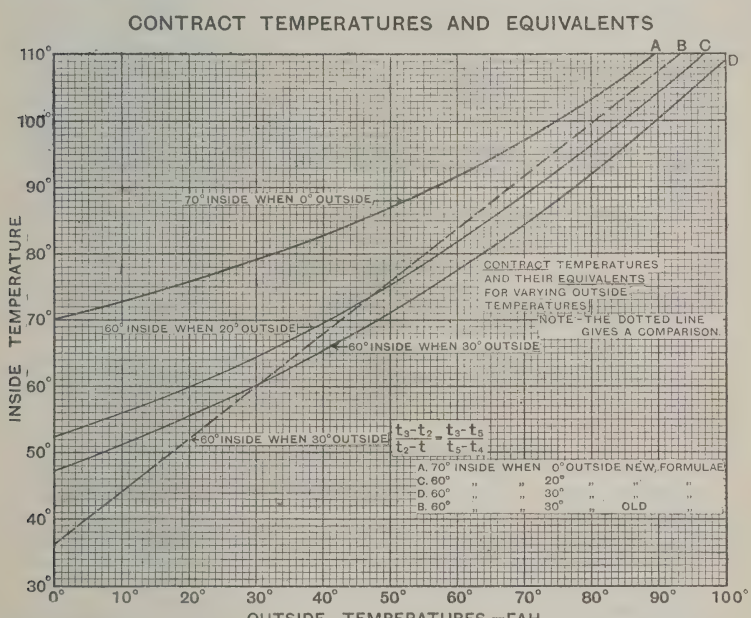

FIG. 10.

The following empirical formula is found to agree closely with *actual tests*:—

$$t_4 = [t_1^{12} - t_2^{12} + t_3]^{\frac{1}{12}}$$

where,

t_1 = contract inside absolute temperature F.
t_2 = contract outside " "
t_3 = existing " "
t_4 = estimated inside " "

The curves shown in fig. 10 are worked out from the above formula for reference under different contract conditions.

The time factor is an important one, as will be seen from fig. 11, which is from an actual test of a large public building warmed by steam-heated accelerated hot water. The upper curve shows the inside temperature, and the lower curve the outside temperature.

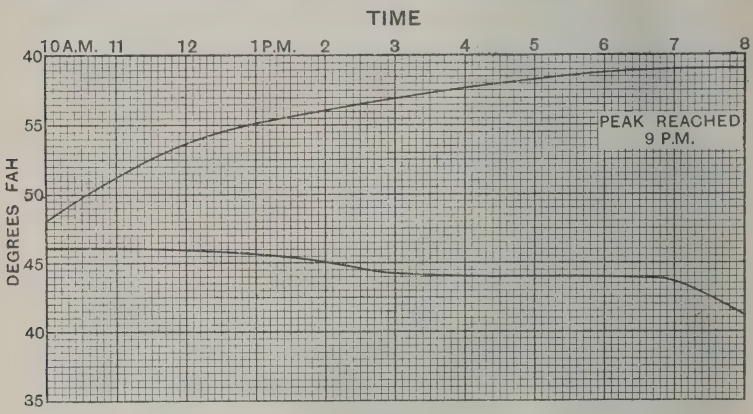

FIG. 11.

HOT WATER SUPPLY.

Hot water supply can be divided into three classes :—

1. Domestic hot water supply suitable for ordinary houses.
2. Hot water supply for institutions, hotels, etc.
3. For industrial work.

Domestic Hot Water Supply.

The general apparatus for this purpose in an ordinary house is a boiler behind the range, a cylinder in a convenient position, and a supply tank. Points which should have attention are as follows :—

Boiler and its flues should be so fixed in the range as to be easily cleaned ; also it should have an emptying tap.

Cylinder should be as near the boiler as possible, so as to ensure an easy circulation.

Feed tank should be in an accessible position unprotected from frost.

The fuel efficiency of a range boiler is low, and experience proves that even in quite small houses an independent boiler is more economical. It will be found that the major portion of the fuel used in a range is taken by the boiler, and not by the ovens required for cooking.

Institutions and Hotels Hot Water Supply.

For this class of work where steam is not required for other purposes, independent hot water boilers are the most economical. The type of boiler will depend on the nature of the water ; where the water is hard it is desirable to have the boiler of as simple a form as possible, with ample provision for cleaning out, a bolted top being very desirable in this connection. In some cases it may be found necessary to either soften the water or put in a system of secondary heating,

in which case the water in the boiler is circulated through a coil which heats the water in a secondary manner. Where the water is not hard, the sectional boilers bower-barffed have proved very successful and highly efficient. In domestic supply it is desirable that the cylinder, which would usually be of a horizontal type with dome ends, should be as near the boiler as possible; from this cylinder, secondary circulations of considerable length may be taken to the various parts of the building, to supply the different fitments. In arranging hot water supply circulations and draw-offs, it must always be remembered that where there is a branch off the circulation, and the tap on the end of that branch is open, so that water will flow both ways, both from the flow direction and from the return direction, the return, therefore, should connect to the cylinder at a high point. This is most important, and many failures have been due to neglect of this necessary arrangement.

In many cases steam is required, especially in institutions and hotels, for different purposes, such as cooking, etc., in such cases instead of having a separate hot water supply boiler, it is desirable to heat the water by steam; this is done by means of a calorifier; in principle it is simply a coil of steam pipe enclosed in a vessel of water, the steam being condensed and the latent heat of the same being conveyed through the coil to the water outside. This system also lends itself to thermostatic control. For this class of work it is very necessary that the pipe from the supply tank to the storage cylinder be of ample size. In some installations of a large size it is desirable to do away with the supply tank and simply keep the installation full by means of a pump, the pump automatically starting on a tap being opened. This system has many advantages, but is not so well known as the usual one of having a supply tank.

Method of ascertaining Heat necessary for a given Supply of Hot Water.

The basis of the calculations is that one British Thermal Unit will raise the temperature of 1 lb. of water 1° F. This figure varies a little according to the temperature of the water, but the variation is so small that for the purpose of hot water supply calculation, it may be neglected.

On this above basis we get the following simple formulæ

$$B = \frac{G \times 10 \times T}{H} + R,$$

where,

B = British Thermal Units per hour.
G = gallons of water.
T = degrees it is required to raise the temperature of water.
H = time in hours allowed for obtaining the required temperature.
R = radiation losses from pipes and cylinder, per hour.

Exampl .

It is required to raise 100 gallons of water from 40° F. to 150° in 2 hours; then

$$B = \frac{100 \times 10 \times 110}{2} = 55{,}000.$$

With regard to radiation losses, we may assume the cylinder and pipes loss to be, say, a mean of 10,000 B.Th.U. per hour; the total B.Th.U. per hour would then be

$$55{,}000 + 10{,}000 = 65{,}000.$$

It is assumed that the circulating pipes and cylinder would be covered with non-conducting material to conserve the heat.

A boiler will transmit on an average from 25,000 to 7,000 B.Th.U. per hour per foot of boiler surface, 2,500 being for secondary flue surface, and 7,000 for fume firepot surface. An average of 5,000 may be taken for an ordinary independent boiler with normal firing. A tube in a well-designed calorifier will transmit from, say, 8,000 B.Th.U. per foot at 1 lb. pressure to 37,000 B.Th.U. at 50 lbs. pressure. The pressure of the water surrounding the tubes has quite an appreciable effect on transmission, apart from the temperature of the steam.

Apart from the usual hot water supply in a hospital, a special sterilised supply is required for surgical work in the operating theatres; steam is generally used for this purpose, and the water is heated to sterilised temperature, or generally boiled, and the apparatus so arranged that the sterilised water does not come into contact with unsterilised water or air before it is delivered at the taps for the use of the surgeon.

Hot Water by Gas.

Gas is often used for the purpose of heating water, especially in small installations, and a very usual application of this, in an ordinary size house, is to connect up the gas-heating boiler to the circulating pipes, so that during the summer when the range is not required (the gas-cooker being used for cooking) the gas-heater boiler can be used when desired. Apart from the geysers, etc., the systems of heating the water are arranged in a general manner, as regards arrangements of circulation, etc. The amount of gas necessary is on the basis of the calorific value per cubic foot. The average calorific value of town gas is, say, about 500 B.Th.U.'s per cubic foot. Assuming the boilers of the heaters to have an efficiency of 80 per cent., this would mean that 400 B.Th.U.'s of the 500 should be actually transmitted to the water, so that, taking the amount of water to be heated as mentioned above, namely, 100 gals., to be raised 110°, which requires 65,000 B.Th.U.'s, this divided by 400 will give 16,250 cub. ft. of gas necessary.

Heating Water by Electricity.

For domestic uses, surgical work, industrial, and other purposes, a method of heating water by electricity is very handy; but there is a disadvantage, it is very expensive if a very large quantity of water is required; this will be seen from the following:—

The electrical Board of Trade Unit contains 3,411 B.Th.U.'s, and as the efficiency of electrical heating apparatus is very high, it may be considered that 3,000 B.Th.U.'s of the 3,411 would be transmitted to the water. Again, taking the quantity mentioned above, the amount of electricity required would be 65,000 B.Th.U.'s divided by 3,000, which gives us 21·9 units of electricity required. With regard to the type of heater, one very handy form, and one easily replaced, is the 'Immersion Heater.'

Industrial Hot Water Supply.

Hot water is required in a great many industries, and the method of heating the same is generally similar to the foregoing methods, although, very often, waste heat of the furnaces in various industrial processes can be utilised for heating the boiler. For some requirements, such as bottling, washing, etc., where it is desirable to have the water under considerable pressure, the closed pump system lends itself to this class of work. (*J. Roger Preston.*)

Heating and Drying.

Not infrequently rooms and chambers are found provided only with steam pipes, which have to do duty at night and in the day time in order to keep pace with requirements. Such rooms are very bad drying places, and very slow into the bargain, because the essential air current is lacking, and failure attends the introduction of a fan under these circumstances, owing to the influx of cold air following its use and lowering the temperature. To be effective the air must be raised to the required temperature before distribution and should act as a vehicle for the conveyance of the heat to and about the drying rooms or chambers.

To derive the maximum benefit from the use of exhaust steam, drying rooms of considerable size should have two or more divisions, as by this means operations may commence in one section soon after starting the engine, and conveniently proceed so that the operators may work in the cool part and finish up within a period of time to coincide with shutting off steam.

The proper temperature to effect rapid and perfect drying varies considerably, and depends upon the nature and texture of the material to be treated. Provided, however, the warm air current is fairly proportioned, then mechanical drying will considerably enhance the value and quality of the work, and vastly expedite and cheapen the process.

Heating and Drying by Gas.

Gas can be readily applied for the provision of a current of heated air for drying purposes on a small or large scale. Simplicity, low installation costs and accurate control (by themselves if desired) are the principal advantages. The temperature and degree of humidity of the heated air may if desired be put under automatic thermostatic control.

THE HUDSON AERO-CONDENSER.

This arrangement, figs. 12 and 13 (*The Hudson Economiser Co.*), is for the purpose of heating and drying by means of the spent steam from the exhaust pipe of the engine. The apparatus consists of a number of flat hollow galvanised steel plates, assembled in groups or batteries

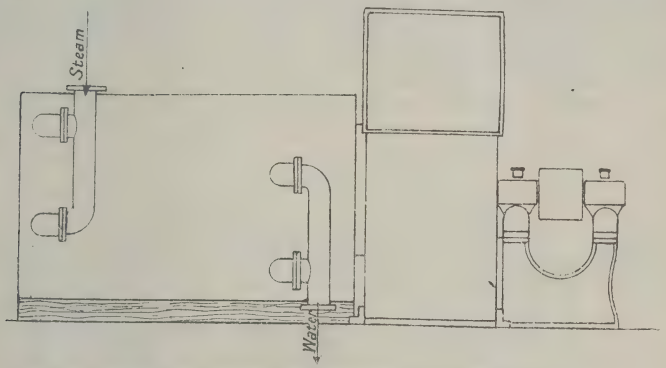

FIG. 12.—PATENT AIR HEATER AND CONDENSER, WITH CENTRIFUGAL FAN. (Top Horizontal Discharge.)

and arranged in a sheet iron case, to work in combination with a fan or blower. The plates are connected by an improved method, which provides a passage for the steam into and through the whole series, and preserves a given space for the air to pass between the separate elements. Cold air is drawn or forced by the fan through the spaces between the plates and absorbs the heat from

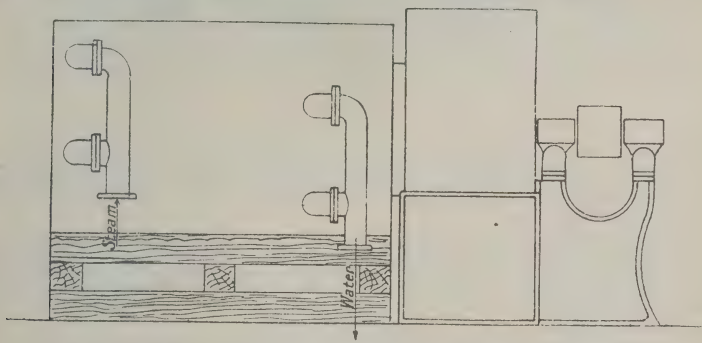

FIG. 13.—PATENT AIR HEATER AND CONDENSER, WITH CENTRIFUGAL FAN. (Bottom Horizontal Discharge.)

the steam circulating within. The steam and air are thus split up and divided into very thin alternate layers which move in opposite directions and rapidly exchange their temperatures, reducing the steam almost instantaneously from the vaporous condition to that of water and tending in like manner to raise the temperature of the air to a corresponding degree. The water of condensation falls to the bottom of the plate, and from thence to the drain pipe, to which may be attached an air pump when required for the production of vacuum.

The compact method of construction may be gathered from the fact that in each cubic foot of space occupied by the condensing battery there is no less than 38 square feet of effective surface.

and equal in point of area to 114 linear feet of 1-inch steam tube. The over-all measurement of an apparatus capable of passing 10,000 cubic feet of air per minute and raising its temperature 60° to 70° above the surrounding atmosphere is 2 ft. 2 ins. × 2 ft. 2 ins. × 4 ft. 6 ins.

The apparatus may be used in combination with a fan of the open type, or with a centrifugal fan, and the suitability or merits of one type compared with the other depend on the method proposed for the distribution of the hot air. The positive action of the centrifugal fan renders the best service in the delivery of air through ducts or channels of considerable length, and especially so when these have bends or branches which offer resistance to the passage of air, but in other circumstances the open-type air propeller has the advantage in moving a large volume of air at a minimum expenditure of power.

The apparatus may be fixed in a vertical or horizontal position, and will drain equally well in either case.

Drying Machinery.

The Ruggles-Coles Rotary Drying Machine.

This form of dryer (manufactured by *Electro-Metals Limited*, 56 *Kingsway*, *London*, *W. C.* 2) is of the double-shell type (fig. 14). It consists of two long concentric steel plate cylinders, set with the delivery end slightly lower than the feed end. Between the shells is the space which holds

Fig. 14.

the material being dried. The two cylinders are rigidly connected midway between the ends by six heavy cast braces. Additional support is obtained by placing swinging arms between this centre and each end, which allow for the unavoidable expansion and contraction due to differences in temperature. By means of this construction, shearing of rivets or loosening of joints is entirely eliminated.

The dryer is supported on two steel tyres riveted to the outer cylinder. These rest on four bearing wheels arranged in pairs on swinging arms, which latter rest on substantial cast-iron bases. The front base has thrust bearing wheels to hold the tyres on the supporting wheels. Distribution of the weight of the dryer takes place on eight bearing wheels, each of which has two bearings which prevent wear or overheating. The dryer is rotated by means of a heavy spur wheel fixed between the tyres and driven by a pinion shaft and pulley.

The interior construction of the dryer is as follows :—Lifting plates are fastened to the inside of the outer shell, running parallel to the axis of the dryer for its entire length. The revolving of the dryer causes these plates to lift, and drop the material being dried on to the hot inner shell, and by the inclination of the dryer the material is carried from the feed end to the delivery end. On the inside of the discharge head at the delivery end are riveted buckets which discharge the dried material through a central delivery casting. At the feed end the inner cylinder extends beyond and through the stationary head, and connects directly with the flue from the furnace. This inner cylinder forms an extended combustion chamber for the unconsumed gases leaving the furnace. Doors are provided at both ends of dryer for inspection purposes.

While the necessary draught for drying may be produced by a chimney stack, this is only possible where the exit gases are at a high temperature, about 450 to 500 degs. F., and if the gases were allowed to escape at this temperature the efficiency of the machine would be very low indeed.

The average temperature of the exit gases, depending of course upon the class of material to be dried, is 150 deg. F. or less. It is necessary, therefore, for an exhaust fan to be used for drawing the gases out of the dryer.

The operation of this type of dryer is as follows :—

The heated air and products of combustion from the furnace pass through the brick-lined connecting flue into the inner shell, thence to the rear end, where they turn and go back through the material being dried, and through an exhanst fan or stack to the outer air. The material is fed through the front head into the space between the two shells, is picked up by the lifting buckets, and dropped on to the inner shell. By the revolution of the machine it is dropped again to the outer shell to repeat the operation until, due to inclination of the machine, it reaches the rear end, where it is elevated and discharged through the centre of the rear head.

As the products of combustion travel twice the length of the shell, the capacity is practically the same as a single shell dryer of double its length.

On entering the machine, the temperature of the products of combustion is high (about 1,400°), but they begin to transfer their heat at once, through the wall of the inner shell to the cold and wet material, being held on top of it by the radial vanes. As they pass toward the rear end they give up practically all their heat, so that when they turn to pass back through the drying material they have been reduced to about 250 degrees. Additional outside air is then admitted to mix with them, so that the outside shell is cool at all times and the loss by radiation practically nothing. In passing back through the drying material being dried, from the delivery end to the feed end, they are still further reduced in temperature until, when they pass out through the fan or stack, they have been reduced to 150° F. or less, and the loss of heat in the exhaust is less than 7 per cent.

By this system of not allowing the products of combustion to come into contact with the material until they have been reduced to a very low temperature, the material can be delivered perfectly dry at a temperature below 212 degrees, so that little loss is occasioned by the sensible heat of the finished product. This is particularly valuable in a coal dryer, as no volatilisation or ignition is possible, while the economy of direct heat is obtained. On account of the small amount of radiation and the low temperature of the exhaust gases and dried materials an efficiency of 75 per cent., or better, is obtained in these dryers, figured from the calorific value of the fuel.

The class ' A ' type of dryer, generally described above, is made in eight different sizes and can be safely used where no harm is likely to be caused by the products of combustion coming into contact with the material being dried.

There are many materials which may be heated to a high temperature but which cannot be dried by direct heat on account of possible injury from the products of combustion. Again, many materials necessitate a steam-heated dryer. To deal with the former a modified form of dryer is used where the hot gases from the furnace, after passing through the central cylinder, return through tubes and out to the exhaust fan. For the latter, steam-heated pipes are used, the condensate being blown out automatically six times for every revolution of the dryer.

Several other types of Ruggles-Coles dryers exist, the whole range of designs providing a means by which practically any sort of material can be safely and satisfactorily dried.

SECTION XXXV

PART II

VENTILATION.

Amount of Air Necessary for Ventilation.

This should be based upon the number of occupants, the purpose for which the room is intended, and the number of hours it will be in constant use at one time.

The amount of carbon dioxide (CO_2) found present may be taken as an indication of the sanitary condition of the air and of its change of condition. Taking a standard of 6 volumes of CO_2 per 10,000 of air, each occupant would require about 3,000 cubic feet of air per hour.

The loss from any one surface, or amount of air, can be ascertained by the following formula:

$$U = H\ (t_1 - t_2)\ S.$$

Where U = British Thermal Units; t_1 = inside temperature F.; t_2 = outside temperature F.°; H = factor or heat loss from one sq. ft. of surface per deg. difference.

The combined losses from the various surfaces will give the total loss. For large rooms, 10 % less than the above is sufficient at ordinary temperatures generally required in this country, viz. 60° inside when the outside temperature is 30° (i.e. a difference of 30°), but the higher temperature of 70° inside is required in some countries.

Apart from the losses of heat through walls, etc., badly fitted window frames, direction of prevailing winds and aspect are points requiring consideration.

The curve (Fig. 15, p. 2128) shows the result of an actual test of air, observed in a large building heated by low-pressure hot water, the water being heated by high-pressure steam.

Distribution of Air.

The position and size of inlets and outlets depend upon the system of ventilation and style of building. In ordinary extract ventilation, the inlets are generally behind the radiators, the outlets at ceiling level. It is advisable to have extra outlets at floor level, as they assist to carry away any matter that may have fallen into the lower strata of air. Under certain conditions it may be advisable to have some outlets at the window-sills; cross ventilation may occasionally be applicable.

Convection currents are a most important factor in ventilation, and should be very closely studied; this can be conveniently done by blowing air through HCl and NH_3, thereby causing a dense white smoke (not heated), or by balanced mica vanes.

Out of over 100 tests, it was found that the CO_2 in upward ventilation under normal conditions increased with the height, while in downward ventilation it was fairly equally distributed. Inlets should never be quite at floor level or in such a position as to catch the dust. Where permissible, a brisk movement of air in a room gives a feeling of freshness.

Air Ducts and the Flow of Air.

The flow of air through a building resembles an electrical circuit, the inlets, outlets, and ducts acting as the resistance, and absorbing some of the aeromotive force. *To ensure an even flow in various ducts requires considerable care*, the resistance must be low, as the initial force in ventilation is small, usually equal to about 0·25 ins. of water, or 17 pneumatic units. In natural ventilation it is much less than this.

Air Cooling.

Tempering or heating coils may be used for this purpose by circulating calcium chloride brine through them.

Cooling costs much more than heating, owing to the condensation of the vapour present in the air. An ideal system is to have a combination cooling and heating plant, by which means the temperature and relative humidity are under complete control. In practice the air may be cooled from 15° to 20°, generally reducing the room temperature about 10°. The amount of brine to be circulated should be based on a drop of about 3°; the specific heat of the brine may be taken as 0·82, and in calculating the heat required for the reduction in temperature, the condensation of the vapour, according to the amount present or assumed, must not be forgotten. The heat in B.Th.U.'s required, divided by 12,000, will give the size of plant required, in tons of refrigeration per day of twenty-four hours.

Air Washers and Humidification.

The air washer finding the most favour at the present day for public buildings, and probably the most cleanly, is an arrangement of nozzles producing a fine spray. The washing action of this in part is probably due to a similar action to that found in Dr. Aitken's Dust Counter.

After passing the sprays, the air comes in contact with the eliminator plates, which collect the surplus moisture; the air at this point should be at such a temperature that, when raised to the room temperature, it will have a relative humidity of 60 per cent. to 70 per cent.

The relative humidity with either sprays, evaporating, or cooling coils, may be controlled in a similar manner to temperature, a 'humidistat' being used instead of a thermostat.

Flow of Air through Pipes.

The following will be found a handy formula for the flow of air through pipes:

$$C = \frac{39d^{2\cdot5}}{\left(\frac{L}{H}\right)^{\frac{1}{2}}}$$

where,

d = diameter of pipe in inches; L = length of pipe in feet; H = drop of pressure in inches of water; C = cubic feet of air per minute.

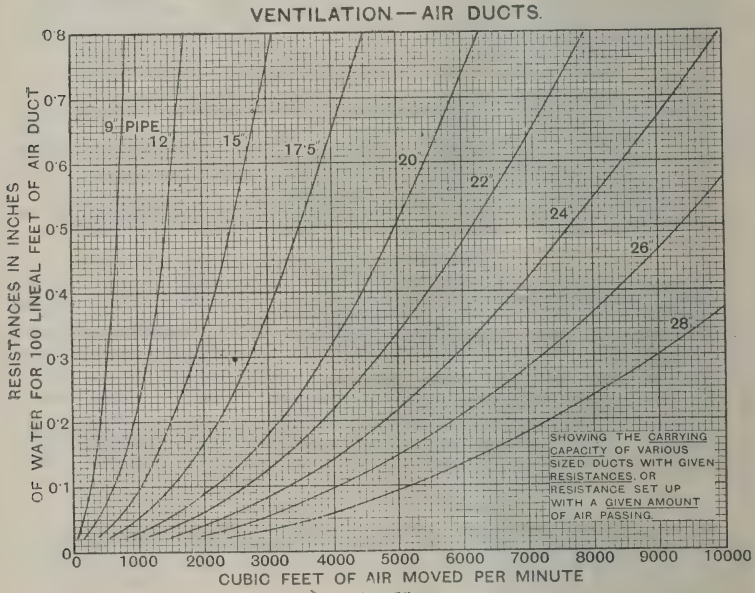

FIG. 15.

Fig 15 gives the carrying capacity at different pressures.

The number of bends, loss due to entry and registers, are a variable quantity. A bend may be taken as equivalent to a pipe 18 diameters in length; loss due to entry and register, 80 diameters.

Movement of Air Caused by Difference of Temperature.

As the air in a flue such as a chimney or outlet duct from a warmed room is at a higher temperature than the outside atmosphere its density is less, and the tendency is for it to rise. The resulting velocity of flow varies within wide limits, but is theoretically given by

$$V = 480\sqrt{\frac{h(T-t)}{t+460}},$$

where V = velocity of air in feet per minute: h = height of flue; T = temperature of heated air; t = outside temperature.

The actual velocity is considerably lower in practice, and the result from above formula should be multiplied by 0·25 to 0·6, according to size, shape, and materials.

THE BOYLE 'AIR-PUMP' VENTILATOR.

In the latest patented forms of Boyle's patent 'air-pump' ventilators the wind, striking against and being deflected by curved vanes causes a suction effect which draws out the foul air and effects perfect ventilation.

One form of the 'air-pump' ventilator, known as the *ridge* ventilator, is shown by fig. 16. The wind blows through the openings, and in passing over the curved plates causes a strong upward draught.

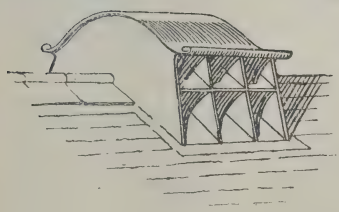

FIG. 16.

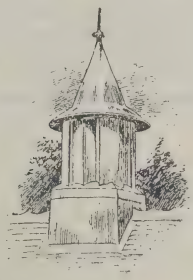

FIG. 17.

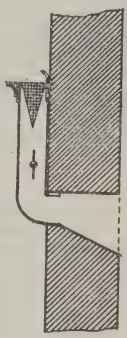

FIG. 18.

In the 'air-pump' ventilator (fig. 17) the curved vanes are set vertically.

For the necessary admission of fresh air to take the place of that extracted by the ventilator, Boyle's Air-Inlet Bracket, shown by fig. 18, may be adopted. The top of the inlet should be about 5 ft. 9 ins. above the level of the floor, and the outside opening should be covered with an iron grating.

Ventilation by Means of Fans.

PROPELLER FANS.

When the resistance of the ducts is small, say not more than 0·25 W.G., the propeller type of fan is suitable; it is cheap and easily fixed. As the resistance increases, the output drops very rapidly, as will be seen from fig. 15, p. 2128, plotted from actual tests.

To minimise noise, fans are arranged to run at a low speed; the output under these conditions is still more affected by resistance. Many failures are due to this point. The remedy is to have liberal sized ducts and fans.

An approximate formula for ascertaining the output of propeller fans is:—

$$O = KD^3R.$$

where,

O = output in cubic feet per minute; D = diameter in feet; R = revolutions per minute; K = a constant varying from 0·55 to 0·85, according to make of fan.

In testing several well-known makes of fans, K was found to vary as above. An open-bladed fan is more efficient than a close-bladed one under nearly all conditions.

CENTRIFUGAL FANS.

When the resistance is likely to be higher than 0·25 W.G., a centrifugal fan should be used; the efficiency is higher, but so is the price.

The actual outlet area of an ordinary centrifugal fan is about twenty-two times the capacity area; owing to the 'venacontracta' the effective area is about 0·8 of the actual, therefore the velocity at the outlet is 0·83 that of the peripheral speed. The amount of air required and resistance being known, the effective area can be calculated.

The ducts for 'propeller' fans, when required, should always equal the area of the fan at the fan; and care should be given to the design, so that the velocity of the air is as low as practicable. More than 760 feet per minute velocity will result in a considerable reduction of the output of the fan.

If silence is desired the peripheral speed of a 'propeller' fan should not exceed 4,000 feet per minute, and is safe at about 3,000 feet per minute.

The capacity of a 'centrifugal' fan varies very considerably according to design. For ventilating, drying, boiler draft, and similar work fans with blades curved forward at the tip are coming into general use: and they are capable of giving very high efficiencies. For a given duty the size of the casing, and therefore space occupied, is less than that of straight-bladed fans.

The power required to run a 'centrifugal' fan for a given duty is given by the following formula:—

$$\text{H.P.} = \frac{\text{C} \times \text{w.g. in.} \times 5{\cdot}2 \times 100}{33000 \times \text{E}},$$

where C = volume in cubic feet per minute; w.g. = resistance in inches of water; E = efficiency.

The efficiency is a very variable quantity, and depends upon the make of fan, also as to whether a suitable size of fan is used. If a suitable fan is chosen E will be about 40 per cent. with a straight-bladed fan, and about 50 per cent. with a curved forward bladed fan. A straight-bladed fan usually has six or eight blades, and a curved forward bladed fan from sixteen upwards.

When air is passed through ducts (steel, wood, or brick) a resistance is set up which varies as the square of the velocity. In other words, if the velocity is doubled the resistance will be quadrupled.

According to Professor Unwin, the resistance at 50° F. may be obtained by the following formula:—

$$\text{R} = \frac{\text{LV}^2}{14450d},$$

where R = resistance in inches of water (i.e. in. w.g.); L = length of duct in feet; V = velocity of air in feet per second; d = diameter or side of duct in inches;

from which, for a given resistance in inches w.g., the capacity of a given duct is

$$\text{Cubic feet per minute at } 50° \text{ F.} = 40\sqrt{\frac{d^5\text{R}}{\text{L}}}, \text{ for a circular duct;}$$

$$\text{" " " } = 50\sqrt{\frac{d^5\text{R}}{\text{L}}}, \text{ for a square duct.}$$

For different temperatures, multiply results by $\sqrt{\frac{460+t}{510}}$, where t = actual temperature (F.°) of air.

For a given resistance in ins. w.g. and given length, the size of duct is

$$\text{Diameter of duct} = \sqrt[5]{\left(\frac{\text{C}}{40}\right)^3 \times \frac{\text{L}}{\text{R}}},$$

$$\text{Side of square duct} = \sqrt[5]{\left(\frac{\text{C}}{50}\right) \times \frac{\text{L}}{\text{R}}},$$

where C = cubic feet per minute; L = length of duct in feet; R = resistance in inches of water.

The following particulars may be taken as representative of good practice for cased fans (fig. 19) suitable for ventilation purposes.

(*Oswald Stott.*)

Blowers and Exhausters.

STURTEVANT BLOWERS AND EXHAUSTERS.

The design of a fan depends upon the pressure against which it has to discharge. A blower designed for low pressure is not suitable for high, and *vice versâ*. Figs. 20 to 26 show various types.

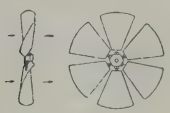

FIG. 20.

AIR PROPELLER.

For moving large volumes of air from one part to another where the resistance is low. Used for ventilating and exhausting.

MULTIVANE CENTRIFUGAL FAN.

For moving large volumes of air against 1 to 4 ins. water gauge. Fan wheel has shallow blades with corrugations to prevent lateral slip. Used for ventilating, drying apparatus, mechanical draught for boilers, etc.

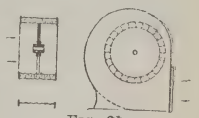

FIG. 21

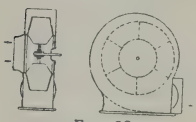

FIG. 22.

STEEL PLATE CASED CENTRIFUGAL FAN.

For air pressures up to 8 or 10 ins. water gauge. The square section steel plate casing is used, but the wheel has deeper blades and side plates (shrouds). Used for dust exhausting, conveying, etc.

CAST IRON CASING FAN.

For obtaining higher pressures up to 15 ins. water gauge, the casing must be more carefully designed and preferably made in cast iron. The wheel is narrower and deeper than that for lower pressures. Used for blowing forges, furnaces, etc.

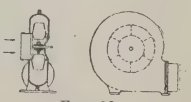

FIG. 23.

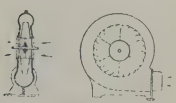

FIG. 24.

HIGH PRESSURE FANS.

For blowing cupolas, etc., requiring air pressures from 12 to 30 ins. water gauge. The scroll must be most carefully designed and the wheel have a greater number of blades. For sizes and capacities of this fan see page 2252.

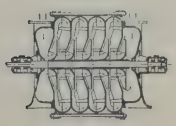

FIG. 25.

MULTISTAGE FANS.

For blowing and exhausting air at pressures up to 3 to 4 lbs. per square inch.

Rotary Blowers.

Fig. 26.

These are used for many duties, for blowing and exhausting air or gases where pressures up to 5 lbs. per square inch are required.

Power Variation of a Blower at Constant Speed.

Propeller Fans.—Power rises slightly with pressure; volume decreases rapidly as pressure rises.

Centrifugal Fans.—Power increases as pressure falls, and volume increases.

Rotary Blowers.—Power increases directly with pressure, volume remaining about constant.
(*Sturtevant.*

The 'Wing' Fan.

(*F. W. Potter & Co.*)

The general arrangement of the blades of the Wing fan or air propeller is shown by fig. 26. It is claimed that the Wing fan, for a given amount of power, will move a greater volume of air than any other pattern, owing to the shape, angle, and curvature of the blades, and the method of securing them to the central boss. It has been found that an angle of 27½° to 30° is the best all-round angle for combined output and efficiency.

A distinctive and useful feature of the fan is the adjustability of the angle of the blades, the latter being readily set to any angle. If desired, the direction of the air current may be reversed, this reversal of the air current being effected without impairing the efficiency of the fan.

The blades of the Wing fan are usually made of steel, but for certain purposes they are made of copper, aluminium, or Muntz metal.

The fan wheel is mounted on a spindle running in bearings lined with best quality Babbitt metal, and the framing is constructed of cast iron or wrought iron according to circumstances.

The Wing fan is manufactured in all sizes, arranged with pulley for belt drive, or direct coupled to electric motor.

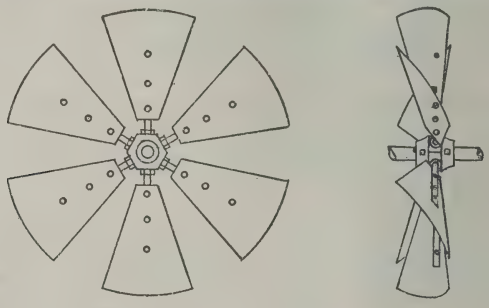

Fig. 27.

Economy of Power.—Where conditions permit of the choice between a propeller type and a centrifugal type of fan, the following rules are useful:—

(*a*) For open ventilation use propeller fans.
(*b*) Make main air duct same diameter as fan, or larger, avoiding acute or sharp angle bends.
(*c*) When small ducts and sharp bends are unavoidable use centrifugal fans.
(*d*) Use large fans at as low a speed as will overcome whatever resistance is in the way of free passage of air.

Example.—A 10 ft. Wing fan at 90 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 1·2 h.p.

A 5 ft. Wing fan at 720 revs. per min. delivers 71,000 cu. ft. of air per min., absorbing 19·2 h.p. Volume for volume, therefore, the smaller fan uses 16 times the power absorbed by the larger fan.

(*c*) Use two fans of the same diameter at low speed instead of one at double the speed.

Example.—A 48 in. Wing fan at 600 revs. per min. delivers 30,200 cu. ft. of air per min., absorbing 3·6 h.p.

Two 48 in. Wing fans at 300 revs. per min. deliver 30,200 cu. ft. of air per min., absorbing ·9 h.p. together.

Volume for volume, therefore, one fan uses four times the power absorbed by two fans.

MOTORS FOR DRIVING VENTILATING FANS.

Too much cannot be said regarding the location of the motor. On account of the nature of the work it is frequently necessary to place the machine in an out-of-the-way place, although this does not necessarily mean that it must be in an inaccessible location. If it is so placed that it is difficult to care for, it will probably be neglected, with the result that the service will be impaired and the maintenance charge will be high. The placing of a motor in an inconvenient place because nothing else will go there, is false economy generally, and results in dissatisfaction. The question of motor efficiency in regard to fan drives is an important one and involves two factors—the efficiency of the motor when operating under normal speed, and the efficiency at other than normal speeds. Although the latter is, to some extent, influenced by inherent characteristics of the motor, the largest factor is the method of control, especially with direct-current motors. If, on account of its lower cost, a motor is selected, where adjustable speed is required, that will, when operating at normal speed, drive the fan at the maximum required speed, and it is necessary to operate for considerable periods at reduced speed, low efficiency will result.

The cost of the power lost in the armature external resistance will usually pay a handsome dividend on the additional capital required to install a motor and controller that, at normal speed, will drive the fan at the lowest speed required and beyond this point adjust the speed by field control.

The horse-power required to drive a centrifugal fan can be estimated from the following formula:

$$HP = \frac{5{\cdot}2 \times Q \times WG}{33{,}000 \times E}$$

Where, HP = horse-power of motor; Q = cubic feet of air per minute; WG = pressure of air in inches by water gauge; E = efficiency of fan, which is approximately 0·5 for steel plate fan, 0·65 for Sirocco, and 0·45 for cone type.

The following mathematical relations are theoretically true for all centrifugal fans: Volume of air delivered varies as the speed; pressure of air delivered varies as the square of the speed; horse-power required varies as the cube of the speed. Hence a fan, which, when operated at 100 r.p.m. delivers 8,000 cub. ft. of air at ½ oz. pressure, requires 2 h.p., will, when operated at 200 r.p.m., deliver 16,000 cub. ft. of air at 2-oz. pressure and will require 16 h.p. It is therefore necessary, in selecting a motor for driving a fan, to figure the horse-power requirements at the maximum speed of the fan.

Reduction of the area of the inlet or discharge of a centrifugal fan will reduce the power required, whereas increasing the area of either will increase the power. Disc fans produce a relatively low pressure, and it is customary to figure their output on a basis of velocity. The

relations between volume, speed, and horse-power for centrifugal fans hold good for disc fans. However, if the outlet of a disc fan is restricted, the pressure and the power required increase, and with a totally closed outlet the power needed is almost double that with an unrestricted outlet. (*' Power.'*)

The Plenum System.

This system (*The Sturtevant Engineering Co. Ltd.*) is well adapted for the economical warming and ventilation of workshops, large halls, theatres, and other large buildings. The apparatus consists of a fan which draws in fresh air, delivering it through a heater where it is

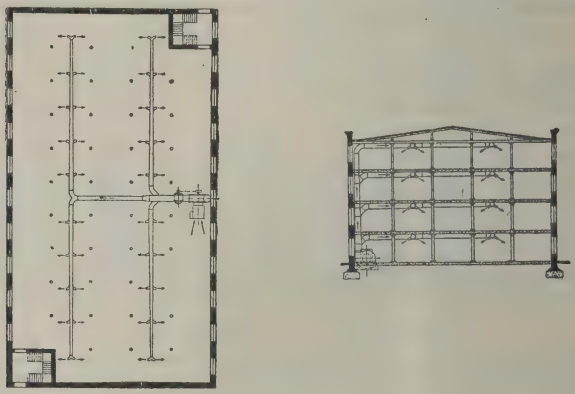

FIG. 28.

warmed to the required temperature, and then evenly distributed through a series of ducts to every part of the building. The fan is usually of the steel-plate type driven by belt from line shafting, steam engine, or electric motor; the heater is built up with a nest of pipes for

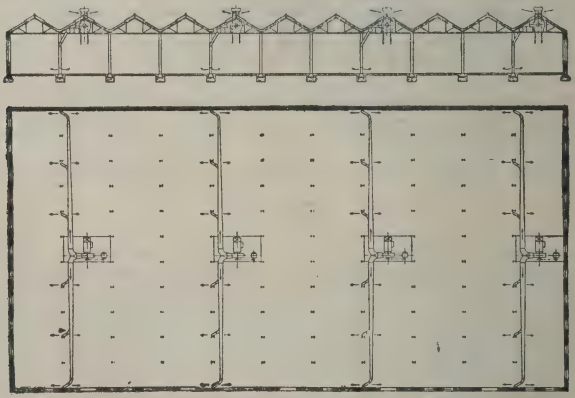

FIG. 29.

use with live or exhaust steam, hot water, furnace gases, etc. Ducts for distributing the air are constructed of galvanised sheet steel, masonry, wood, or other materials, and may be built in the walls or floors, or suspended from the roof or walls.

The system ensures even distribution of warmth throughout the whole building with proper ventilation. In the summer the heater can be eliminated and fresh air distributed throughout the buildings. Workshops can be quickly warmed up in the morning before work is commenced, by recirculating the air. The fan and heater can be installed at one central point either inside the building or outside, and they are under complete control of one man who can regulate the temperature of the air supply as required.

Two types of buildings equipped with this system are shown by figs. 28 and 29. Fig. 28 illustrates a building of several storeys, in which the apparatus is placed in the basement, one air main being carried up through the building with overhead horizontal distributing pipes on each floor.

Fig. 29 shows a large workshop of considerable height, in which the apparatus is divided into four units in order to keep down the size of the air piping. The sets of apparatus are placed out of the way in the roof, the air being distributed by overhead pipes and discharged at floor level through downtake pipes arranged alongside the column. An alternative arrangement would be to install one set of apparatus and connect it with each of the pipe mains.

Notes on the Progress of Mechanical Ventilation.

The point now reached in the practice of ventilation cannot be ascertained by a mere examination either of public buildings or of those edifices erected in recent years by our urban school boards; valuable information can, however, be obtained by observing the effect of the regulations issued by the Secretary of State under the Cotton Cloth Factories Act, 1897. The Chief Inspector of Factories in his Annual Report for 1900, referring to a regulation on the ventilation of humidified weaving sheds, says that it 'for the first time in the history of factory legislation, aimed at a scientific standard of ventilation based on the actual purity of the air breathed by the workers. This was to be determined by ascertaining the proportion of carbonic acid (CO_2) present in the air of the shed.' The regulation, which was made after an exhaustive enquiry by a committee consisting of Sir Henry Roscoe (chairman), the late Sir Wm. Roberts, and Dr. Ransome, reads as follows:—

'The arrangements for ventilation shall be such that, during working hours, in no part of the Cotton Cloth Factory shall the proportion of carbonic acid (carbon dioxide) in the air be greater than 9 volumes of carbonic acid to every 10,000 volumes of air.'

In practice this is complied with if the CO_2 in the shed does not exceed that outside the factory at the time by more than 5 volumes per 10,000.

In the Report, a table gives the results of tests made in 35 weaving sheds (affecting over 6,000 workers), and shows the improvement effected by (mechanical) ventilating arrangements, viz., that the number of volumes of CO_2 due to respiration (as the 5 above mentioned) was reduced on an average from 9·0 to 3·9, and in some instances in the proportion of 3 to 1. With these may be compared tests taken recently by a qualified observer in a manufacturing district. As the tests in weaving sheds are taken by H.M. Inspector at any time without previous notice, and at any point he may choose, it is clear that the distribution of ventilating effect is satisfactory.

The cost of installing and working the plant is very moderate, varying with the number of operatives, and the excellent value in ventilation for the outlay is no doubt partly consequent on the fact that shafting for driving the fans employed is easily available throughout the sheds.

Large numbers of fans are used in these weaving sheds; they are generally 14 ins. in diameter, and are fixed a moderate distance apart. Some in each shed draw fresh air downwards through the roof and blow it abroad immediately below the tie beam level; others, a smaller number suitably placed, continually exhaust vitiated air, discharging it upwards through the same roof.

One of the points thus secured is that none of the air passed through the building remains inside long enough to become overcharged with CO_2, and another is that there is slight plenum maintained, preventing any inrush of cold air through open doors, etc.

These sheds are, as a rule, warmed by lines of steam pipes suspended overhead, and a coil of smaller steam piping is often fitted inside the air inlet tube, so that in cold weather the fresh air is warmed as it is drawn in by the fan. The arrangement, as above described, includes little or no resistance to be overcome by the fans; the driving power required is therefore very small.

Size of Outlet Shafts.

The total sectional area of the outlet shafts, looking only to the atmospheric pressure as a motive force, can be approximately calculated for varying conditions of temperature and different heights of shafts from the following formula :—

x = total sectional area, in inches, of the required outlet shafts. D = total cubic feet of fresh air to be supplied by warm and cold air inlets. H = height of heated air column from level of inlets to top of outlets. t = excess, in degrees F., of the mean temperature of heated air column over outside air.

Then $$x = k\frac{D}{9\sqrt{Ht}};$$

where k is a constant depending on the size, height, and nature of the shaft ; its value is generally taken at $\frac{1}{3}$ to $\frac{1}{2}$.

With ordinary open fireplaces the sectional area of the outlet shaft need only be half the value thus found, the smoke flues doing duty for the rest.

SECTION XXXV

PART III

LIGHTING

Standards of Light.

The legal standard unit for measuring the intensity of light is assumed to be that produced by a sperm candle, 'short 6.' burning 120 grains per hour.

A spermaceti candle 0·85 in. in diameter burns about 1 in. per hour, but for practical purposes the Harcourt lamp burning pentane, having a value of 10 candles (see Gas Section), the official gas referees' standard, is more convenient. In Germany the standard used is the Hefner (an amylacetate lamp). It is now coming largely into use in connection with the extended use of German-made rare metal metallic filament glow lamps. Its value is about 88 standard candles.

By an agreement which came into force on April 1, 1909, between the National Physical Laboratory, the Bureau of Standards, and the Laboratoire Centrale d'Electricité, a common unit of light was adopted for Great Britain, the United States, and France, namely, 1 pentane candle = 1 bougie décimale = 1 American candle, which is practically identical with the British Parliamentary candle above-mentioned. The Hefner unit is 0·90 of the international candle, and the Carcel unit = 9·6 int. candles.

Illumination.

Illumination, or the amount of light received by an object per unit area, is measured in terms of foot-candles. Thus a small surface held one foot away from a standard candle would have an illumination of one foot-candle.

The intensity is directly proportional to the C.P. and inversely proportional to the square of the distance, i.e. $I = \frac{C.P.}{d^2}$. If 1 C.P. be considered as the centre of a sphere of 1 ft. radius, the intensity on the internal sphere will be unity (spherical C.P.). The surface illuminated will be 4π sq. ft. Hence, if the sphere be of radius r, the surface will be $4\pi r^2$, and $I = \frac{4\pi}{4\pi r^2} = \frac{1}{r}$ candle feet. If a surface be oblique to the rays, $I = \frac{C.P.}{r^2} \cos\theta$, $\cos\theta$ being the angle of incidence.

I to light a room is generally based upon the assumption that 16 C.P. 8 ft. high is sufficient for a surface of 8 ft. square (64 sq. ft.), but this depends largely upon the reflecting power of ceilings and walls which varies greatly (see table).

Approximate Reflecting Power of Surfaces.

	Per cent.		Per cent.
White, rough	82	Blue paper	25
Cream	80	Wood, dirty	20
White, smooth	70	Brown paper	13
White printed matter (grey)	60	Brown, dark	4
Wood, clean	50	Black cloth	1·5
Yellow paper (light)	40	Black velvet	·5
Yellow, dark	30		

Under favourable conditions, I, for a given surface illumination, may be considerably reduced but, on the other hand, the figure given above may not be sufficient.

In fig. 1, if A is a lamp (electric or otherwise) giving 16 c.p. in a horizontal direction, the illumination at the point B, four feet distant, would be $\frac{16}{4^2} = 1$ foot-candle, since the intensity of light varies inversely as the square of the distance. To get the normal illumination at any given point, the candle-power in the proper direction must be divided by the square of the distance to the point illuminated. As previously explained, if the surface illuminated is not at right angles to the direction of the light, the value of the illumination obtained as above must be multiplied by a reduction factor, taking into account the angle at which the rays strike. A beam of light coming in the direction OD (fig. 2) falls upon a plane AB, illuminating it

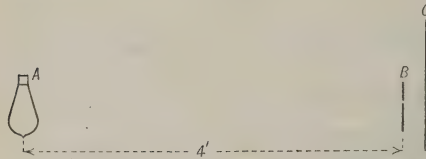

FIG. 1.

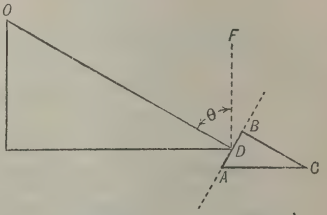

FIG. 2.

with an intensity of 1 foot-candle. Then the illumination on the plane AC, which intercepts the same amount of light as AB, would be less than 1 foot-candle (as the light is spread over a larger surface) in the ratio of AB to AC, which is the cosine of the angle ODF. Thus the illumination effective on any plane at a given point will be

$$\frac{\text{c.-p.}}{(\text{distance})^2} \times \cos\theta$$

where θ is the angle between the direction of the ray and a perpendicular to the plane considered.

Photometers.

Lights of different colour cannot be compared accurately. No two observers agree upon the candle-power of a light by the ordinary photometer.

The Simmance-Abady Flicker Photometer is based on the fact that if a spot be illuminated in rapid alternations by two different coloured lights of equal intensity the spot will be steadily illuminated without appearance of flicker.

To obtain, by means of this photometer, the candle-power of a powerful light of a white colour relative to the standard Pentane burner, the light to be tested is made to shine on one side of a polished prism, and an Argand flame of the same colour as the Pentane lamp flame shines on the other side. The two sides incline at an angle of 90°. The prism (or, rather, right-angled mirror) is driven rapidly to and fro in the line of the lights through a short distance, an electric motor serving to drive it. The alternation of the mirror is very rapid, and the two pencils of light on the opposite sides are reflected alternately to the eye. The Argand light is regulated by a lever until the spot loses its flickering appearance; the two lights are then in balance. The Argand burner is now compared on the ordinary bar method with the standard flame. The Flicker photometer is so arranged that the first and second lights have a ratio of 100 : 1. Thus by multiplying the ratio of the second and third by 100, the ratio of the first to the third or standard is secured irrespective of colour influence.

Distribution Curves.

The basis of most calculation of illumination is the distribution curve of the lighting unit (lamp plus reflector or globe). Such a curve is shown in fig. 3, and indicates the distribution of light in a vertical plane, the lamp being hung tip downward. The distance from the centre to any point on the curve is directly proportional to the candle-power in that direction, which may conveniently be read off by the aid of the equally spaced concentric circles on the diagram.

The effect of a reflector in directing the light and improving the distribution may be seen

from a comparison of the two curves in fig. 3. The bare lamp (Curve A) throws nearly one-half the light above the horizontal where it is ordinarily of little use. On the other hand,

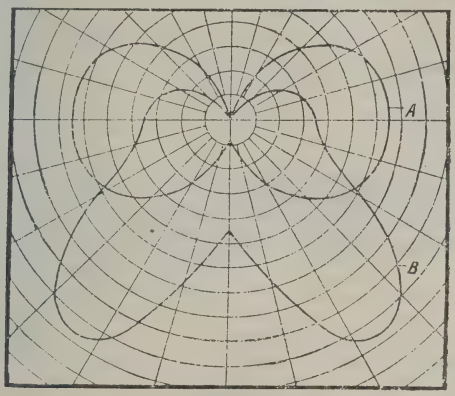

FIG. 3.

with a properly designed reflector (Curve B), the total light below the horizontal besides being more advantageously directed is increased by over 20 per cent.

REQUIREMENTS OF GOOD ILLUMINATION.

Illumination must be acceptable to the eye. We should be able to see objects clearly and with a minimum of fatigue. To accomplish this result certain conditions must be fulfilled.

(1) There must be sufficient illumination. Since objects are seen by means of the light which they reflect, more light must be thrown on dark objects than on light ones.

(2) There must not be too much illumination. Too strong a light tires the eye, partly due to the muscular effort of contracting the iris, and partly because of the strong light reaching the sensitive retina.

(3) Intensely bright lights in the field of vision should be avoided. The iris closes somewhat in order to afford a protection from such lights, and the amount of light received from illuminated objects is thereby so reduced that they cannot be seen clearly. This accounts for the well-known dazzling effects of searchlights and of many headlights. The intrinsic brilliancy or candle-power per square inch of luminous area should therefore be kept as low as possible ; it should not ordinarily be higher than 4 to 6, if the source of light is in the field of vision. Clear bulbs should certainly never be used where the filaments are continuously in view. When reflectors are used it is generally desirable to ' bowl-frost ' the lamps, i.e. frost only the lower portion of the bulbs.

(4) Flickering lights should be avoided. Poorly regulated circuits, such as those having varying power loads, cause disagreeable flickering. Metal filament lamps have an inherently better regulation than carbon filament lamps.

(5) The light should have a continuous spectrum, i.e. one containing every colour, in order that the relative colour values of objects illuminated may be the same as when seen by daylight. For matching delicate tints, as in silk and paper mills, the light should be as white as possible, while for general illuminating purposes a ' warm ' light is best ; cold glaring lights too rich in green and blue are to be avoided.

The size of the units is somewhat a matter of choice. In deciding upon the proper sizes of lamps to use, one must consider the spacing of present outlets, if building is already wired, and the location of pillars, beams, etc. In general the fewest units consistent with good distribution will be the most economical, as the total cost of outlets, fixtures, and lamps, as well as the maintenance charges, will be reduced.

(*Bulletin of the National Electric Lamp Association.*)

Reflectors.

The importance attaching to a suitable reflector as a means of efficiently distributing the light in the direction required, in addition to concealing the bare filament of the lamp, cannot be over-estimated. Particularly does this apply in the case of the half-watt lamp, the glare

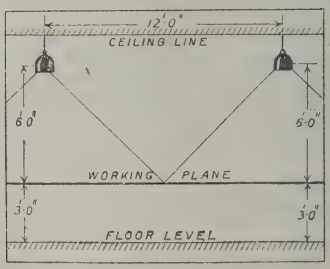

FIG. 4.

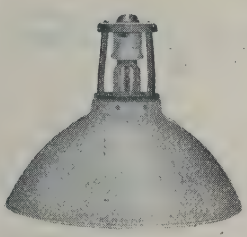
of which, consequent upon the high intrinsic brilliancy, renders a reflector or shade of some sort absolutely necessary. Care must be taken to avoid too much light from any particular direction, causing shadows and uneven illumination. The following four types of reflectors may be used :—

Extra Extensive Type :—Spaced at a distance apart equal to two and a half times their mounting height.

Factory Lighting.



The necessity of efficient lighting in Factories is more than ever emphasised at present, when it is appreciated that the majority are engaged in producing important commodities requiring the utmost efficiency in all conditions pertaining to their production.

This efficiency in Illumination can only be obtained by the use of scientifically designed fittings—our speciality—and the large range of designs included in our latest list enables the Engineer to meet all conditions.

Fittings for use with half-watt lamps have been given particular attention, as we consider that the combination of the half-watt lamp with a Benjamin Reflector reaches a degree of efficiency hitherto unattainable.

We retain an Engineering Department at your free disposal for the formulating of Industrial Lighting Schemes and cordially invite your enquiries.

Specify Benjamin British Made Reflectors, full particulars of which will be sent on application.

Concentrating Type Reflector Fitting for half-watt lamps up to 1500 watts.

THE

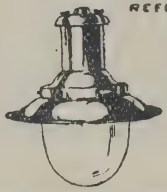
Benjamin Electric Ltd.,

BRANTWOOD WORKS,

Tariff Road, Tottenham, London, N. 17

A few Benjamin Lines

CONCENTRATING TYPE REFLECTOR FITTING.



INTENSIVE TYPE STEEL REFLECTOR

DISTRIBUTING TYPE REFLECTOR FITTING

CONCENTRATING TYPE CLUSTER FITTING

HALF-WATT LANTERN.

PARABOLIC TYPE REFLECTOR FITTING

DISTRIBUTING TYPE CLUSTER FITTING

& a few of their outstanding features.

THE ORIGINAL & MOST WIDELY USED of any form of Industrial Lighting Fittings.
PRACTICALLY INDESTRUCTIBLE—constructed throughout of Steel
SCIENTIFIC DESIGN giving the best distribution of light.
ALL FITTINGS SUPPLIED COMPLETE WITH HOLDER.
FOR USE WITH HALF-WATT OR ONE-WATT LAMPS.
WIDE RANGE OF DESIGNS for every class of Installation.
LOW INITIAL COST with no renewal expenses.
BRITISH MADE in our own London Works.

REGISTERED TRADE MARK

THE BENJAMIN ELECTRIC LIMITED,
Brantwood Works, TARIFF ROAD, TOTTENHAM, LONDON, N. 17.

Extensive Type:—Spaced at a distance apart equal to twice their mounting height.

Intensive Type:—Spaced at a distance apart equal to one and a half times their mounting height.

Focusing Type:—Spaced at a distance apart equal to their mounting height.

The mounting height is the distance between the centre of the light source and *the working plane.*

Fig. 4 shows the importance of adhering to these spacing rules as closely as possible, uniform

FIG. 5.—General Lighting in a large Cable Works (Benjamin Reflector Fittings).

illumination being obtained on the working plane with the two extensive type reflectors only when spaced correctly (twice their mounting height).

In this fig. the working plane is shown 3 ft. above floor level, but this height will vary according to conditions and class of work carried on.

Local lighting is necessary where an intensive illumination is needed over a limited area, as in the cases of machines, lathes, benches, etc. Also it is essential that the light should be well shaded owing to its close proximity to the operator's eyes.

A combined scheme of local and general lighting is necessary in the case of a great number of industrial installations, the local lighting being used in places requiring a greater intensity of illumination than that given by the general lighting units. In addition, a scheme of this sort is to be recommended, inasmuch as the inclusion of the general lighting is the means of avoiding fatigue to the eyes of the operators consequent upon the great contrast between the brightly illuminated local points and the dark surroundings.

The above recommendations deal more particularly with the direct system of illumination. Other forms include indirect and semi-indirect systems, both of which, however, are dependent to a large extent on the surroundings, such as ceilings, walls, etc., for efficient reflection. Owing, however, to the general absence of such favourable surroundings in the typical industrial establishment or engineering workshop, they are not to be recommended. There are, of course, instances such as drawing offices, etc., where such methods are the only ones likely to give the desired results, the entire absence of glare and the perfect diffusion of light being important points in their favour. From the standpoint of economy the semi-indirect and indirect systems of illumination do not compare unfavourably with the direct system when the conditions are suitable for their adoption.

Calculation of Illumination.

A short way of computing illumination is based on the fact that a certain definite quantity of light is required to illuminate one square foot of surface with an intensity of one foot-candle. This unit is known as the 'Lumen'; therefore when a lamp is capable of illuminating 400 sq. ft. with an average of one foot-candle it may be rated at 400 (effective) lumens. To arrive at a satisfactory result, however, the effective lumens per watt of the lamp used should be known. This constant is the most useful in illumination calculation, as it is invariable and can be used as a factor in a simple manner to give effective lumens, wattage, or intensity in foot-candles.

The average generated lumens per watt for half-watt lamps is 14, and for one-watt lamps 9 lumens per watt. Based on a variety of installations, it has been ascertained that approximately 50 per cent. of the generated lumens are effective, allowing for absorption, etc. Therefore the effective lumens per watt can be safely taken as 7 for half-watt lamps, and 4·5 for one-watt lamps.

If A = area to be illuminated ; C = a constant ; I = intensity in foot-candles required ; W = watts required ; then

$\frac{A \times I}{C}$ = watts ; $\frac{C \times W}{A}$ = intensity in foot-candles ; $\frac{I \times A}{W}$ = constant (effective lumens per watt).

Example: It is required to know the necessary wattage for an installation, the following data being given :—

I = 5 ft. candles ; A = 500 sq. ft. ; C = 7 (constant for half-watt lamp).

Then

$$\frac{I \times A}{C} = \frac{5 \times 500}{7} = 357 \text{ total watts.}$$

The area should be next divided into squares with units located in centre of each (bearing in mind the type of reflectors it is proposed to use).

The above recommendations apply for areas and works with the usual surroundings and conditions ; in the case of dark surroundings, or where the colour of the material or machines worked upon is dark, it is advisable to allow more light, increasing the wattage by 20 per cent. to 50 per cent. or even more, according to conditions. The necessity of this is an established fact and should always be borne in mind when deciding on the light required.

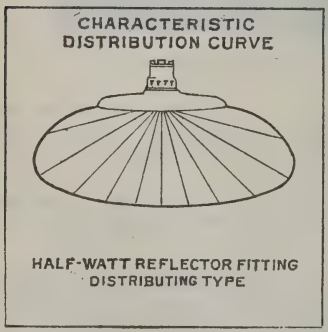


Fig. 6.

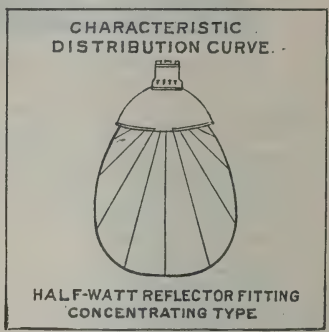

Fig. 7.

Figs. 6, 7 respectively show the characteristic distribution curves of a distributing reflector fitting, which to obtain even illumination should be spaced at a distance apart equal to one and a half times to twice the mounting height, and a concentrating reflector fitting, which should be spaced at a distance apart equal to its mounting height.

It should be borne in mind that polar distribution curves represent the intensities corresponding with different angles to the vertical or horizontal axis of an illuminant. The area enclosed by such curves must not be associated with the total quantity of light emitted by the source.

SOME TYPICAL REFLECTING SHADES.

The selection of the correct form of reflecting shade for a given set of conditions constitutes nine-tenths of the art of lighting. The polar curves in fig. 8 show some features which will indicate the scope for the exercise of judgment in this matter.

The upper diagram contains two polar curves. The symmetrical one (heavy dotted) shows

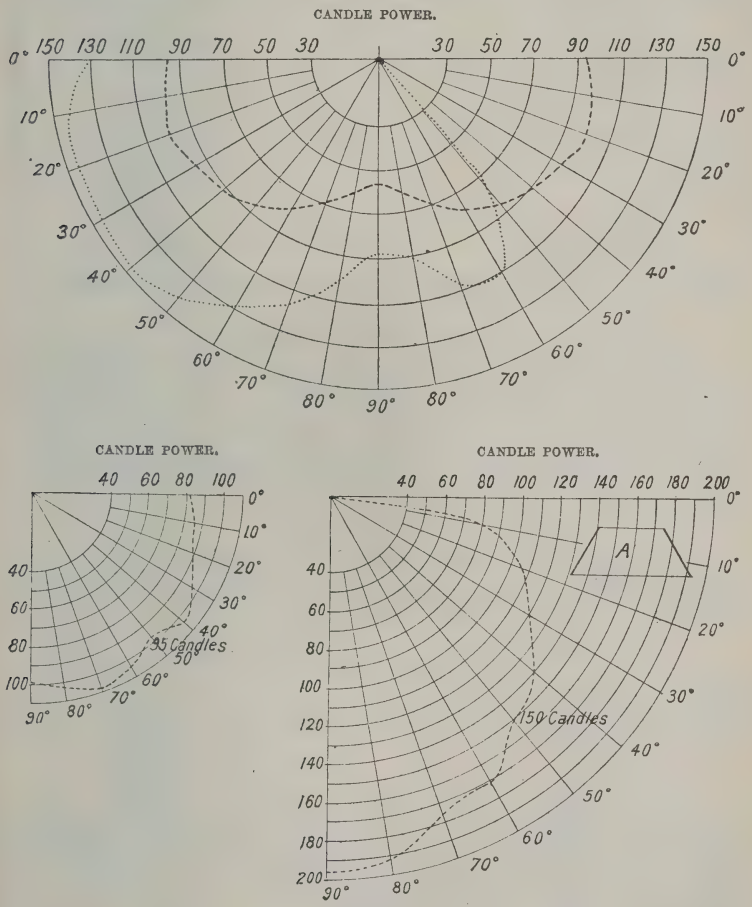

FIG. 8.

the distribution of light from the naked mantle. The asymmetrical curve shows the redistribution of light due to the use of what is technically known as a parabolic shade. A shade of this kind would be chosen when the light has to be distributed mainly in one direction.

The two lower diagrams show respectively the distribution of light from a bare mantle and

the same mantle when used with a reflecting shade (enamelled steel) of the form outlined in section at A. Shades of this type are extensively used for factory lighting purposes and for other purposes where a symmetrical downward illumination is desired.

TABLE SHOWING THE INTENSITY OF ILLUMINATION REQUIRED IN VARIOUS CLASSES OF INDUSTRIAL ESTABLISHMENTS.

Place.	Foot-candles Required.
Carpenters' Shop	3·0 to 5·0
Drawing Office	6·0 to 10·0
Factory (Machine Shop)—	
General and Localised	1·0 to 2·0
General only	3·0 to 5·0
Local	4·0 to 6·0
Foundry	3·0 to 5·0
Pattern Shop	4·0 to 6·0
Paint Shop	3·0 to 6·0
Power House	2·0 to 3·0
Sewing Rooms—	
Light Goods	4·0 to 6·0
Dark Goods	8·0 to 10·0
Warehouse and Stock Room	1·5 to 2·0
Wharf	1·5 to 2·0

Factory and Workshop Lighting.

The report of the Departmental Committee appointed by the Home Secretary to inquire into 'the conditions necessary for the adequate and suitable lighting (natural and artificial) of factories and workshops,' recommends that the working areas be lit in such a way that on a horizontal plane at the floor level the illumination will not be less than 0·25 foot-candle. In ironfoundries the minimum illumination should be 0·4 foot-candle. Passages, stairways, lobbies, and similar parts of the building should have a minimum illumination at the floor level of 0·1 foot-candle. Open yards and approaches should be lit as favourably as a fairly well lighted side street, namely, with 0·05 foot-candle at the ground level, and this illumination is to be maintained from one hour after sunset until one hour before sunrise.

GAS LIGHTING IN FACTORIES.

This may be either of high pressure (60 to 100 inches water gauge) or low pressure (4 to 6 inches water gauge).

The amount of gas that must be consumed to provide a given number of foot-candles of illumination over the area of a workshop may be computed as follows:—

High pressure $\frac{A \times i}{200}$ = c. ft. per hour; Low pressure $\frac{A \times i}{100}$ = c. ft. per hour,

where A is the area to be lighted in square feet and i is the average illumination required in foot-candles.

Thus assume a workshop having a floor area of (say) 2,000 sq. ft., and an average illumination of 4-ft. candles is required. According to the foregoing formula, the lighting units as a whole would have to consume,

High pressure $\frac{2{,}000 \times 4}{200} = 40$ c. ft. per hr.; Low pressure $\frac{2{,}000 \times 4}{100} = 80$ c. ft. per hr.

It must, however, be remembered that the higher efficiency of the high-pressure system is only obtainable by the installation of a gas compressor, unless, as frequently happens, a high-pressure gas supply is provided ready for use. The installation of a compressor and means for driving involves an expense which must be set off against the higher lighting efficiency. This expense is relatively trifling on a large plant but assumes larger proportions on smaller sizes. Generally it will not pay to put in high-pressure plant unless the total candle-power exceeds 1,000 candles. High-pressure gas is frequently used for purposes other than lighting, in which case the same apparatus will serve for the lighting.

It remains to subdivide the installation into separate lighting units, so as to ensure as nearly as possible a uniform illumination in order that all parts of the workshop are equally available for practical use.

For instance, to develop the light from 80 cubic feet of low-pressure gas, any one of the following arrangements may be used.

No. of Lamps.	Each consuming cub. ft. per hour.	Total Consumption of all Lamps.
20	4	80
16	5	80
10	8	80
8	10	80

Even larger lamps may be used, units ranging from 25 to 4,000 candle-power being available. The particular arrangement that may be used will depend partly upon the structural features of the building and the kind of work being done. Sometimes a uniform illumination must be aimed for, or in other cases it may be desirable to have certain areas extra-illuminated, the intervening areas being somewhat subdued.

Generally it is not advisable to rely upon the reflecting power of walls, because in the first place the use of reflecting shades prevents much of the light from the lamps reaching the walls, and secondly, although the whitewashed surfaces have a reflection coefficient of 80 per cent. when new, this rapidly deteriorates to less than half this value, due to dust created by moving machinery.

The greater the candle-power of the lighting unit used, the higher it should be placed; and in order that the illumination from the separate lamps shall overlap they should be disposed so that the distance between their centres is $1\frac{1}{2}$ to 2 times their height above the level at which work is being done.

The following points may be noted :—

If gas lamps have to be arranged amongst running shafting or belting, remote control may be used to ensure safety in lighting and extinguishing.

If there is excessive vibration the premature fracture of mantles can be prevented by using anti-vibrators.

Gas lamps may be arranged if required for use at various heights.

If the air round the lamps is extraordinarily dusty, the use of Keith-Blackman's 'group' system will ensure their perfect working.

For large work, lamps 9 feet to 10 feet above floor level will be found convenient. This would need moderate size lamps, consuming 10 to 15 cubic feet per hour and spaced 9 to 12 feet between centres.

For smaller work, lamps consuming 5 cubic feet per hour, set at 7 to 8 feet above floor level and 6 to 9 feet between centres, will be found suitable.

Electric Lighting in Factories.

In the preliminary estimate the lighting load may be assumed as between 55 and 60 per cent. of the manufacturing load. The circuits should be divided into three classes—machine-tool circuits, consisting of one 16-c.p. lamp for each machine tool, which should be turned on by the engineer as soon as light begins to fail in the factory; day circuits, which are on throughout the entire day, consisting of one 32-c.p. lamp for each office desk, drafting board, etc., and 16-c.p. lamps in the storehouse and isolated parts of the factory; and general lighting circuits, which should be turned on five minutes before time of shutting down, consisting of arc lights at each elevator, stairway, or main entrance, all the out-of-door lighting, and incandescent lamps in locker and washrooms, passage-ways, etc. One 16-c.p. light placed 7 ft. from the floor will satisfactorily light 250 sq. ft. in a storehouse, and from 100 sq. ft. to 110 sq. ft. general lighting for the factory proper.

Modern Lighting Fittings.

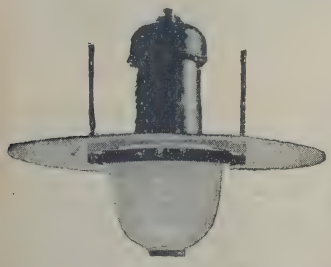

Fig. 9.—'Strela' lantern for street lighting with half-watt type lamps. Equipped with holophane refractor bowl (shown in section in fig. 10).

Fig. 10.

Fig. 11.

Figs. 9 and 10 (*The British Thomson-Houston Co. Ltd.*) show one of the latest types of street lighting fittings employing half-watt type lamp and holophane bowl refractor, giving wide angle distribution of light, in horizontal plane, with low diversity factor. The refractor is supported by a frame with sliding rods, and can be lowered for the purpose of cleaning or replacing lamps.

Fig. 12 is a fitting for interior lighting.

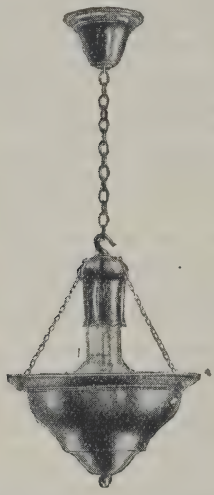

FIG. 12.—'Lumina' fitting for interior lighting with half-watt type lamps, semi-indirect type, with over reflector.

FIG. 13.—Mazdalux reflector.

For industrial lighting B.T.H. Mazdalux metal reflectors, fig. 13, give excellent results.

In indirect or concealed lighting, the luminous source is entirely hidden behind an opaque surface. The lamps, supported in mirror reflectors, project their light upon the white ceiling, from which it is diffusely reflected, giving an agreeable and attractive illumination for rooms, halls, etc. By this means the light is well diffused and closely approaches the illumination given by diffused daylight. With the B.T.H. 'Eye-rest' system, which employs a suspended metal or plaster bowl, containing upturned silvered glass reflectors, this effect is obtained in a very efficient manner, and by utilising different forms of reflectors it is possible to maintain this efficiency for various conditions. Indirect lighting is not shadowless, but the shadows are soft and transparent instead of being hard and opaque, as is usually the case with direct lighting.

In the B.T.H. 'Tubolite' system, tubular lamps are mounted in porcelain holders, and in the position of maximum efficiency within polished aluminium reflectors. The latter may be erected behind cornices to illuminate ceiling surfaces evenly; the system is also used largely for showcase and picture lighting.

In semi-indirect lighting most of the light is thrown on to the ceiling, while a proportion is transmitted through the translucent glass bowl of the fitting. The general advantages of indirect lighting apply also to semi-indirect lighting, but the visibility of the light source (at a greatly reduced brilliancy), in the latter case, gives a more familiar aspect to the installation. The British Thomson-Houston Co. have embodied this principle in some of their latest fittings, using dishes and hemispheres of the well-known Veluria and Alabas glass. These fittings give very effective and efficient lighting results.

ARTIFICIAL DAYLIGHT.

In producing artificial daylight, the object for which it is to be used should be considered. For artists' studios and for picture galleries the main thing is to prevent the blues from darkening and the yellows from turning pale. So long as the colours are well rendered the light is satisfactory. For dye works and drapers' shops accurate matching must be possible, and the effect on certain difficult colours, such as the purples and greens, must be studied. It is a mistake to imagine that it is more easy to match pale colours by artificial light because there is not much colour present. In the grading of flour a very small deficiency of blue in the artificial light makes the light slightly yellow, or if the right proportion of green is wanting, the light will have a pink tinge. If one of these colours is present in the flour the result will be a brightening of apparent whiteness instead of the manifestation of a tint. It is not necessary to produce a light the spectrum of which extends to violet-blue, because there is little luminosity in that part. Hues which are apparently violet are generally found to be purple when analysed.

SECTION XXXV

PART IV

FIRE EXTINCTION.

STANDARDS OF FIRE-RESISTANCE.

STANDARD TABLE FOR FIRE-RESISTING SINGLE DOORS, WITH OR WITHOUT FRAMES.

Classification.	Sub-Class.	Duration of Test at Least.	Minimum Temperature.	Thickness of Material.	Minimum Superficial Area under Test.	Minimum Time for Application of Water under Pressure.
		Min.	Deg. F.		Sq. Ft.	Min.
Temporary protective class	A	45	1500	2 in. and under	20	2
	B	60	1500	Optional	20	2
Partial protective class	A	90	1800	2½ in. and under	20	2
	B	120	1800	Optional	20	2
Full protective class	A	150	1800	½ in. and under	25	2
	B	240	1800	Optional	25	5

(*International Fire-prevention Congress.*)

Fire-Resisting Substances.

Exhaustive tests seem to show that sulphate of aluminium is one of the best fire-resisting substances for wood, as it checks combustion by forming an infusible and non-conducting coating, while such substances as ammonium sulphate or ammonium phosphate when heated check combustion by emitting an incombustible gas.

The following is the formula for what is known as the United States 'Government whitewash mixture,' which also acts as a fire-retarding coating over interior wooden surfaces:—Slake a half bushel of quicklime with boiling water, keeping it covered during process; strain and add one peck of salt dissolved in warm water; put 3 lbs. ground rice in water and boil to a thin paste; ½ lb. of powdered Spanish whiting; 1 lb. of clean glue dissolved in hot water. Mix well and let it stand for several days. Keep the mixture in a kettle or receptacle, and apply as hot as possible with a whitewash or paint brush.

(See also pp. 343, 349.)

Fire Streams.

TABLE SHOWING PRESSURE REQUIRED AT NOZZLE AND AT PUMP, WITH QUANTITY AND PRESSURE NECESSARY TO THROW GOOD EFFECTIVE STREAMS VARIOUS DISTANCES THROUGH DIFFERENT SIZE NOZZLES, USING 100 FEET OF ORDINARY 2½-INCH RUBBER-LINED HOSE AND SMOOTH NOZZLES.

Size of Nozzle, ¾ inch.

Pressure at nozzle, in lbs. per sq. in.	40	50	60	70	80	90	100

N.B.—The above pressures are based on the supposition that the hose is coupled direct to the delivery of the pump and while the stream is flowing; if, however, the hose is coupled to a hydrant which is supplied direct from the pump, then the corresponding fire pump pressure must be greater than the hydrant pressure by an amount equal to friction loss and difference of head between hydrant and pump.

The pressures given in the table are *indicated* pressures, not effective pressures; effective pressures would be slightly greater.

The distances given are for *effective* fire *streams* adapted for fire purposes, and are not for mere isolated drops. (*Freeman.*)

Fire Streams and Electric Circuits.

It has always been believed to be dangerous to those handling a hose line to allow the stream to come in contact with an electric circuit. Prof. F. C. Caldwell has found by experiment that there is no danger of shocks when the distance between the nozzle and circuit is more than 25 ft., irrespective of the voltage. (*'Power.'*)

Fire Extinguishers.

Sawdust possesses some special merits as a fire extinguisher when dealing with small outbreaks of liquid combustibles, such as lacquer and petrol, which are usually difficult to extinguish by ordinary means. Sand is generally looked upon as the best substance to use in such cases when it can be applied promptly, but tests have shown sawdust to be superior.

The British Fire-Prevention Committee carried out a series of tests, the results of which tended to prove that sawdust intimately mixed with bicarbonate of soda and applied in bulk has certain advantages over sand and similar materials as an extinguishing medium for comparatively small fires occasioned by the ignition of the vapour of petroleum spirit (petrol) and other inflammable liquids. Ordinary sawdust, as obtained from saw-mills, is the most suitable for this purpose. It must be free from shavings and chips of wood, but it does not require to be either specially dried or to contain added moisture. The addition of bicarbonate of soda, although not essential, is advantageous. The Committee found an effective proportion of bicarbonate of soda to sawdust to be 10 lbs. to 1 bushel (or, say, 12 lbs.) of sawdust. The Committee wished to emphasise the fact that so far their investigations had been limited to small quantities of inflammable liquids, not exceeding 2 gallons, and the areas over which they were spread did not exceed 6 ft. square. These conditions are met with in motor garages and hangars, for which, in the opinion of the Committee, the proposed mixture is applicable and economical. The Committee added that their tests showed that the application of this or any similar mixture in small quantities from tubes or canisters does not give satisfactory results.

Electric Vehicle Equipment of the London Fire Brigade.

In machines in which the same petrol motor is utilised both for vehicle propulsion and pump-operating, the engines develop 65 h.p. at 1,100 revolutions, and centrifugal pumps have an output of 500 gallons per minute, at a working pressure of over 120 lbs. per sq. in

In the more hilly districts of London the stations are equipped with petrol-motor escape vans, fitted with engines of about 50 h.p., some petrol-electric vehicles, that is, machines with petrol engines as the prime mover, with electrical in place of mechanical transmission of the power to the road wheels, being also on order.

The majority of the electrically-propelled fire appliances are of the Cedes type; they are equipped with series-wound motors mounted in the hubs of the front road wheels, which are thus driven direct without the intervention of any gearing, the Cedes Co. claiming an efficiency of from 78 to 85 per cent. for their motors, which are rated at 15 electrical h.p. The power is provided by a battery of 84 Tudor cells of a capacity of 200 ampere-hours at a 6-hours' discharge rate, giving a normal running output of about 30 h.p. The cells are carried in trays, either under a bonnet in the front of the driver or just to the rear of the forward wheels below the driver's seat. The machines can run about 30 miles on one charge if necessary, but owing to the nature of the service they stand fully charged ready to give out the maximum output on receipt of a call. There are electric brakes on the front wheel motors, and two hand and foot controlled mechanical brakes on the rear wheels, which are sufficient under ordinary circumstances. The controller is of the series-parallel type, with seven notches for three forward speeds, two reverse motions and two brake positions. All the contact fingers of the controller are interchangeable and can be removed without the use of any tool. Should a finger burn out, it can be replaced by another in two or three seconds.

The weight of an electric escape van ready for running, but without ladders, hose, and small gear, and men, does not exceed 3½ tons, the total weight of the van complete being about 5¼ tons. The test requirements of the electric escape vans are that they shall be able to maintain a speed of 25 m.p.h. on the level with a full load of ladder, equipment and firemen, or 29 m.p.h. with men and equipment but without ladder. They must be able to climb a gradient of 1 in 20 at 14½ to 16 m.p.h., while the battery must be capable of enabling a distance of 30 miles to be run on one charge at 20 m.p.h. In practice, these speeds can easily be exceeded, from 28 to 29 m.h.p. being reached on the level, with plain tyres, and from 26 to 27 m.p.h. when non-skids are fitted. The escape vans carry a ladder capable of being extended to at least 50 ft., and are also furnished with supplementary ladders, hose and tools for getting to work from hydrants, and a cylinder holding about 30 gallons of water, fitted with 180 ft. of rubber garden-hose for extinguishing small fires. This type of appliance, the crew of which is on duty night and day, is ready for an

instantaneous turn-out, and only attends fires on the ground immediately protected by the station, the distance it may travel to fires rarely exceeding one mile.

The electric motor turn-table ladders are kept at the stations in localities where there are many high or warehouse buildings. These appliances, whilst intended, generally speaking, for attending local calls, are considered available in case of serious fires in high buildings within a radius of about five miles. Owing to their weight, which, complete in fire-attending order, ranges from 5¾ to 6 tons, it is not considered necessary to specify that the electric motor turn-table ladders, which can be safely used as water towers to a height of 60 ft., shall travel at more than 20 miles per hour, but with plain tyres they can attain 27 m.p.h., or with non-skids 25 m.p.h. Several of these machines are fitted with 5-h.p. electric motors for raising the ladders, some to a height of nearly 100 ft., an operation which is accomplished in the rapid time of 10 seconds. The motor, which takes its current from the vehicle battery, serves as a brake when lowering the ladder.

Whenever an electric vehicle goes out, its battery is immediately put on charge on its return.

The average annual cost of an electric escape van, under the heading of repairs to chassis and body, and tyre renewals, is 25*l*. Taking into account the first cost, depreciation and maintenance, an electric escape van and a petrol escape van came out to practically the same running and maintenance cost, viz. 150*l*. per annum, which is less than that for horse traction.

It is no uncommon thing for an electric escape van to turn out in seven or eight seconds, whereas with other types of motor vehicles the best time is 15 seconds.

Dubbing for Preserving Leather Hose.

Melt 2½ lbs. of perfectly clean tallow, free from salt, and mix with it when hot 1 gallon or 9 lbs. of cod oil.

The best mode of clearing tallow for this purpose is to boil it in water, which will take up the salt and other impurities, and can be poured away when cold.

Care must be taken not to boil the oil, as this would deprive it of some of its principal qualities.

The tallow must be first melted, and when it is warm the oil is to be poured on, and stirred into it until the whole mixture is perfectly cold. This will make a good stiff dubbing.

Legal.

Definitions of Minerals and Mines.

By the term 'mineral,' as used in legal documents, is meant a constituent of the earth's crust which possesses in its severed condition an intrinsic value by virtue of its composition, that is to say, 'any substance that can be got from within the surface of the earth which possesses a value in usé apart from its mere possession of bulk and weight' (Lord Fletcher Moulton, Court of Appeal, Nov. 23, 1908). The meaning of the word 'mineral' may be affected by the context; according to Lord Halsbury, in 'a grant of *mines* and *minerals*,' it 'is a question of fact what these words meant in the vernacular of the mining world, the commercial world and landowners at the time when they were used in the instrument' (Lord Provost of Glasgow *v.* Fairie, 13 App. Cas. 1888).

In this country a *mine* is defined as a working for mineral carried on by artificial light without intentionally disturbing the surface, whilst a *quarry* is an excavation for the extraction of mineral open to the day; the distinction is important from a legal point of view. It must be noted that a quarry less than 20 feet deep is by law classed as a factory. In many other countries, notably in the United States of America, the distinction between a 'mine' and a 'quarry' depends not upon the method of working but upon the mineral wrought, any working for e.g. building stone, whether underground or open, being classed as a quarry. In legal instruments *mine* sometimes has the wider meaning of the space containing the minerals, or even from which the minerals have been extracted.

Ownership of Minerals.

In this country the mineral occurring within any area is the property of the owner of the freehold of the surface, with some few exceptions, the most notable of which are the Forest of Dean and the Isle of Man, where the minerals are Crown property. Minerals containing precious metals—where these metals form the essential value of the mineral—are the property of the Crown wherever found (except in Scotland). Minerals under copyhold land are mostly the property of the Lord of the Manor, who cannot, however, as a rule, deal with them save with the consent of the copyholder, for, although the property in the minerals is in the Lord, the copyholder has them in possession.

Generally speaking, in this country the minerals are leased to those exploiting them. 'A mining lease is really a sale payable by instalments' (Henn Collins, Master of the Rolls, *In re* Aldam's Settled Estates, Chanc. 2, 1902). Most often the rental is based on the tonnage exploited, the rate per ton or *royalty* being fixed. For coal this may range from 2*d.* to 2*s.*, but is usually between 4*d.* and 7*d.*, the average for the United Kingdom having been pre-war, probably just

about 5½*d.* per ton (Royalties Commission, 1889); it is now (1920) about 7½*d.* Sometimes the rental is a fraction of the value of the coal, this ranging from $\frac{1}{8}$ to $\frac{1}{20}$; sometimes the rental is a proportion of the profit made; sometimes a price per inch thickness of coal seam per acre wrought out forms the rental. In addition to royalty, wayleaves have often to be paid for; average wayleave in United Kingdom is about ½*d.* per ton (Royalties Commission, 1889).

Royalties on stratified ironstone vary from 2½*d.* to 1*s.* 6*d.* per ton, averaging about 6*d.*

In the hæmatite mines of Cumberland and Lancashire the royalties vary normally from 1*s.* to 2*s.*, averaging about 1*s.* 4*d.* In the Forest of Dean royalties on iron ore vary from 3*d.* to 5*d.* per ton.

Royalties in Cornwall on tin and copper ores range from $\frac{1}{20}$ to $\frac{1}{30}$ of the value of the mineral raised

Royalties on lead and zinc ores range from $\frac{1}{8}$ to $\frac{1}{20}$ of the value of the ore raised.

Royalties are often on a sliding scale, the ratio increasing with the market price of the mineral or of its metallic contents.

Principal Clauses in Colliery Lease.

Description of contracting parties (lessor and lessee) and of property demised.

Powers granted to lessee:—
- To break surface, make shafts, adits, etc.
- To win and work coal, bring to bank, make merchantable, dispose of.
- To work by instroke or outstroke or both.
- To make and dispose of coke and other products.
- To have necessary surface accommodation.
- To have necessary wayleaves.
- To construct roads, tramways, railways, etc.
- To erect buildings, machinery, plant, etc.
- To work quarries of lime, clay, etc. (sometimes for own use only).
- To remove coals, dead and live stock, plant, etc., after expiration of lease.
- To relinquish at stated times before termination of lease.
- To renew lease for a further period.
- To generally do all things necessary for getting coal, etc.

Reservations to lessor:—
- Of mines and minerals not demised.
- Of certain rights and wayleaves.
- Of use of ways, railways, etc.

'Habendum':—
- Lessee to have and hold property for a fixed term of years.

'Redendum':—
- Annual certain rent or deadrent, usually merging into royalty.
- Royalty per ton or otherwise.
- Rent for surface occupied.
- Rent for wayleaves, waterleaves, or other facilities.

Provisoes:—
- No royalty payable in respect of colliery consumption.
- Power to make up short workings of previous years.
- Power to carry over excess workings to subsequent years.
- For distress in case of default in payments.
- For re-entry if rents, etc., remain unpaid for certain period.

Covenants on part of lessee :—
For due payment of rents and royalties.
For due payment of taxes.
For compensating for damage done to surface or to neighbours.
For erecting (or against erecting) buildings, houses, coke-ovens, etc.
For keeping proper accounts accessible to lessor, and rendering the same.
For keeping proper mine plans, and permitting inspection of mine.
For leaving proper barriers.
For working in approved and miner-like manner.
Against sub-letting without authority.
For giving up possession in good condition at determination of lease.
For keeping mine, plant, buildings, etc., in good repair.
For properly fencing or securing shafts, adit mouths, etc.
For giving lessor power to purchase plant, etc., at a valuation on determination of lease.
Covenants on part of lessor :—
For proper title.
For quiet enjoyment.
Arbitration clause.

Leases of ironstone mines as also of metalliferous mines follow practically the same lines; as regards the latter, it is usually set forth that the royalty shall be a certain part of the value of the minerals, cleaned, dressed, smelted, or otherwise rendered merchantable, as the case may demand, at the expense of the lessee. There are often clauses specifying that a certain amount of development work, driving, sinking, etc., shall be performed.

A tacknote or license to prospect is often granted; this differs from a lease, inasmuch as it transfers no interest in the property. Its usual form is a license for one year to explore for all or for certain specified minerals within a definite area, usually for a nominal consideration, the licensee making compensation for all damages, and paying a royalty on all minerals gotten and sold. The license is generally renewable at the option of the licensee for a term of years, usually three, and the licensee is entitled to a lease upon conditions specified; this specification often takes the form of a schedule embodying the conditions of a draft lease.

Classification of Mineral Deposits.

A mineral deposit may be defined as a portion of the earth's crust containing mineral matter of intrinsic value under favourable conditions.

The mineral substances that form the subject of mining operations may be classified as under :—

Group I., Fuels; II., Ores; III., Salts; IV., Gems; V., Rocks.

Group I. contains the different varieties of coal, asphalts, bitumen, and other solid hydrocarbons, mineral oils, etc., while sulphur may conveniently be included.

Group II. contains the various heavy metals either in the native state or in combination.

Group III. contains the haloids, sulphates, carbonates, silicates, phosphates, borates, etc., of the alkaline earths and alkalies.

Group IV. contains those minerals that are prized as gems on account of their hardness, brilliancy, and transparency, as well as the semi-gems, such as opal, turquoise, etc., which though opaque are prized as precious stones on account of the beauty of their colouring and their rarity.

Group V. comprises the various rock masses, such as granite, slate, limestone, etc., the exploitation of which is more properly considered under quarrying.

With respect to their mode of occurrence, mineral deposits may be classified morphologically as follows :—

Tabular = Beds, veins.
Irregular = Masses, lenses, pipes, etc.

A more complete classification, based on genetic as well as morphological characters, is as follows :—

- **Class I.—Symphytic;** Syngenetic, contemporaneous or stratified
  - Group *a*, clastic.
  - Group *b*, formed by chemical agencies.
  - Group *c*, formed by organic agencies.
  - Group *d*, disseminated through beds.
- **Class II.—Epactic;** Epigenetic, subsequent or non-stratified.
  - Sub-Class A—Veins.
    - Group *a*, fissure.
    - Group *b*, bedded.
    - Group *c*, contact.
    - Group *d*, gash.
  - Sub-Class B—Masses.
    - Group *a*, stockworks.
    - Group *b*, disseminated in igneous rocks.
    - Group *c*, connected with igneous rocks.
    - Group *d*, connected with soluble rocks.

Class I.—Group *a* includes auriferous alluvials, tin-bearing alluvials, ironsands, etc. Group *b* contains deposits due to chemical precipitation, to evaporation or to metasomatic changes. Practically all the stratified ironstones belong to this group. Of group *c* the most important

representative is coal. Group *d* includes the Knottensandstein of Mechernich, the Kupferschiefer of Mansfeld, the Banket beds of Johannesburg, and similar deposits.

Class II.—Sub-Class A. Group *a* includes most of the important vein systems of the world, such as those of Cornwall, etc.

Group *b* includes veins parallel to the stratification.

Group *c* embraces certain veins following the contact of dissimilar rocks.

Group *d* contains veins carrying galena and zinc blende that characterise certain limestone districts, e.g., that of Missouri.

Sub-Class B. Group *a* consists of masses traversed by minute veinlets carrying ore, such as the tin deposits of Saxony.

Group *b* comprises such deposits as the Kimberley diamond-bearing pipes, the copper deposits of Lake Superior, etc.

Group *c* are very largely lenticular in form; the pyrite deposits of the Huelva district are a typical example.

Group *d* may be represented by the red hæmatite deposits of Cumberland and Lancashire.

Branches of Mining.

I. Prospecting, the most important part of which is 'boring.'

II. Exploiting, including the various operations of opening up mineral deposits by shafts or adits, extracting and transporting the mineral, securing, pumping and ventilating the workings, and the proper care of the men employed.

III. Dressing or preparing the mineral extracted for the market.

COAL.

Classification.

Coal is generally classified under the three main heads of 'lignite' or 'brown coal,' 'bituminous coal,' and 'anthracite.' Bituminous coal is further classified according to the purposes for which it is best adapted, such terms as gas coals, house coals, furnace coals, smithy coals, steam coals, etc., being usually employed. The classification that is most widely adopted is based upon Gruner's work, and is as follows :—

Description of Coal.	Composition of Ash-free Coal.			Percentage of Fixed Residue.	Nature of Residue.	Calorific Power.
	Carbon.	Hydrogen.	Oxygen.			
						Cal.
Lignite . .	70–75	5·6	15·25	50	Non-coking .	6,000
Dry coals with long flame (furnace coals)	75–80	4·5–5·5	15–19·5	55–66	Pulverulent or very slightly coking	8,000–8,500
Fat coals with long flame (gas coals)	80–85	5·0–5·8	10·0–14·2	60–68	Completely agglomerated, porous	8,500–8,800
Fat coals proper (smithy coals)	84–89	5·0–5·5	5·5–11·0	68–74	Completely agglomerated, more or less porous	8,800–9,300
Fat coals with short flame (coking coals)	89–91	4·5–5·5	5·5–6·5	74–82	Coked, compact	9,300–9,600
Anthracite .	90–93	4·0–4·5	3·0–5·5	82–90	Pulverulent .	9,200–9,500

Seyler's classification is based upon the percentage of hydrogen in the ash-free coal and the ratio of carbon to hydrogen :—

Genus.	H per cent.	C : H.
1. Anthracite	< 4	> 22
2. Carbonaceous	4–4·5	20·3–23·35
3. Semi-bituminous	4·5–5	16·6–20·4
4. Bituminous	5–5·8	14·6–18·2
5. Per-bituminous	> 5·8	12·9–14·7

(*Strahan & Pollard.*)

Other classifications are also used; one much liked in America is based upon the 'fuel ratio,' that is the figure obtained by dividing the percentage of fixed carbonaceous residue by the percentage of volatile matter.

Calorific Power.

The calorific power may be calculated from the ultimate analysis by the 'Deutscher Verband' formula :—

$$\text{Cal. power in calories} = 81\ C + 290\left(H - \frac{O+N}{8}\right) + 25\ S - 6\ W,$$

where C, H, O, N, S, and W are the percentages, respectively, of Carbon, Hydrogen, Oxygen, Nitrogen, Sulphur, and Moisture.

Gontal's formula is applied where only the proximate analysis (percentages of fixed carbon, volatile matter and ash) is known.

Let C be percentage of fixed carbon, V of volatile matter, A of ash; then

$$\text{Cal. power in calories} = 82\ C + a\ V,$$

where a is a coefficient depending upon the percentage of volatile matter in the ash-free coal, i.e. upon $\frac{100\ V}{100-A}$ as follows :—

$\frac{100\ V}{100-A}$	5	10	15	20	25	30	35	40
a	145	130	117	109	103	98	94	80

The ash of coals varies usually between 3 and 15 per cent.

1 lb. of ordinary coal requires theoretically 130 cub. ft. of air for complete combustion.

Coke.

Ordinary bituminous coal, containing 25 to 30 per cent. of volatile matter, coked in a modern regenerative bye-product coke-oven plant, yields approximately :—

Coke	70–75 per cent.
Tar	3·5–4·5 „
Ammonia as ammonic sulphate	1–1.25 „
Crude benzol	1 „

Surplus gas, 3,000 to 5,000 cub. ft. per ton of coal.

The composition of this gas is about as follows :—Hydrogen, 48 to 55 per cent.; methane, 25 to 34 per cent.; carbonic oxide, 6 to 8 per cent.; carbonic acid, 2 to 2·5 per cent.; hydrocarbons, 2 to 4 per cent.; nitrogen, etc., 5 to 12 per cent. The calorific power is about 480 to 600 B.Th.U. gross, or 425 to 550 B.Th.U. net.

Weight of Coal.

The specific gravity of coal varies from 1·1 to 1·6, most bituminous coals approximating to 1·3. The following table shows the weight of coal contained in one acre of superficial area per inch thickness of seam.

Table of the Weight of Coal under Different Circumstances.

Specific Gravity.	Weight in the Natural Bed, per Acre, per Inch Thick, in Tons.	Weight of a Cubic Foot in the Broken State, in Lbs.	
		Large Coal.	Small Coal.
1·10	111·411	42·62	37·12
1·15	116·475	44·56	38·81
1·20	121·540	46·50	40·50
1·25	126·604	48·43	42·18
1·30	131·668	50·37	43·87
1·35	136·732	52·31	45·56
1·40	141·796	54·25	47·25
1·45	146·860	56·18	48·93
1·50	151·925	58·12	50·62

To find the contents of coal of any given specific gravity per acre multiply the figure in the table by the thickness of the seam in inches; the thickness measured along a vertical line should always be taken, as the correct result will thus be obtained, whatever may be the inclination of the coal seam.

The weight of coal in its broken state, that is, as it comes to the surface, in tubs or otherwise, will depend on its largeness; it has here, however, been computed to weigh in proportion to the solid coal as 62 is to 100, and the weight of the small as 54 is 100.

The calculation now most commonly adopted in the North of England to ascertain the weight of coal in the solid state is to reckon 19 cwts. per cubic yard = 78·815 lbs. per cubic foot. On this calculation, a seam 1 foot in thickness would contain 1,532 tons 13 cwts. 1 qr. 10 lbs. per acre, and a seam 1 yard thick would contain 4,598 tons per acre.

A summary way of reckoning the quantity of available coal in a given area of a seam is to take an acre of coal 1 inch thick to produce 100 tons. This leaves a sufficient margin for faults and losses in barriers and in working.

METALLIFEROUS MINERALS.

By *metalliferous* minerals or *metallic* minerals are meant those minerals that are technically utilisable for the extraction of the ordinary, commercial heavy metals, metals of the alkalies and alkaline earths being excluded; this is almost identical with the meaning of *ores*, or with Group II. of above classification. In United States of America and Canadian statistics, a wider meaning is given to *non-metallic* minerals, which includes all minerals not actually used for the extraction of metals, e.g. ochre, although this is an oxide of iron, because it is used as a pigment and not as a source of iron.

COMPOSITION OF MORE IMPORTANT ORES.

Name.	Formula.	Percentage of Metal.
Magnetite	Fe_3O_4	Fe 72·4
Hæmatite	Fe_2O_3	„ 70
Limonite	Fe_2O_3,H_2O	„ 60
Brown hæmatite	Hydrated ferric oxide, with 10–15 per cent. H_2O	„ 45–55
Siderite	$FeCO_3$	„ 48·3
Ilmenite	$(TiFe)_2O_3$	„ 30–40
Pyrites	FeS_2	„ 46·7
Pyrrhotite	Fe_5S_6	„ 60·5
Pyrolusite	MnO_2	Mn 63·3
Manganite	$Mn_2O_3H_2O$	„ 62·5
Wad	Impure hydrated manganese oxide	„ 25–50
Chalcopyrite	$Cu_2SFe_2S_3$	Cu 34·6
Chalcocite	Cu_2S	„ 79·8
Malachite	$2(CuO)CO_2H_2O$	„ 56
Cinnabar	HgS	Hg 86·2
Galena	PbS	Pb 86·6
Cerussite	$PbCO_3$	„ 77·5
Anglesite	$PbSO_4$	„ 68·3
Blende	ZnS	Zn 67
Calamine	$ZnCO_3$	„ 52
Stibnite	Sb_2S_3	Sb 71·8
Mispickel	$FeAs_2S_2$	As 46
Cassiterite	SnO_2	Sn 78·7
Wolfram	$(FeMn)OWO_3$	W 70
Scheelite	$CaOWO_3$	„ 74·8

IRONSTONE.

Ironstone is the term applied to stratified or symphytic deposits workable for iron, iron ore to epactic deposits, veins or masses. Bessemer ore or hæmatite ore is generally understood to mean iron ore with less than 0·035 per cent. of phosphorus when the ore contains about 50 per cent. of iron. Such ores are usually quoted on a basis of 50 per cent. of iron, with a definite increase or deduction in price for each unit of iron above or below that figure, and a penalty for every unit of silica above a given percentage, often 8 per cent.

The yield of ironstone is often taken roughly at 2,000 tons per foot thick per acre.

TABLE OF BRITISH MESOZOIC IRONSTONES.

Formations.			*Name of Ironstone.*
CRETACEOUS—Neocomian	Wealden	Lower Greensand	Seend, Wiltshire.
		Weald Clay	
		Hastings Sand	Sussex and Kent.
			Westbury, Wiltshire.
			Claxby, Lincolnshire.
JURASSIC	Upper Oolite		
	Middle Oolite	Corallian	Dover, Kent.
		Oxford Clay	Westbury, Wiltshire.
	Lower Oolite	Great Oolite	
		Estuarine Beds	
		Northampton Sands	Northamptonshire.
			Cleveland Dogger or Top Seam.
	Upper Lias	Upper Lias Clay	
		Toarcian	Isle of Raasay.
	Middle Lias	Middle Lias Limestone	Cleveland Main Seam.
			Cleveland Pecten Seam.
			Cleveland Avicula Seam.
		Marlstone	Blenheim, Oxfordshire.
			Melton Mowbray, Leicestershire.
			Caythorpe, Lincolnshire.
	Lower Lias		Frodingham, Lincolnshire.

COMPOSITION OF BRITISH MESOZOIC IRONSTONES, DRIED AT 100° C.

	Iron.	Silica.	Lime.	Sulphur.	Phosphorus	Loss on Ignition.

Raasay	25	10	17	0·5	1·0	20

COPPER, TIN, LEAD AND ZINC ORES.

Copper, tin, lead and zinc ores are usually sold by assay. The value is calculated on the current market price of the metal multiplied by the percentage of metal present less the percentage estimated to be lost in the operation of smelting; from the value thus found there is then deducted the 'returning charge,' being the estimated cost of smelting the ore, including the smelter's profit, etc. The following were the generally accepted (pre-war) methods :—

COPPER ORES.—Weight paid for is gross weight less moisture and less 1 per cent. draftage. Wet assay less 1 per cent. for ores assaying 3–4 per cent. (deduction varied proportionately for richer or poorer ores); for value per unit (1 per cent.) take 0·01 of price of best selected copper, less returning charge of 2*s.* 3*d.* to 2*s.* 6*d.*

Example.—Cargo of 1,000 tons ore assaying 4 per cent. copper, ¼ per cent. moisture. Net weight $= 1{,}000 - \left(\frac{1{\cdot}25}{100} \times 1{,}000\right) = 987{\cdot}5$ tons.

4 per cent. − 1 per cent. = 3 per cent. copper to be paid for.

Best selected quoted that day 82*l.* 10*s.* per ton = 16*s.* 6*d.* per unit, less 2*s.* 3*d.* returning charge = 14*s.* 3*d.* 3 units at 14*s.* 3*d.* = 42*s.* 9*d.* per ton of ore.

Value of cargo 987·5 tons at 42*s.* 9*d.* = 2,110*l.* 15*s.* 7½*d.*

LEAD ORE.—Weight paid for is net dry weight. Percentage paid for is dry assay less 4 units, on basis of soft foreign lead price in London, subtracting 40*s.* per ton for returning charge. Silver above 3 oz. per ton paid for at current rate for fine silver. Price is understood to be delivered smelter's works.

Example.—150 tons net of galena assaying 78 per cent. of lead and 5 oz. of silver per ton, quotations being : lead, 20*l.* per ton; silver, 2*s.* 3*d.* per oz. Lead, 150 tons at (78 − 4) per cent. = 111 tons at 20*l.* = 2,220*l.*, less 150 tons at 40*s.* = 1,920*l.* Silver, 150 × (5 − 3) oz. = 300 oz. at 2*s.* 3*d.* = 33*l.* 15*s.* Total value of ore, 1,953*l.* 15*s.*

Zinc Ore.—Weight paid for is net dry weight. From percentage of zinc, as determined by wet assay, subtract 9 units, multiply by $\frac{18}{20}$ of price of spelter, and subtract returning charge of 3*l.*; difference is price per ton delivered smelter's works.

Example.—If ore assays 50 per cent., London quotation for spelter being 18*l.*, the ore is worth $£\left(\left[\frac{50-9}{100}\cdot\frac{18}{20}\cdot 18\right]-3\right) = 4l.\ 0s.\ 3d.$ per ton.

The general gangue of most ores is quartz; solid quartz averages about 165 lbs. per cub. ft. (13½ cub. ft. to the ton), broken about 100 lbs. (22½ cub. ft. to the ton), but varies considerably. The weight of veinstuff containing metalliferous minerals can be calculated from the specific gravity of the minerals.

Table of Specific Gravities and Weights per Cubic Foot of Minerals.

Mineral.	Sp. gr.	Cwts. per cub. ft.	Mineral.	Sp. gr.	Cwts. per cub. ft.
Copper pyrites	4·1–4·3	2·34	Ilmenite	4·5–5·0	2·64
Copper glance	5·5–5·8	3·15	Hæmatite	4·5–5·3	2 73
Malachite	3·7–4·0	2·20	Brown hæmatite	3·4–4·4	2·17
Cinnabar	8·9–9·0	5·00	Spathic ore	3·4–3·9	2·04
Galena	7·3–7·7	4·18	Pyrolusite	4 3–4·9	2·67
Cerussite	6·4–6·5	3·60	Cassiterite	6·4–7·1	3·76
Anglesite	6·1–6·4	3·50	Wolfram	7·1–7·6	4·12
Zinc blende	3·9–4·2	2·23	Scheelite	5·9–6·1	3·34
Calamine	4·0–4·5	2·40	Quartz	2·5–2·8	1·50
Stibnite	4·5–4·6	2·50	Calcspar	2·5–2·8	1·50
Pyrites	4·8–5·2	2·78	Dolomite	2·8–2·9	1·56
Mispickel	6·0–6·4	3·45	Fluorspar	3·0–3·2	1·73
Magnetite	4·9–5·2	2·80	Felspar	2·5–2·8	1·50

A rib of mineral 1 in. thick = 3 cub. ft. per square fathom.

Calculation of Mineral Mixtures.

The percentages of two minerals present in a mixture can easily be calculated if the sp. gr. of the mixture and of the ingredients is known. A convenient method is that proposed by R. T. Hancock.

Take a weight of x grms. of the mixture containing two ingredients of sp. gr., a and b respectively, where $\frac{1}{x} = \frac{1}{a} - \frac{1}{b}$ or $x = \frac{ab}{b-a}$; then the volume of this weight of a alone will differ from that of the same weight of b alone by 1 c.c., and for every 1 per cent. of a (the lighter substance) present in the mixture, the volume will be greater by 0·01 c.c. than the volume of b alone and for every 1 per cent. of b present, less by 0·01 c.c. than the volume of b alone. It is usually convenient to take $10x$ grms., when the differences will be 0·1 c.c.

Example.—To determine percentage of cassiterite (sp. gr. 7) and 'black sand' (sp. gr. 4·5) in a mixture of these. Since $\frac{1}{4\cdot5} - \frac{1}{7} = \frac{1}{12\cdot6}$, take 126 grms. Volume of mixture, measured by pouring the mixture into a burette partly filled with water and noting the difference in the burette readings, = 20 c.c. Volume of 126 grms. of black sand would be $\frac{126}{4\cdot5} = 28$ c.c. Hence percentage of cassiterite = 10 (28 − 20) = 80 per cent.

BORING.

Boreholes are put down by one or other of the following methods :—

I. Percussive: (*a*) Using solid rigid rods.
(*b*) Using ropes.
(*c*) Using hollow rods (water-flush method).
(*d*) Using a hydraulic ram.

II. Rotary: A. Core drills.
(*a*) Using diamonds.
(*b*) Using steel cutting teeth.
(*c*) Using chilled shot.
B. Hydraulic rotary oil drill.

Generally speaking, percussive methods are used when the primary object is to get a hole down rapidly, where information as to the nature of the ground passed through is of less importance, whilst rotary core drills, by the use of which a more or less continuous core is obtained, are employed when an accurate knowledge of the strata passed through is the first consideration.

Sometimes both methods are combined ; thus in some of the boreholes put down in Kent, boring through the secondary rocks was performed by percussion, whilst rotary core-boring was substituted after the coal measures had been reached. Percussion boring by the ordinary 'English' method can be used to depths of about 500 ft., costing about 10*s.* to 20*s.* per foot, and advancing 2 ft. to 6 ft. per twenty-four hours. Beyond this depth a free-falling cutter must be used, and in this way depths of 3,000 ft. or more may be reached.

Rope boring with round ropes on the American system is used almost exclusively in boring for oil, salt, etc. The plant for a hole 2,000 ft. deep would weigh about 80 tons complete and cost about 2,000*l.* ; holes range from 6 ins. to 15 ins. in diameter. In Pennsylvania and Ohio such boring has been done for as little as 2*s.* per foot, and contracts are usually let at prices ranging from 4*s.* to 8*s.* The rate of boring is from 20 ft. per day upwards. In Middlesbrough, 8-in. holes have been put down to depths of about 1,000 ft. at a cost of about 8*s.* per foot with a speed of 60 ft. per day. Boring with flat ropes by the Mather and Platt system is used for very large boreholes, as for instance for waterworks ; holes up to 45 ins. in diameter have been bored by this method.

The water-flush method, of which there are many varieties (Fauck, Raky, etc.), is used in hard rocks for boreholes of medium size (rarely under 8 ins. in diameter). Very fast boring can be done in this way ; e.g. in the Ruhr district a borehole was put down to a depth of nearly 2,000 ft. at an average speed of 157 ft. per twenty-four hours ; 30 to 50 ft. is quite a usual rate down to depths of about 2,000 ft., and over 20 ft. a day has been bored down to a depth of over 3,000 ft.

The hydraulic ram method appears to offer certain important advantages, especially for boreholes of moderately large diameter, but has hardly passed the experimental stage.

Core Boring.

Diamond boring is in use to-day for hard rocks ; the main drawback is the high price of the 'diamonds' (bort, used in the softer rocks, costs 2*l.* to 3*l.** per carat, carbon costs 6*l.* to 12*l.* per carat), which tells severely against boreholes larger than 6 ins. in diameter. The cost of diamond boring in this country is about 7*s.* 6*d.* per foot down to 500 ft. and 12*s.* to 18*s.* down to 1,500 ft. for a 5-in. borehole. A 5-in. borehole put down in Scotland to 1,800 ft. cost only 6*s.* 4*d.* per foot ; the rate of advance was about 6 ft. per day. In British Columbia a borehole 2,200 ft. deep cost 8*s.* 6*d.* per foot, and was bored at the rate of 10 ft. per day. In Victoria the Government does much boring to aid prospectors ; the bores are mostly shallow, but in one case a depth of 1,110 ft. was reached in about 120 days ; the average cost of boring in coal measures in 1912 was 9*s.* 3*d.* and in the harder rocks 14*s.* per foot. In Nova Scotia 2 in. diamond boreholes put down by the Government in moderately hard ground to depths of 200 to 400 ft. averaged about 9*s.* per foot in 1913.

Steel cutting teeth can only be used in tolerably soft ground. The cutter should make 15–25 r.p.m. A 10-in. borehole in Kent was put down by this method by the Calyx Company to a depth of 1,400 ft., the speed at times reaching 10 ft. per hour.

The chilled shot method is very generally applicable, and is used for relatively large bore holes in hard ground. The cutter should run at 100–150 r.p.m. ; about No. 5 shot is generally used. It is usually somewhat slower but cheaper than diamond boring. The consumption of shot with a cutter 4½ ins. in diameter ranges from 0·15 lb. per foot bored in shale to 1·2 lbs in hard sandstone, but may be much higher in broken ground, where shot escapes into the fissures. In Nova Scotia 6 in. Government boreholes by this method averaged 10*s.* 6*d.* per foot in 1913.

The hydraulic rotary drill is the name given to a form now much used in boring oil-wells ; it cuts out the whole of the material, leaving no core, the debris being brought to the surface by a water-flush. Over 100 ft. per day has been bored by this method.

Location of Bore-holes for Valuation of Alluvial.

When ground is systematically tested by pits or boreholes at regular intervals, three conventional views are possible :—

1. That there should be so many pits or holes per acre, or
2. That the distance between pits or holes should be so much, or
3. That no point on the ground should lie beyond a certain distance from a pit or hole.

The first two are those most generally held, but the last seems the most logical, and to attain it with the least amount of work the holes should lie at the corners of a series of equilateral triangles, the length of whose sides, or the distance of the pits apart, is equal to the maximum distance under condition (3) multiplied by $\sqrt{3}$. A line is run in any desired direction and staked at intervals equal to the distance between pits. From these stakes lines are turned off at angles of 60° or 120°, and staked at similar intervals starting from the turning-off point. The stakes are numbered to indicate their position on their own line and the number of the turning-off point, so that the pits sunk at them can be readily identified.

The advantages of this method over the more usual square lay-out are considerable. There is 6 per cent. less work involved in the lay-out of the holes, and 23 per cent. less in the sinking and sampling. The computation of values can also be more accurately done. Interpolation

* All costs throughout this article refer to prices before 1913.

of values can be done on the plan, much as in contouring from spot levels, and a reliable assay plan prepared. (*R. T. Hancock.*)

The following is a list of some of the more important boreholes in the world :—

	£ s. d.		£ s. d.
Czuchow, Rybnik, Upper Silesia . 7,350 ft.	2 3 4 per ft.	Bezuidenville, Transvaal . . 5,800 „	2 2 0 „
Virgina, U.S.A. (1918) 7310 „		Schladebach, Prussia . . . 5,737 ft.	1 1 2 per ft.
Macdonald, Penn. U.S.A. . . . 7200 „		Dornkloof, Transvaal . . . 5,582 „

Dentingen, Lorraine 5,925 „			

Drilling Shot Holes.

Performed by hand, either by jumper for moderately hard rocks, by hammer and drill for hard rocks, or by the coal miner's hand machine, now used almost exclusively in coal and very largely in ironstone (W. Charlton, *Trans. Inst. Min. Eng.*, 1902, vol. xxiv., p. 526). Average rate of boring is 4 to 8 ins. in bituminous coal, 2 to 4 ins. in shale, per minute.

'Mushrooming' of shank end of drill causes loss of 20 lbs. steel per man per annum. Tempered pear-shaped shank ends are being used at East Rand Proprietary Mines. (*Journ. Chem. Met. and Min. Soc. South Africa*, 1919, vol. **xix.** p. 168.)

Mechanical Drilling.

Also either rotary or percussive. Rotary drills mostly of the twist-drill type confined to the softer rocks; Steavenson electric drill averages 40 ins. per minute in ironstone, uses 6 h.p. Siemens and others make small electric drills, taking 1 to 2 h.p., boring 6 to 10 ins. per minute in coal. For boring in hard rock the Brandt machine has been used in the Simplon tunnel and in some German collieries ; hydraulically driven under head of 1,500 lbs. per sq. in. ; bores 15 ft. per hour in gneiss. The Kellow drill used in North Wales is similar ; has drilled 5 ft. per minute in slates.

Percussive drills are almost exclusively worked by compressed air (for Air Compression, see p. 1075). Drills are of two kinds: piston drills, in which the drill bit is rigidly connected with the piston rod, and hammer drills, in which the piston rod strikes on the end of the drill bit, the latter being lighter, smaller, and running at much higher speeds.

Drills may be classified by their valve action :—

1. Valve moved by external tappets.
2. „ „ internal „
3. „ „ air with auxiliary valve moved by tappet.
4. Valve moved by air.
5. Valveless, the piston itself acting as a valve.

Most modern drills belong to Class 3, but several types belonging to Classes 2 and 4 are also in use ; very many hammer drills belong to Class 4.

Piston drills are further classified by their piston diameter, ranging from 2 to 4 ins. ; 2¼-in. drills are largely used for stoping, 2¾ to 3¼ ins. for drifting, 3 to 3½ ins. for sinking. In 1902 70 per cent. of the drills in use on the Rand were 3¼ drills. Such drills use 60 to 90 c. ft. of free air per minute at pressures between 60 and 90 lbs. per sq. in. A 3-in. drill evolves about 1¾ h.p., for which about 5 h.p. must be applied to the drill piston and 10 to 25 h.p. to the steam end of a direct-driven air compressor.

Average speed of boring, including setting up, is 10 to 25 ft. per 10-hour shift. Costs of boring in hard rock in Sweden are about 8*d.* to 10*d.* per foot bored, of which 40 per cent. is for wages and 30 per cent. for power ; average boring speed is 5 ft. 6 ins. to 8 ft. per hour for downward holes and 4 ft. to 6 ft. 6 ins. for upward holes.

Hammer drills use 25 to 50 cubic feet of free air per minute ; speed of boring about the same as piston drills, but holes are usually smaller. Hammer drills with a relatively rapid turning action of the bit and using bits with a chisel edge, but specially twisted steel, are used very successfully in coal.

A complete 6-piston-drill plant costs about 500*l.*

Two-stage compressors, delivering air at 100 lbs. gauge pressure, weigh on the average 27 lbs. and cost on the average 12*s.* in the U.S.A. per cubic foot piston displacement.

Sharpening Steel Bits.

A good blacksmith and striker can sharpen 30 to 40 bits per hour.

By the use of power drill-sharpeners, many of the shortcomings attendant upon the hand-sharpening process are got rid of, and drills can be kept true to gauge, with the result that where these machines are used it is possible to accomplish more drilling, whilst the cost of sharpening is considerably reduced.

According to experiment, the fastest cutting bit is the Carr (double chisel bit with central hole) the Z, + and 6 edged star in this order ; cutting speed $\propto$ (drill diameter) $^{-2}$; cutting speed $\propto$ air pressure ; pressure of 85 lbs. per square inch most generally satisfactory.

(*Bull. Amer. Inst. Min. Eng.*, August 1917, p. 1079.)

EXAMPLE.—Required the amount of free air necessary to operate thirty 5-in. 'H' drills at 9,000 ft. altitude, using to operate these drills air at a gauge pressure of 80 pounds per sq. in.

From Table I we find, when operating the drills at 80 pounds gauge pressure at sea level, that one 5-inch 'H' drill requires 190 cubic feet of free air per minute.

From Table II we also find that the factor for 30 drills at 9,000 feet altitude is 20·38; multiplying 190 cubic feet by 20·38 gives 3,872 cubic feet air per minute, which is the displacement of a compressor for the above outfit under average conditions, to which must be added pipe line losses, such as friction and leakage.

The Leyner compressed air operated drill sharpener, which can be handled by one man, is capable of sharpening up to 100 drill bits per hour, the number depending upon the size of the bits and steels to be handled.

In the case of small quarry plants or contract work, where drilling is done in the open, dry steam at a pressure of from 80 to 100 lbs. can be used, but will not give such good results as compressed air. Where a number of drills are used, a compressed air plant should preferably be installed, and is indispensable in underground drilling. With a properly laid pipe line of suitable size, there is very little loss in conveying compressed air from a central plant over very large distances.

Notes on Rock Drills.

In mining practice, drills are required to be of rapid boring capacity, and at the same time of light weight, so that the work may be both rapidly advanced and the whole outfit moved in awkward places with a minimum of trouble. In driving main headings, the piston type of drill, mounted on columns, is generally used. Where space is limited, it is not uncommon to mount two drills on arms attached to one column, two runners and a helper being sufficient to handle the machines so arranged ; in large tunnels the drills, from 1 to 4 in number, and of heavy pattern, are frequently mounted on drill carriages, thus enabling the equipment to be rapidly moved away from the face when the round of holes is ready for firing, without the necessity of dismantling. In stopes, raises, or small headings, the telescope-feed hammer drill, which is largely used, is a one-man drill, and is a rapid boring machine. Where the rock is of such a nature as to cause a considerable amount of dust, a condition which is to be met with in almost every metalliferous mine, drills having an automatic water feed are used. In the case of the heavy drills, the water is fed through the piston and drill bit under pressure ; of this type is the Leyner-Ingersoll. Telescope-feed stope drills can also be arranged for water feed through the heads and drill bits, which have a central hole running from the shank to the cutting face for this purpose.

For hammer drill work, drill bits are furnished with single chisel, double chisel, 6 point and 'Z' cutters, the steels themselves being sometimes hollow and sometimes round, hexagonal or spiral, the section depending upon the class of rock to be bored.

The Hardy-Simplex Air Hammer Rock Drill (*Patent*).

(*The Hardy Patent Pick Co. Ltd., Sheffield.*)

In this drill, fig. 1, the valve action is as follows:—When the air pressure is suddenly reduced at one end of the valve, the piston uncovers the main exhaust ports, and the full pressure

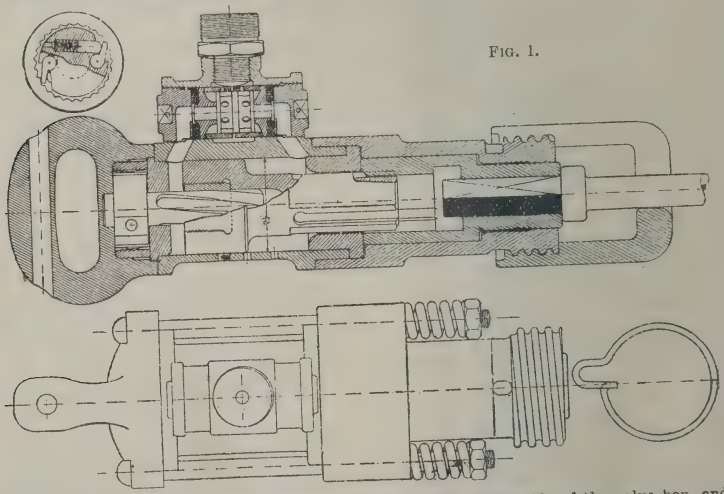

Fig. 1.

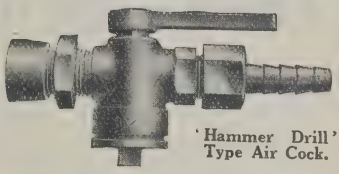

acting on the opposite end causes the valve to travel to the other side of the valve box and thereby change the direction of the air pressure and reverse the piston or hammer. The action of the valve does not depend on compression set up by the piston in order to accomplish its

THE

Dressing of Minerals

By HENRY LOUIS, M.A., D.Sc., A.R.S.M.

Member of the Institution of Civil Engineers; Fellow of the Institute of Chemistry of Great Britain; Fellow of the Geological Society; Member of the Institution of Mining Engineers; Professor of Mining and Lecturer on Metallurgy at Armstrong College, Newcastle-on-Tyne.

THE 'Dressing of Minerals' is a term that is intended to include all the series of operations that intervene between the extraction of a mineral from its natural deposit and its production in a condition ready for sale or for further use in the arts or manufactures; it practically covers the whole series of operations which have for their object the separation of a mass of mixed minerals into its mineralogical constituents, or the cleaning of ore constituent from the accompanying mineral or minerals which may be looked upon from the technical point of view as the impurities of the former.

The object of Professor Louis is to give an account of the theory and practice of the subject, and the present volume—the first English treatise on the subject—will prove of the greatest service to the miner or metallurgist who desires to understand the principles upon which the art is based, as also to the manufacturer who supplies the necessary appliances, and above all to the student who is preparing for either of the above professions.

SUMMARY OF CONTENTS.

I.—General Considerations. II.—Volumetric Sizing. III.—Sorting and Washing. IV.—Comminution. V.—Separation by Specific Gravity. VI.—Appliances depending essentially on Vertical Fall. VII.—Jigs. VIII.—Horizontal Current Separators. IX.—Shaking Tables. X.—Pneumatic Separation; Magnetic Separation; Electrostatic Separation; Separation by Surface Tension. XI.—Accessory Appliances. XII.—General Construction of Dressing Works.

LONDON:

EDWARD ARNOLD & CO., 41-43 Maddox St., W.1

reversal. It is not dependent on a tight piston and cylinder. It moves only $\frac{1}{64}$ in. in order to cut off the main air supply, but it has a further considerable travel before readmitting air. By the arrangement, all valve losses are practically eliminated, and the delay in readmitting air in quantity for the reversal of the piston diminishes internal resistance, so that a very powerful blow is given with a very small air consumption.

The valve will preserve its air tightness practically indefinitely, whilst at the same time it is perfectly balanced, and so light as to have great rapidity of action. The cylinder and valve box are forged together in one piece of special steel, bored, case-hardened to a glass hardness, and then accurately ground. The valve and valve bush are both manufactured from special alloy steels, both parts being hardened to suit the demands made on them. The rotation is effected by means of a rifle bar and a ratchet wheel situated at the rear of the machine in combination with a number of straight grooves cut in the piston or hammer working through a steel guide nut, situated in the chuck or drill holder. All parts of the rotation device are of hardened steel and are readily renewable.

The drills are retained by means of a cap which is provided with a strong round thread, screwing over the front of the drilling machine and embracing the collar on the drill shank. The cap is slotted its full length, thereby enabling the machine to be at once disengaged from the drill steel should this for any reason become necessary.

The drills are made in three sizes, viz., the B5, B6, and B7, weighing 23 lbs., 27 lbs., and 40 lbs. respectively. The B5 pattern is for all overhead work in any class of rock; it is also used for coal boring on long wall faces and in headings, etc. The B6 pattern will bore easily holes up to 10 ft. in depth where necessary, in rock of any hardness, the speed of boring varying from 6 to 8 ins. per min. in hard granite to 30 ins. per min. in soft sandstone, and up to 48 ins. per min. in hard coal. Air at 60 to 80 lbs. per sq. in. The B7 pattern has been designed specially for 'down holes' in very hard ground in mine shafts and in quarries. It will easily drill holes up to 25 ft. in depth, starting at 3 ins. in diameter. Its normal boring speed in hard granite is 8 to 10 ins. per min. with air at 80 lbs. per sq. in.

Compressed Air Drilling Plants.

Air Receivers.

An air receiver is not intended so much for storage as to equalise pressure, and to allow of an even flow of air through the pipe, there being a certain amount of pulsation from the air compressor discharge itself. In long pipe lines a smaller receiver should be placed in the pipe line near the point of application of the compressed air, furnished with suitable drain cocks, for the purpose of drawing off the superfluous moisture which might collect, and the consequent prevention of freezing in the line. The following table gives sizes and details of receivers which are usually considered standard practice:—

Table III.—Air Receivers and Pressure Tanks for Standard Working Pressures. Tested to 165 lbs. Water Pressure.

(For Air Compressors see p. 1076.)

'Ubel' Air-Service Cocks.

The 'Ubel'-Inverted Spring Plug Air Cocks, fig. 2 (*United Brassfounders and Engineers Ltd.*), are of special construction, embodying many improvements as a result of extensive experience in the use of Rock Drill and other Air-Service Fittings. The design and construction of these cocks is such that, whilst perfectly air-tight, they cannot possibly stick, and can be opened and shut under pressure with great ease. The standard fittings are supplied either all gun-metal or cast iron, or all malleable iron. Cast and malleable iron cocks are also largely supplied, having gun-metal plugs. This arrangement is strongly recommended in cases where there is much moisture in the pipe line, for the reason that this construction prevents any possibility of the ground surfaces rusting together. The standard sizes (screwed standard W.I. pipe) are ¼ in., ⅜ in., ½ in., 1¼ in., 1½ in., 2 in., the all gun-metal fittings weighing respectively 1 lb. 8 ozs., 3 lbs. 6 ozs., 4 lbs. 10 ozs., 6 lbs. 4 ozs., 8 lbs. 4 ozs., and 13 lbs. 8 ozs.

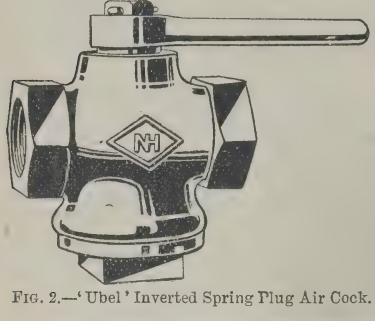

Fig. 2.—'Ubel' Inverted Spring Plug Air Cock.

The 'Purser' Combined (Inverted Spring Plug) Cock and Air-Saver has for its object the prevention of waste, the arrangement being that it automatically closes under 'no load,' and will not entirely open except under approximately full load conditions. An auxiliary valve inside the plug of the cock has its position regulated by small ports in the plug and in the body of the cock. When the cock is open, and the machine to which it is attached is under full load, the air pressure above and below the valve is in equilibrium, allowing the cock to operate as an ordinary plug cock. Should, however, the cock be opened or left open, under 'no load' conditions, the pressure above the auxiliary valve is relieved, and the air entering the cock on the inlet side having access to the underside of valve raises same, thus automatically closing the passage in the cock. The ports are so arranged that when the valve is in the top position, compressing the spring and closing the passage of the cock, a small quantity of air passes through the cock. This air serves a double purpose. (1) It enables the face of the stope to be cleared for subsequent operations. (2) When the load is again applied it assists in building up the pressure between cock and machine operated, until equilibrium is again effected on either side of the auxiliary valve, when the spring forces valve back into its original position, thus leaving the passage of cock again open. The standard sizes are similar to those of the 'Ubel' Inverted Spring Plug Air Cock described above. The weights are, respectively, 3 lbs. 4 ozs., 4 lbs. 6 ozs., 6 lbs. 6 ozs., 8 lbs. 4 ozs., 13 lbs., and 21 lbs.

Metallic Tubing.

Flexible Metallic Tubing (*The Flexible Metallic Tubing Co. Ltd.*, 112 Queen Victoria Street, London) is specially suitable for mining work. Its durability renders it economic, and it diminishes 'breakdowns,' as the tubing cannot kink and is not easily crushed; it is also unaffected by changes of atmosphere, or by vermin, white ants, etc.

BLASTING.

Explosives are divided into low explosives, with a slow rending action and fired by simple ignition, and high explosives, with a rapid shattering action, fired by means of a detonator. The rate of explosion of gunpowder, typical of the former, is 3 to 4 metres per second, and of blasting gelatine, typical of the latter, up to 7,000 metres per second.

For blasting in fiery coal-mines explosives known as safety explosives are employed, which have a lower temperature of detonation. No explosive can, however, be considered really safe in a fiery atmosphere. In this country only those explosives are allowed to be used that have passed the Government tests and which are scheduled in the Home Office Order in force for the time being. A shot-hole in coal should never be placed in the solid, i.e. in coal that has not previously been kirved.

If D be the depth of a properly placed shot-hole, the volume of rock blasted out averages with one free face $0{\cdot}37\ D^3$; with two free faces volume $= 0{\cdot}84\ D^3$, and with three free faces $1{\cdot}33\ D^3$. In drifting and shaft sinking the volume blasted out is approximately $0{\cdot}75\ D^3$. If L be the line of least resistance, D = about 1·75 L.

The quantity of explosive required for charging a shot-hole may be calculated by the following formula, modified from Chalon :—

Let Q be the quantity of explosive in lbs., L the line of least resistance in feet, then

$$Q = \epsilon\kappa L^2,$$

where ϵ is a coefficient depending on the explosive and κ a coefficient depending on the character of the rock.

Low-tension electric fuses require a tension of about 1 volt; medium, about 4 volts; high, about 100 volts. Low tension fuses best in series, high tension in parallel.

Liquid air is used extensively in the ironstone mines of Lorraine; a cartridge containing sawdust, powdered cork, soot, or a similar substance impregnated with liquid air or liquid oxygen is employed. No detonator is required, but the shot must be fired within 15 minutes of charging. The addition of aluminium powder to the charge greatly increases the detonating action. The quantity of liquid air used is 0·3 litre per ton of ironstone, and the cost of this explosive per ton blasted is given as 0·303 per cent. as against 0·571 per cent. with cheddite and 0·597 per cent. with compressed black powder. Liquid oxygen is preferred to liquid air, because the latter is apt to produce fumes containing oxides of nitrogen which injuriously affect the miners, whereas with the former no noxious gases at all are evolved.

Under Explosives Order No. 1194 of 1921, the production in the mine of an explosive by impregnating carbonaceous material with liquid air or oxygen is now permitted under licence, thus modifying Section 50 of the Explosives Act, 1875.

Detonators.

Detonators.—These are known by numbers, the charge of which varies somewhat. The following is about the average practice:—

Detonator numbers	1	2	3	4	5	6	7	8
Weight of mixture in grains	4½	6	8	10	12	15	23	30

The mixture consists of 80 per cent. fulminate of mercury, 20 per cent. chlorate of potash.

Detonating Cord (Cordeau détonant) consists of a flat tube of lead, tin or aluminium usually 7 mm. wide, 3 mm. thick, filled with nitro-methylaniline or trinitrotoluol, containing usually about 10 grams of explosive per metre. An explosion is propagated through this at a velocity of about 7,000 metres per second. A piece of this cord is attached along a row of blasting cartridges and ensures their complete and instantaneous detonation, even in wet holes. It is stated that the efficiency of the explosive is increased by 20 per cent., and that experiments at Lievin have shown that an explosive mixture of firedamp is not ignited by the detonation of 3 metres of cord.

Ordinary fuse burns at the rate of 30 seconds per foot.

(See also EXPLOSIVES, Section XXXVIII.)

Drifts.

In collieries, drifts of ordinary size, say 35 to 50 square feet in sectional area in ordinary coal measures, range in price for hand labour in **1913** from 1*s.* to 2*s.* per linear yard for each square foot, according to nature of strata and width of drift, being less the wider the drift. The cost in shale is about two-thirds of the cost in ordinary sandstone. Mean rate of advance of such drifts, about 4 to 6 yards per week in sandstone, 6 to 8 yards per week in shale, 3 shifts per day, two miners in face with two to three labourers.

For inclined drifts rising at high angles the prices will be up to 50 per cent. higher; for drifts dipping at a high angle up to 100 per cent. In very hard sandstone the speed of driving will be about one-half, and the costs about double those given above, and in hard tough igneous rocks, such as basalts, the speed may fall to one-fourth, and the cost rise to four times these figures.

By the use of rock drills the speed may be greatly increased, especially in hard rocks, but the actual drivage costs are not much diminished, except in the harder rocks.

In making height where a top or bottom canch of stone has to be blasted, the price for a top canch of shale ranges from 1½*d.* to 2*d.* per inch for a width of 6 ft.; sandstone, 2*d.* to 3*d.* Bottom canches cost about 20 per cent. more than top canches. These prices include stowing the stone

Driving in hard carboniferous limestone drift 30 sq. ft. in cross-section, cost about 60*s.* per

yard ; three men in three shifts can drive about 4 to 5 yards per week by hand. In one case with hand-drilling the cost was 55*s.* per yard, and rate of advance 4 yards per week, and with machine drilling the cost fell to 25*s.* and the rate of advance rose to 10 yards.

In metalliferous mines.—By hand.—A drift 5 ft. by 7 ft. in the clear, in rock of medium hardness, can be driven by hand at a rate of 30 to 40 feet per month by employing two ten-hour shifts per twenty-four hours. In soft rock as much as 100 ft. per month can be penetrated. The cost in moderate rock with labour at 12*s.* per shift will average about 2*l.* per foot, including timber and strap rails.

By machine.—A 5-ft. by 7½-ft. drift was run in Colorado, U.S.A., at the rate of 236 feet per month. This speed is above the average and was due to a well-trained crew (three shifts per day) working on a bonus system. Rock was granite, gneiss, and schist, very hard to drill and breaking badly. Labour, 16*s.* per shift. Cost, 2*l.* 14*s.* per foot.

At Cripple Creek, wages 13*s.* 6*d.* per eight-hour shift, ground moderately hard, 896 ft. of 5 ft. by 7 ft. drifts were run by machines, at a cost of 1*l.* 4*s.* per foot ; 1,229 ft. of 5 ft. by 7 ft. crosscuts were run at a cost of 1*l.* 9*s.* per foot.

At Park City, Utah, with miners' wages at 12*s.* per eight-hour shift, a timbered drift 7 ft. by 11 ft. was run in quartzite by means of 3½ inch air drill, 3 shifts per 24 hours, at rate of 4·75 ft. per day, at a cost of 2*l.* 4*s.* per foot of drift, or 7*s.* 1*d.* per ton of material broken. No hoisting.

At the same mine crosscuts 7 ft. by 7 ft. in the clear are run by air drills at a rate of 8 ft. per day at a cost of 2*l.* 15*s.* per foot or 15*s.* per ton of material broken.

The Chipeta Adit in Colorado, U.S.A., 7½ ft. by 7½ ft. in clear, was run in hard rock a distance of 1,712½ ft. in 152 days. The best monthly average was 342½. Two 3½ in. air drills were employed. The cost, including track and pipe, power, timber, labour and explosive, was 2*l.* 4*s.* per foot. The amount of powder (40 per cent.) consumed was 14½ lbs. per foot of tunnel. Wages 16*s.* per day.

In Western Australia the drifts vary in size from 5 ft. by 7½ ft. to 6 ft. by 7 ft., and the crosscuts from 5 ft. by 7 ft. to 8 ft. by 8 ft. In eleven of the principal mines the rate of driving and crosscutting varies from 25 ft. to 90 ft. per month, averaging 60 ft. Working costs range from 46*s.* to 103*s.* per foot, averaging 60*s.* The total costs of drives were from 3*l.* 6*s.* to 4*l.* 2*s.* per foot and crosscuts from 3*l.* 3*s.* to 3*l.* 14*s.* At the Braden Copper Mine, Chili, all development work in the nature of drifts, crosscuts and upraises with average section of 4·53 square metres are run at an average cost of 14*s.* per foot driven. This cost includes all labour (native Chilian), supplies, explosives, machinery, and tramming. No timber is used. The work is done under contract and rock is moderately hard and breaks well. Machine drills are used. The rate of progress is about 130 ft. per month or 13 ft. per month per man.

Timbering Drifts.

Props 3 ins. to 5 ins. diameter and crowntrees 5 × 2½ ins. are often used in colliery drifts ; in main roads balks of much larger size may be used.

Resistance to crushing of pit props in tons per square inch of small end :

Scandinavian white wood, 1½ ; Larch, 1½ ; Scotch Fir, 1¼ ; Oak, 1 ; Beech, 1⅜.

Prof. Hudson Beare gives the following :—

Scots Pine, 1·767 ; Spruce, 1·892 ; Larch, 1·871 ; Japanese Larch, 1·379 ; Finnish Red and White Wood, 1·784 tons per square inch of mean area of prop.

In main roads ferro-concrete props are coming into use : their crushing strength is about 1·3 tons per sq. in. Tests by W. A. Machin (*Trans. Nat. Assoc. Col. Man.*, xv., p. 155) gave 1·58 to 1·82 tons per sq. in. on Keedon props 6 ft. long, about 4½ ins. square.

Instead of balks, steel H girders are often used. The following are some of the usual sizes :—

Depth by width, in ins.	6 × 6	6 × 5	6 × 4	5 × 4	4½ × 4
Weight in lbs. per linear foot	31	27	24	22	18
Tons that will be carried in middle by beam 1 ft. long, supported at both ends	160	130	120	105	60

Drystone arching for roadway 6 to 7 ft. high and 3 ft. to 4 ft. 6 ins. wide in Alston district costs about 12*s.* 6*d.* per linear yard for labour. The cost of labour for ordinary arching ranges from 7*s.* to 10*s.* per linear yard. Concrete arching varies from 6*s.* to 10*s.* per cubic yard of concrete put in. Arches of steel H girders supporting galvanised sheets have been used successfully in big drifts.

A coating of magnesia cement on the timbers of mines is stated to be an economical and efficient assurance against fire, especially in the arid regions where timber becomes highly inflammable and is difficult to replace. It is elastic, adheres firmly to almost any surface, and is stable and durable.

A layer of cement put on by means of the 'cement gun' (p. 400) is sometimes used for covering timbers, also the sides and roofs of drifts, etc.

SHAFTS.

Modern shafts are generally either rectangular or circular in cross-section; the former are used in sinking upon narrow veins or seams, where the ground is not very heavy nor the amount of water excessive, or where good timber is cheap; under other conditions round shafts are preferred, but local custom also exercises much influence. Inclined shafts are practically always rectangular; elliptical shafts have been sunk in some places (Forest of Dean) but are now rarely used.

Rectangular Shafts.

Rectangular shafts for large mines may be up to 25 ft. long by 15 ft. wide in the clear. Exceptionally large shafts are used in Pennsylvania, e.g., No. 5 Wilkesbarre anthracite mines, 52 ft. by 12 ft., Exeter Red Ash, 46 ft. 2 ins. by 13 ft. 10 ins.

Round shafts, say from 8 ft. to 24 ft. diameter in the clear; a colliery shaft to wind 1,000 tons per day is usually 16 to 18 ft. diameter.

Rectangular shafts are mostly wood-lined; they are either cribbed or timbered with sets holding lagging in place. In Fifeshire shafts up to 30 ft. by 12 ft. are cribbed with 'barring' of 9 ins. by 3 ins. up to 6 ins. by 12 ins. The timber for a shaft 23 ft. by 8 ft., including buntons, etc., would amount to about 125 cubic feet, and would cost, including nails, wedges, etc., about 13*l.* 10*s.* per fathom. The cost of sinking (the ground is usually easy) and putting in the timber is about 30*l.* per fathom. In the iron-ore mines of Cumberland and Lancashire shafts about 10 ft. by 5 ft. are cribbed with 10 ins. × 5 ins. plank, the ends being half checked; the total cost including sinking, timbering, timber, stores, etc., is about 30*l.* per fathom, the ground being carboniferous limestone that requires blasting. Sets are made of squared timber 4 ins. × 6 ins. for a small shaft up to 9 ins. × 15 ins. for a very large one; sets are 3 ft. to 6 ft. apart, held together by hook bolts of 1¼ in. round iron with wing nuts.

Horned sets or bearer sets are put in about every 6 sets or so, depending on the nature of the ground; lagging is often 9 ins. × 3 ins. plank.

Round Shafts.

Round shafts are lined with brick or concrete in ordinary strata; special methods are adopted where shaft traverses water-bearing strata and the lining is required to keep back water. For shafts over 18 ft. in diameter ordinary brick may be used; for smaller shafts wedge bricks should be employed. Let f be the width of the inner face of the brick, b of the outer face, l the length of the brick and R the radius of the shaft. Then $b = \frac{(R + b)f}{R}$; if, as is often the case, $l = 2f$, this becomes $b = f + \frac{2f^2}{R}$. Instead of bricks, firebrick lumps 6 ins. × 8 ins. × 12 ins. to 8 ins. × 10 ins. × 15 ins. may be used. They should also be made wedge shaped in accordance with the above formula. A shaft 10 ft. in diameter lined one brick thick requires about 350 bricks laid in mortar, per foot of depth. The thickness of the lining depends on the nature of the ground and the diameter of the shaft.

Cost of Sinking.

Sinking in ordinary coal measures costs 1*l.* to 2*l.* per fathom for each foot in diameter of the shaft; to this must be added surface labour, fuel, etc., 30*l.* to 50*l.* per week. If more water than 100 gallons per minute is met with, these costs will increase rapidly. Walling, including the cost of the bricks, amounts to between 15*s.* and 30*s.* per cubic yard of brickwork. Walling a shaft 13 ft. in the clear, 15 ft. over all, cost about 15*l.* per fathom = 30*s.* per cubic yard; walling a shaft 22 ft. in the clear, 25 ft. over all, cost 24*l.* 5*s.* per fathom = 15*s.* 6*d.* per cubic yard. A walling curb costs about 10*l.* Sinking a shaft 12 ft. in the clear cost 24*l.* per fathom (sinkers and waiters-on 13*l.* 10*s.*; general labour 7*l.* 10*s.*; explosives and stores, 3*l.*). Sinking a shaft 13 ft. in the clear costs 23*l.* to 30*l.* for labour in ordinary strata, and 70*l.* to 100*l.* in basalt, per fathom.

Sinking two shafts at Hylton colliery in 1897–99 cost as follows per fathom :—

	Shaft 20 ft. in the clear.						Shaft 15 ft. in the clear.					
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
Labour—Sinkers (incl. explosives)	21	0	6				17	0	0			
Wallers	7	7	2				5	11	0			
Miscellaneous	8	7	4				2	16	0			
				36	15	0				25	7	0
Materials—Bricks	9	12	0				5	2	0			
Cement, lime, sand	4	16	0				2	11	0			
Walling cribs	2	6	0				2	0	0			
Miscellaneous	0	15	0				0	10	0			
				17	9	0				10	3	0
Total per fathom				54	4	0				35	10	0

Sinking three 20 ft. shafts at Horden, each 210 fathoms deep, against a flow of 9,000 gallons of water per minute, cost 350,000*l.* (*J. J. Prest.*)

The cost of sinking and tubbing a section of 22-ft. shaft at Blackhall with feeders of water from 300 to 2,885 gallons per minute was as follows :—

	£	s.	d.	
Underground labour	70	10	10	per linear yard.
Surface „	26	13	7	
Materials, coal and stores	87	2	1	
	£184	6	6	

The cost of sinking a 22-ft. shaft through limestone and tubbing it, against feeders of water averaging 3,000 gallons p.m., may be averaged at about 275*l.* per yard of depth.
(*J. J. Prest*, Tr. Inst. M. E. xlvii. p. 611.)

Shafts may be lined with cement, either by setting sheet iron cylinders and ramming concrete round these, lifting the cylinders when the cement has set, or by walling with thin blocks or slabs (about 2 ft. 6 ins. × 3 ft. 6 ins. × 5 ins.), and ramming cement behind this facing ring. The cost of an 18-in. monolithic lining in a 22-ft. finished shaft was made up as follows :—

	s.	d.	
Mixing concrete	1	0	per cub. yd.
Cement	4	2	„
Lining shaft with concrete	2	6	„
Coal and stores	0	9	„
Steel cylinders and other plant	1	4	„
Total	9	9	per cub. yd.

There were 28 cubic yards to the fathom, hence the cost per fathom was 13*l.* 13*s.* It took seven hours to complete the concreting of one fathom.
The cost of walling a similar pit with brickwork was 24*l.* 3*s.* 3*d.*
Lining a 22 ft. shaft at Blackhall with a monolithic cement concrete (6 : 1) lining cost per linear yard :—

	£	s.	d.
Labour in loading sand and gravel	1	18	6
Enginemen and attending mixer	0	4	1
Cement	3	13	6
Interest and depreciation on shuttering, etc.	0	19	0
Coal, stores, etc.	0	10	6
Labour in shaft	3	1	7
	£10	7	2

Lining with concrete blocks 3 ft. 6 ins. × 2 ft. 6 ins. × 5 ins. backed solid by ramming in concrete, all also 6 : 1, cost practically the same. The average cost of sinking and walling with 18 in. concrete was 26*l.* 1*s.* 8*d.* inclusive. Suitable bricks would have cost 45*s.* per 1,000, and at this price brickwork in cement would have cost 15*l.* per running yard. (*Loc. cit.*)

In a 14 ft. pit the total costs of labour for sinking and concreting came to 15*l.* 15*s.* per fathom. The cost of the concrete was about 21*s.*, and the labour of lining the shaft with it about 1*s.* 6*d.*, or altogether 22*s.* 6*d.* per cubic yard. There were 10½ cubic yards per fathom, so that the cost of the concrete lining amounted to 11*l.* 16*s.* per fathom ; with four men at the surface and four men in the pit, the concrete was put in at the rate of a fathom in six hours. At Karwin, Silesia, an 18 ft. shaft was lined with concrete put in from above downwards at the rate of a fathom in fourteen hours at a cost of 62*l.* per fathom complete ; the same shaft lined in the upper part with brickwork had previously cost 132*l.* per fathom. Ferro-concrete has been used in place of simple concrete. At Zweckel, near Gladbeck, a shaft was lined with ferro-concrete slabs backed with concrete, into which the iron framework of the slabs was continued, for 23*l.* per fathom. At Rheinelbe a shaft 20 ft. in diameter was lined with Monier ferro-concrete 11 ins. thick at a cost of 2*l.* 5*s.* 6*d.* per cubic metre of lining, or 30*l.* 12*s.* per fathom of shaft ; for a similar shaft at the Hansa colliery lined 9½ ins. thick the prices were 2*l.* 3*s* 6*d.* per cubic yard or 29*l.* 14*s.* per fathom.

Shaft Lining.

In heavily watered strata a lining has to be put in strong enough to resist the pressure of water. The thickness of such lining may be calculated as follows :—

Let R be the internal radius of the shaft, s the maximum admissible stress in the wall, p the pressure to be resisted, all to the same units, which are preferably inches and pounds, then :—

$$\text{Thickness of wall} = R\left(\sqrt{\frac{s}{s-2p}}-1\right)$$

(*Aldis*, N.E. Inst. M. E. xxxii. p. 201.)

The resistance to crushing of the various materials used in lining shafts is :—

Common brick	800 to 1,000 lbs. per square inch.
Fire brick	1,500 to 2,000 „ „ „
Sandstone	2,000 to 5,000 „ „ „
Concrete 1 : 3 : 6 to 1 : 1 : 3. Average	1,500 to 5,000 „ „ „
	3,000 „ „ „
Cast iron	90,000 to 120,000 „ „ „

Safe loads may be taken as $\frac{1}{10}$ of these; for best brick laid in 1 : 3 Portland cement up to 250 lbs.; for ferro-concrete up to 600 lbs. per sq. in.: for frozen sand fully saturated with water at −12° C. up to 340 lbs. per sq. in. (*Alby*, Bull. Soc. Ind. Min. 1895, p. 273.) L. Sauvestre has shown that frozen sand is highly plastic, and that its resistance to crushing increases by $28\frac{1}{2}$ lbs. per sq. in. for each drop of 1° C. (*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I, p. 5.)

The pressure to be resisted is usually taken merely as the head of water, namely (0·434 h) lbs. per sq. in., where h is the head expressed in feet. For quicksands Poetsch adopts a formula equivalent to $p = 1{\cdot}042\ h \tan^2\left(45° - \frac{\alpha}{2}\right)$, where α is the angle of repose of the sand; Poetsch gives $\alpha = 35°$ for fine quicksand, and 20° for coarse sand. These figures are used in calculating the thickness of the ice-wall required in the freezing method of sinking.

Many approximations are used for ordinary shaft linings :—

J. J. Atkinson : Thickness in inches $T = \frac{5{\cdot}2\ R\ h}{s - 0{\cdot}434\ h}$, or for cast iron $T = \frac{5{\cdot}2\ R\ h}{9{,}000 - 0{\cdot}434\ h}$.

Chaudron: for cast iron, $T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{600}$ where $h < 165$ ft. and $T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{600}$, where $h > 165$ ft. (here s is taken at only 7,200).

Riemer takes $s = 11{,}400$, and writes :—

$$T = 0{\cdot}8 + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h < 165,$$

$$\text{and } T = \frac{130}{h} + \frac{0{\cdot}434\ R\ h}{950} \text{ for } h > 165.$$

Cast-iron tubbing is always stiffened by ribs and flanges, and these should be taken into account (see *Morrow*, Trans. Inst. M.E. xxxiv. p. 100).

Coffering.

Coffering may be used for moderate pressures and shallow depths; costs range from 20*l.* 10*s.* per fathom (16-foot shaft) to 38*l.* per fathom (18-foot shaft), being considerably less than cost of cast-iron tubbing.

Tubbing.

Tubbing is put in either by English or German method: in the former, segments are 2 ft. to 3 ft. deep, flanges are external, not machined, and the joints are made with wood sheeting and wedges; in the latter, segments are 5 ft. to 6 ft. deep, flanges are internal, are machined, and the joints are made with lead sheeting and bolts. In both forms the tubbing is carried upon wedging curbs, followed usually by a foundation ring. In some few recent cases the wedging curb has been dispensed with, and the tubbing set direct upon a good bed.

Cost of Tubbing.

Cost of English tubbing varies with the price of pig iron, etc., from 5*l.* to 7*l.* 10*s.* per ton; putting in the tubbing costs 2*l.* to 2*l.* 10*s.* per ton of tubbing put in, or 5*l.* to 7*l.* per fathom of shaft. The following are the detailed costs of tubbing a 15 ft. shaft with 12 segments to the ring, 2 ft. deep, $\frac{3}{4}$ in. thick, each ring weighing 2 tons 10 cwt. :—

	£	s.	d.
Three rings, 7 tons 10 cwt. at 7*l.* 10*s.*	56	5	0
Sheeting, 213 ft. at 8*s.* per 100	0	17	0
Wedges, 3,500 at 10*s.* per 1,000	1	15	0
Labour putting in and wedging	6	0	0
Total	64	17	0
Cost per fathom, about	64	0	0

To the above must be added a due proportion of the wedging curb. The castings for the curb of a 15-ft. shaft cost 25*l.* to 35*l.*, sheeting and wedges 5*l.*, putting in and wedging 10*l.* to 15*l.* Dressing the curb seat may cost from 10*l.* to 40*l.* according to circumstances. About ten men are usually employed in the shaft in wedging tubbing, and they can wedge two to three rings per shift.

The cost of 'German' tubbing usually comes out a little less than English tubbing per fathom. The seams and joints are all machined, this costing 3*l.* 10*s.* to 4*l.* per ring; three shifts of four men can put in and bolt up four rings (20 to 24 ft.) per 24 hours.

The cost of 'German' tubbing in an 18-ft. shaft, the tubbing being 1 in. to 1½ in. thick, 12 segments to the ring 5 ft. deep, was as follows in this country :—

	£	*s.*	*d.*	
Cast-iron tubbing, 13 tons 4 cwt. at 7*l.* 10*s.* .	99	0	0	per fathom
Lead for sheeting and washers, 6 cwt. . .	6	0	0	
Bolts and nuts	3	5	0	
Labour	7	10	0	
Cost per fathom	115	15	0	

In the Minister Achenbach Colliery a shaft 17 ft. in diameter was tubbed with 18 rings of tubbing 8 ft. 2 ins. high, 1 in. to 1½ in. thick, each ring composed of 10 segments. The weights of material employed were :—

Tubbing . . .	192 tons 10 cwt.	Lead washers . . .	1 ton 2 cwt.
Lead strips . .	2 „ 8 „	Bolts, nuts and washers .	6 „ 3 „

Where the ground is weak and apt to run, suspended tubbing can be used to much advantage. This method was used at Astley Green (*Trans. Inst. M. E.* xxxix. p. 543), also at Hamsterley (*Trans. Inst. M. E.* xxxviii. p. 320); the latter shaft was 10 ft. in diameter and 35 ft. deep. The cost was :—

Materials, 627*l.* 2*s.* 10*d.*, labour, 141*l.* 0*s.* 3*d.*, equal to 83*l.* 16*s.* per fathom. The method is to be recommended for safety, speed and economy.

The above, which may be called ordinary methods of sinking, can only be used where a moderate influx of water has to be contended with; the greatest quantity ever dealt with by these means has been in the sinkings at Blackhall Rocks, where the Horden Colliery Company has sunk two shafts through the Magnesian Limestone in which 14,300 gallons per minute were being pumped from a depth of about 90 yards. Very much less than this is generally sufficient to cause special methods to be resorted to, 5,000 gallons per minute being generally considered prohibitive. The increase of cost due to a heavy flow of water in deep sinkings is well shown by a table of estimated costs of sinking in wet ground in Westphalia :—

COSTS OF SINKING SHAFTS 16 TO 17 FT. IN DIAMETER IN WESTPHALIA PER FATHOM.

To Depth of	Where the Average Flow of Water is	
	880 Gallons per Minute.	1,760 Gallons per Minute.
Fathoms.	£	£
27	458	548
55	566	750
82	686	960
110	804	1,170
137	914	1,316
164	1,006	1,554
219	1,188	1,920
273	1,316	2,286
328	1,554	2,652

(*L. Hoffman*, 'Glückauf,' xxxvii. p. 775.)

COST OF SHAFT SINKING IN GOLD MINES.

A shaft 4 ft. by 8 ft. in clear can be sunk in California, where wages are 14*s.* per shift, by hand drilling, at a cost of 4*l.* 10*s.* per foot. This includes labour, timbering, explosives and supplies. The hoisting done by a horse whim and no water to pump. The rate of progress is about one foot per day.

In Nevada a shaft 4 ft. by 8 ft. in clear was sunk 100 ft. in 31½ days by means of hand drilling. The cost per foot was 6*l.* 10*s.* Labour 16*s.* per shift.

Large Shafts.—In Western Australia shafts vary from 4 ft. by 10 ft. to 5½ ft. by 13½ ft. On eleven of the mines in the district the cost per foot of shaft is from 11*l.* to 16*l.*, and from 2*s.* 9*d.* to 5*s.* 6*d.* per cub. foot of material excavated. The average monthly advance was 34 ft. to 60 ft. with an average of 50 ft. Machine drills used on all above shafts.

In Utah, wages 12*s.*, a shaft 17 ft. by 65 ft. was sunk in ground of medium hardness at a cost of 12*l.* per foot driven or 1*l.* 16*s.* per ton of material broken. Machine drills used. Pumping from 300 ft. Rate of sinking 0·9 ft. per day.

On the Rand a shaft (Brakpan, Ltd.) 43 ft. by 9 ft. in the clear was sunk at a rate of 204 ft. per month. The working cost was 14*l.* 10*s.* per foot and the total cost 22*l.* 14*s.* per foot. Ground soft. Hand drilling employed.

The following are some of the Rand shafts and the cost per ton of material handled :—

Shaft.	Size.	Speed per Month.	Cost per Ton.	Method Employed.
			s. *d.*	
Rand Collieries . .	34 ft. by 9 ft.	120 ft.	10 9	Machine
Kleinfontein . .	34 ft. by 9 ft.	107 ft.	11 8	,,
Brakpan . . .	43 ft. by 9 ft.	124 ft.	8 11	Hand.
City Reef . . .	46 ft. by 9 ft.	125 ft. 6 ins.	9 2	,,
Hercules . . .	47 ft. by 9 ft.	119 ft.	8 5	,,
Wolhunter . . .	46 ft. by 9 ft.	95 ft.	10 6	,,

Winzing and Raising.

At Park City, Utah, winzes 11 ft. by 7·5 ft. in quartzite are sunk at a cost of 6*l.* per foot sunk, or 1*l.* 10*s.* per ton of material broken. The advance is about 1 ft. per day. In same mine raises, 17·5 ft. by 5·5 ft., are put up at a cost of 1*l.* 14*s.* per foot or 4*s.* per ton of material broken. The advance is at the rate of 3·3 ft. per day.

In Western Australia winzes are from 4 to 5 ft. in width and 6 to 8 ft. long. They are 50 ft. to 200 ft. deep and the average total cost per foot in eleven of the mines is 4*l.* 15*s.*

The rises in the same district extend from 25 ft. to 120 ft. in height, and are 4 ft. to 5 ft. wide and 6 ft. to 8 ft. long. The total cost on the average is 3*l.* 18*s.* 7*d.* per foot.

Special Methods of Sinking.

In hard, very wet ground :—

Kind-Chaudron : maximum diameter of shaft, 15 ft. ; greatest depth yet attained by it 1,335 ft. ; Nos. 1 and 2 pits Marsden Colliery (the first sunk in this country by this method) cost respectively 362*l.* 8*s.* and 293*l.* per fathom ; in the North of France shafts 8 to 12 ft. diameter to depth of 100 fathoms cost 80*l.* to 240*l.* per fathom, and the rate of sinking varied from 2 to 6 fathoms per month. In Germany it is estimated that to sink 55 fathoms by this process at a depth of about 300 fathoms would cost about 1,400*l.* per fathom for a shaft 14 ft. 6 ins. in diameter.

Poetsch Freezing Process.—Applicable both to fissured firm ground and to running ground. The brine used is a 25 per cent. solution of magnesium chloride cooled down to —20°C., its freezing point being about —35°C. The following table shows the pressures at which ammonia gas liquefies at different temperatures :—

Temperatures.		Pressures in Lbs. per Sq. In.
—20°C.	— 4°F.	27
—10°C.	+14°F.	41
0°C.	+32°F.	62
+10°C.	+50°F.	89
+20°C.	+68°F.	125

Shafts have been sunk to 130 fathoms by this method, the cost for shafts 13 ft. to 16 ft. in diameter ranging from about 150*l.* to 250*l.* per fathom. The cost of sinking two pits, 12 ft. and 16 ft. 6 ins. respectively in diameter, at Anzin, in 1895, to a depth of 50 fathoms, was as follows :—

	£ *s.* *d.*	£ *s.* *d.*
Cost of freezing plant		73 2 0
Cost of freezing operations		48 6 0
Cost of sinking and tubbing : labour .	32 16 0	
Cost of tubbing	66 10 0	
		99 6 0
Total cost per fathom		220 14 0

The cost of sinking a pair of 20 ft. shafts by freezing under ordinary conditions should be :—

	£
To a depth of 50 fathoms	17,500
„ „ 100 „	28,000
„ „ 200 „	50,000

(*W. W. Wilson*, Tr. Inst. M.E. xli. 353.)

Freezing an 18-ft. shaft at Monkwearmouth cost 230*l.* per fathom to a depth of 60 fathoms.

Cement injection has been used with success in several cases, first by M. Reumaux at Lens, by M. Deffieux at the Mine de Marles (1908), and by M. François in this country ; in the former case the cost was about the same as that of freezing. The François system consists in boring 10 to 20 holes within the shaft, the bottom being first, if necessary, sealed with a plug of cement concrete ; cement slurry is forced through these holes at pressures up to 500 lbs. per sq. in., so as to fill all fissures when sinking is resumed ; another section is then cemented, and so on. Cementation in ordinary ground will cost about 50*l.* per yard for a 20-ft. shaft. See paper by *T. Blandford*, Trans. Inst. M.E., liii. (1916–17), p. 22.

This system has been used in sinking a shaft 16 ft. in diameter at the Holditch Iron Mine, Chesterton, Staffs. The shaft is sunk through the water-bearing Keele strata to a depth of 632 ft., the upper bed giving off 30,000 gallons of water per hour. The total time occupied was 69 weeks, and the costs were 40*l.* 4*s.* 4*d.* for labour and 36*l.* 3*s.* 9*d.* for material per yard of finished shaft (1916–17), or together 76*l.* 8*s.* 1*d.* ; it is estimated that sinking with underhung tubbing would have cost 91*l.* 4*s.* 8*d.* The shaft was lined with reinforced concrete. Cement for injection of boreholes 350 tons 13 cwt., for the concrete walling 998 tons 6 cwt., and for the injection of the walling 50 tons 10 cwt. (*A. Hassam and T. T. Mawson*, Trans. Inst. M.E. lviii. p. 16.)

A deep sinking has been carried out by this process at Beeringen in 1920 ; a depth of 1,640 ft. of clay, quicksand, and water-bearing chalk was first sunk through in this way, and subsequently the process was applied to the more difficult task of passing through a bed of running sand 46 ft. thick, at a depth of 2,000 ft. under a pressure of 926 lbs. to the sq. in.

(*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I, p. 5.)

In porous sandstones M. François first injects separately solutions of silicate of soda and sulphate of alumina, and follows this up with cement. This process was used successfully at Hatfield Main.

In the sinking of No. 19 pit at Courrières in 1909, which was sunk by the freezing method difficulties were encountered in the upper part of the shaft owing to running water, and these were overcome by the injection of cement to a depth of 57 ft. ; over 1,000 tons of cement were used. (*Annales des Mines*, Ser. xi., vol. ix., 1920, Pt. I, p. 38.)

In running ground :—

Sheet piling can be used for relatively shallow sinking, near the surface. At Bowburn Colliery, co. Durham, 6 fathoms of wet sand were driven through by wooden piles in 1906 at a cost of 26*l.* per fathom for timber and 34*l.* 10*s.* for labour. Interlocking steel piling (p. 499) of joists of various forms has also been used.

The dropshaft method is employed in various forms, sometimes by weighting a cutting shoe and curb, on which an iron or brickwork cylinder is built up, or more usually by building a brick or concrete pressure block against which work hydraulic rams that force down tubbing of cast iron, or in exceptionally difficult cases of cast steel. The former method (forcing down a shoe by dead-weight) was found much superior to forcing a shoe down by jacks in sinking a shaft 14 ft. by 8 ft. through 70 ft. of loose strata at Des Moines, Iowa (*Trans. Amer. Inst. Min. Eng.*, vol. lv., p. 232). The following table shows probable costs for shafts of normal size in ordinary running ground (Hoffman) :—

For depth.	Cost per fathom sunk.	For depth.	Cost per fathom sunk.
	£		£
From 15 fathoms to 27 fathoms .	320	From 82 fathoms to 110 fathoms .	1,280
„ 27 „ to 55 „ .	732	„ 110 „ to 137 „ .	1,554
„ 55 „ to 82 „ .	1,006	„ 137 „ to 165 „ .	1,830

The *Honigmann* system has been used in a few cases down to depths of 70 fathoms on the Continent ; the shaft is bored out by a dredge-borer, the walls being kept up by internal hydrostatic pressure, and the shaft is lined with tubbing composed of rings of channel iron riveted together and subsequently lined with concrete.

LIST OF DEEP SHAFTS IN THE WORLD (1912).

Mine and Shaft.	Locality.	Depth, Ft.	Mineral Wrought.

Coal Cutters.

In hand kirving, the average height of a kirving is 13½ ins. in front and 1⅜ in. at back, by a depth of 3 ft., giving a volume of 1·9 cub. ft. of coal kirved out per linear foot of coal face (equal to 16 per cent. on a 4 ft. seam). In a 6-hour shift a hewer in ordinary coal will kirve a bord 5 yds. wide to a depth of 1 yd. or about 7½ sq. ft. per hour of shift. A man will kirve about 9 sq. ft. per hour's actual hewing time after the jud has been nicked in a bord; in a wall he can kirve about three-quarters as much as in a bord, and in longwall work he can kirve one and a-half times as much as in average narrow work. Allowing for his other work a hewer in Northumberland and Durham averages about 38 sq. ft. of kirving per shift.

Machine cutting gives up to about 65 per cent. more output per man employed; on the average about 10 per cent. more round coal is made by machine than by hand, and a greater output of coal can be obtained from a given seam.

Coal-cutting machines for longwall work are chain-cutters, disc-cutters and bar-cutters, the former being applicable in seams where the coal is fairly hard, the cleat not too well marked, and the roof tolerably good. The disc machine makes a kirving 3½ ins. to 5½ ins. deep, the bar machine a kirving tapering from 7½ ins. in front to about 3½ ins. at the back. Machines may be air-driven, using compressed air at 35 to 65 lbs. per sq. in. at the machine, or electrically driven (direct, alternating or tri-phase) at voltages of 250 to 450. The power consumption varies between wide limits, between 12 and 30 h.p. Compressed air coal-cutters cost 250*l.* to 300*l.*, electrically-driven coal-cutters 350*l.* to 450*l.*; a complete plant for a pit using 10 machines would cost about 10,000*l.* with the former and 11,000*l.* with the latter form. The area undercut per hour varies from 45 to 140 sq. ft., 90 sq. ft. being about an average, per hour of running time. An average shift's work may be taken as about 500 sq. ft. Air consumption 1,000 to 3,000 cub. ft. free air per sq. yd. undercut.

According to Mr. Mavor (*Trans. Inst. Min. Eng.*, vol. l., 641) a good compressor will compress 6 cub. ft. free air per minute to 60 lbs. per sq. in. per b.h.p. Tests showed coal cutters to use 413 to 1,146 cub. ft. free air per minute, or 620 to 3,642 cub. ft. per sq. yd., at mean pressure of 32 lbs. per sq. in. at machine and 68 lbs. at compressor.

Costs.

Mr. Mavor gives average costs as follows:—

	Per shift. s. d.	Per ton. d.
Interest 5 per cent. on 450*l.*	1 9	0·21
Depreciation 12½ per cent.	4 4	0·52
Labour	33 0	4·00
Air Power	23 0	2·77
Picks, Oil, etc.	8 4	1·00
Repairs	12 10	1·50
Total	83 3	10·00

In narrow work percussive coal-cutters are mostly used, also chain machines. Percussive cutters supported on a fixed column are mostly in favour; they work with compressed air at 50 to 70 lbs. per sq. in., the air consumption being 100 to 300 cub. ft. of compressed air per sq. yd. undercut; different makes run at 300 to 600 blows per minute. A machine has undercut 30 sq. ft. per hour, but their usual performance is 80 to 100 sq. ft. per shift. Percussive cutters of the Ingersoll type on wheels are also used; these machines weigh 5 to 7½ cwts.; they use air at 70 to 90 lbs. pressure per sq. in., with an average consumption of 100 cub. ft. of free air per min., and strike about 150 blows per min.; they will undercut 15 to 50 sq. ft. per hour of running time, or 50 to 200 sq. ft. per shift.

Chain heading machines may be driven electrically or by compressed air, using 10 to 20 h.p.; these machines can undercut about 50 sq. ft. per hour, but it is rare that 200 sq. ft. can be kirved per shift.

The Stanley header cuts roads circular in cross-section through coal, using 15 to 40 i.h.p. A road 5½ ft. in diameter can be driven through coal at the rate of 10 ft. per 8-hour shift or six times as fast as handwork, the cost being sometimes rather less, sometimes rather more than hand labour, namely 2*s*. 6*d*. to 4*s*. per foot of advance, everything included, as against 2*s*. 8*d*. per hand.

In connection with coal-cutters in thin seams face conveyors are much used for bringing the coal to the gateways. There are three main types:—(1) troughs containing scraper-chains, either endless or reciprocating, (2) endless belts, (3) shallow trucks or trays hauled by ropes. The Blackett conveyor is an example of the first type; the chain is 6-inch pitch and rests in a trough 12 ins. wide at the bottom, 18 ins. at the top, 9 ins. deep, made in 6 ft. lengths; it will carry up to 30 tons per hour along faces 100 yds. in length. Most of the other forms have lower capacities, and are suited to smaller outputs or shorter faces. In one case where hand-cutting and filling cost 2*s*. 4*d*. per ton (face costs only), machine cutting and hand filling cost about 1*s*. 8*d*. per ton (1*s*. 4*d*. face costs, plus 4*d*. for power, repairs, stores, depreciation), and machine cutting and conveyor filling 1*s*. 3*d*. (9*d*. and 6*d*. respectively). In most cases a considerable saving is shown, especially in stonework, but the amount varies considerably according to circumstances.

Wages and general costs may be taken as 120 per cent. higher in 1920 than all those here given.

The 'Hardiax' Coal Cutter.

(The Hardy Patent Pick Co., Ltd., Sheffield.)

This cutter consists essentially of a long stroke air-drill, which is fixed in position and held up to its work by means of a solid drawn steel tube provided with powerful jack-screw and toothed head and foot. The machine is seated in a cone cup forming part of a hinged clamp attached loosely to the column. This clamp carries a worm, the teeth of which mesh with those

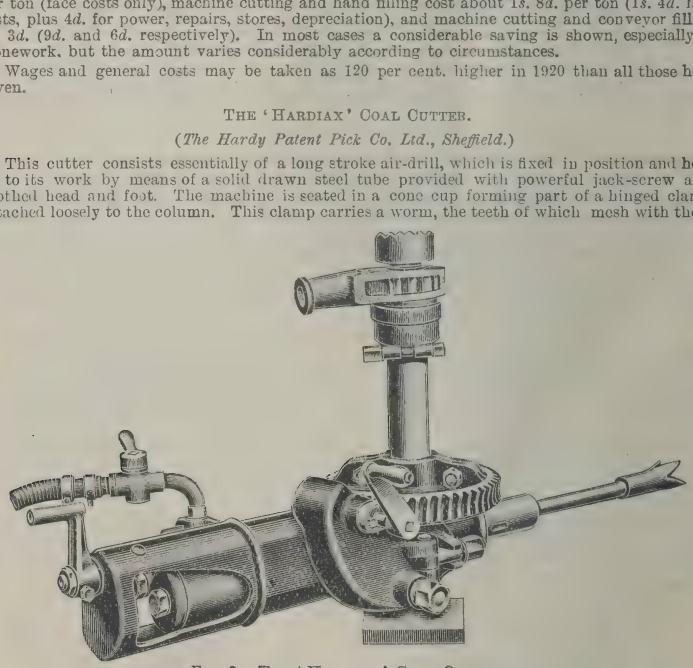

Fig. 3.—The 'Hardiax' Coal Cutter.

of a worm-wheel bolted rigidly on the column. By turning the worm-handle the coal cutter is caused to move around the column, whilst the forward movement into the coal is obtained by the feed screw controlled by a handle at the back of the machine. Figs. 3 and 4 give side views of the complete apparatus fixed for work at floor level. The machine may be fixed to cut at any height between floor and roof. The friction between the hinged clamp

carrying the machine and the column itself is regulated to a nicety, relieving the worm of the shock of the recoil without in any way impeding the free movement of the machine right and left across the coal face.

When air is admitted to the machine the rapid and powerful blows quickly cut away the coal or other material, whilst the machine is swung right and left by the worm gear and fed forward as is necessary. An arc-shaped and continuous channel or undercut is thus speedily made, increasing in depth and width as each successive length of cutter-bar is inserted in the piston of the machine.

As soon as the desired depth is attained at the centre of the working place the operator commences to play in gradually decreasing sweeps upon the right- and left-hand sides of the arc-shaped cut, using longer cutter-bars where necessary, until the undercut or channel is of uniform depth at every point, and square at the sides and corners. When pillars are taken out, or in working on a longwall face, the successive cuts break into one another, giving a continuous undercut of perfectly even depth the whole length of the coal face, whatever this may be. The cut may be any width up to, say, 20 ft. from one setting of the column. The depth of the cut

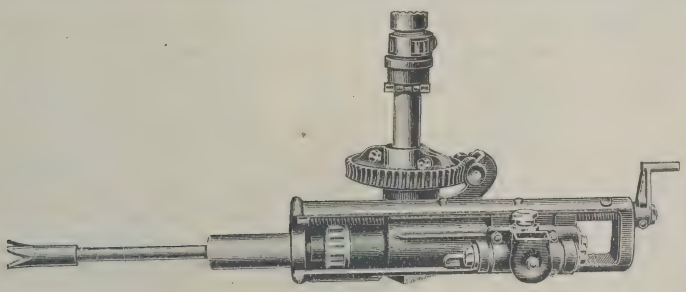

FIG. 4.—THE 'HARDIAX' COAL CUTTER.

is generally from 4 ft. to 6 ft. and the height $3\frac{1}{4}$ ins. to $4\frac{1}{2}$ ins. The diameter of the cutters is varied to suit different requirements.

The special constructional features of the machine are: (1) Crucible Cast Steel Cylinder, (2) Crucible Cast Steel Valve Box, (3) Crucible Cast Steel Cradle, (4) Crucible Cast Steel Gears, (5) Valve and Main Piston Hardened and Ground.

The machine is provided with a new patented piston valve action, giving great cutting power with low air consumption.

The air-pressure should, preferably, be from 40 to 60 lbs. per sq. in. or more, at which pressure the air consumption is approximately 120 cub. ft. free air per minute.

Pillars.

Shaft Pillars.—The 'draw' in ordinary horizontal strata is between 5° and 8° to the vertical; in inclined strata with workings in the direction of the dip the draw increases roughly in proportion to the dip until in strata dipping 18° to 24° the 'draw' is about at right angles to the strata (O'Donahue). In Staffordshire draws between 8° 45′ and 11° 10′ were observed in strata dipping 1 in 24 (W. Hay, *Trans. Inst. Min. Eng.*, xxxvi. p. 427).

In Westphalia the angle of draw in the coal measures is found to be 15° on both rise and dip sides, when the dip of the seam $< 5°$; for dips greater than 15°, it is 15° on the rise side and increases up to 55° on the dip side, reaching this value with seams dipping 35°. In the overlying clay beds, the draw is uniformly about 20°. Depth of subsidence $= K \cdot T \cdot \cos \alpha$, where T is the thickness of the seam, α is its inclination, and K a coefficient, which is 0·8 when the goaf is not stowed at all; with well-stowed goaf K = 0·4 when α is 0°–10°, 0·3 when α is 10°–35°, 0·25 when $\alpha = 35°$.

There are very many formulas for the size of shaft pillars; the following seems to be as satisfactory as any:—

Let D be the depth of the seam, T its thickness R the radius of the shaft pillar, all in feet, then,

$$R = (0{\cdot}19 + 0{\cdot}01\ T)\ D.$$

This formula applies to horizontal beams.

If the seam be inclined at a dip of 1 in x, then the distance from the centre of the shaft to the edge of the pillar on the rise side should be $R + \frac{2}{3}\left(\frac{x}{1+x^2}\right)D$, and on the dip side $R - \frac{1}{3}\left(\frac{x}{1+x^2}\right)D$; a circular pillar may therefore be set out with radius $R + \frac{1}{6}\left(\frac{x}{1+x^2}\right)D$; the distance of the centre of the circle being $\frac{1}{2}\left(\frac{x}{1+x^2}\right)D$ to the rise side of the centre of the shaft.

If a rectangular pillar is preferred, the square circumscribing the circle as above determined may be taken.

Bord and Pillar working.—Pillars may be square but are mostly rectangular, sides varying from 30 to 80 yds.; 30 yds. by 40 yds. to 40 yds. by 60 yds. are usual sizes. Some engineers give areas proportional to depth; for seams 100 to 200 yds. from surface, pillars about 30 by 40 yds.; 200 yds. to 300 yds., 35 by 50 yds.; 300 to 400 yds., 40 by 60 yds.

The Coal Conservation Committee of the Ministry of Reconstruction recommends the following proportions:—

Depth from Surface.	Area of Pillar.
< 100 yds.	300 sq. yds.
100–200 ,,	500 ,,
200–300 ,,	800 ,,
300–400 ,,	1100 ,,
400–500 ,,	1400 ,,
500–600 ,,	1700 ,,

In *panel working* a rib 30 to 60 yds. wide is left between the districts, the latter being usually 20 to 50 acres in area. In American mines the width of rib is often determined by the expression T (5 + 0·01 D), where T is the thickness of the seam and D its depth below surface.

Welsh Stall working.—Single stalls are usually about 12 yds. wide with 12-yd. ribs, double stalls up to 18 yds. wide with 24-yd. ribs between them. In America the following method is sometimes used:—

Width of pillar $W = \frac{T\,D}{100}$, and width of stall $= \frac{D}{W}$, where T is the thickness of seam and D its depth, both in feet.

Subsidences.

According to O'Donahue, the working out of a coal seam 4 ft. thick will cause a subsidence of the surface of 3 ft. if the seam be not more than 200 yds. deep, and from 12 to 18 ins. if it be 800 yds deep. It was shown that at Monkwearmouth, working two seams 6 ft. and 4 ft. thick respectively at depths of 1,725 ft. and 1,600 ft., caused surface subsidences of 6 ft. to 6ft. 9 ins.

In Staffordshire working a 5 ft. seam at a depth of 1,626 ft. caused surface subsidences varying from 1·34 to 1·74 ft.; these reached their maximum in about 29 months.

Working Costs in Getting Coal.

Working brokens is usually about 25 per cent. cheaper than working in the whole coal. Typical examples of basis yard prices in whole coal to show relative costs:

	2 yds. wide.	3 yds. wide.
Winning headways	1*s.* 6*d.*	1*s.* 2*d.* per yard.
Holing walls	1*s.* 5*d.*	1*s.* 2*d.* ,,
Bords	1*s.* 1*d.*	0*s.* 11*d.* ,,

In brokens.—Jenkins, 3 yds. wide, 8*d.*; half-pillar walls, 3 yds. wide, 10*d.*; skirtings, 3 yds. wide, 6*d.* per yard.

Allowances for wet places ½*d.* to 1*d.* per ton; for band up to 2½ ins. thick, ½*d.* per ton, with ½*d.* additional for every further inch in thickness of band. For taking down ramble 3 ins. to 6 ins. thick, 1*d.* additional per ton, with 1*d.* additional for every further 3 ins.

Longwall.—Hewing price is usually about halfway between whole and broken tonnage price. An average hewing price may be taken to be 1*s.* 6*d.* per ton for a 3-ft. seam, the price rising or falling 1*d.* per ton for every 1 in. decrease or increase in thickness of seam.

All these prices are subject to local percentage increases.

PERCENTAGES OF ITEMS IN PRICE OF COAL AT PIT'S MOUTH.

Year	1913.	1901.	1866–96.	1700–50.
	Per cent.	Per cent.	Per cent.	Per cent.

Owners' profits	1 5	1 2	3 9·12†
Pithead value	10 1½	27 3½	35 8·20

Hydraulic Stowage.—The best built packwall will compress down to 70 per cent. of its original height, whilst hydraulically stowed material will not compress to less than 90 per cent. Material used in Germany varies from sand to washery residues about 1¼ in. cube. Cast-iron pipes 6 to 8 ins. diameter are used, often lined with hard cast-iron or porcelain. A cast-iron tube 7½ ins. in diameter ¾ in. thick will transport about 1,300,000 cub. yds. of stowage material before it is worn out. The average cost of tubes is 3*d.* per cub. yd. stowed. Average rate of stowage 25 to 30 cub. yds. per hour; some mines stow over 4,000 cub. yds. per day. The total cost of hydraulic stowage varies from 4*d.* to 1*s.* 6*d.* per ton of coals got—average appears to be under 1*s.*

Colliery Consumption.—According to the Coal Conservation Committee of the Ministry of Reconstruction, 1918, colliery consumption in Britain varies from 5 to 9·43 per cent., averaging 6·8 per cent., of which 6·2 per cent. is produced by the direct combustion of coal under boilers, and the balance from outside sources.

Mining in Veins and Masses.

Methods employed are:

Underhand stoping.
Overhand stoping.
Combined underhand and overhand stoping.
Rill stoping.
Shrinkage stoping or magazine mining.

Irregular deposits, wide veins, thick and steeply inclined seams may be worked by the following methods:—

Lost pillars.
Vertical slices.
Horizontal slices taken transversely.
Horizontal slices taken longitudinally.
Top slicing.
Caving.
Magazine mining.
Square set timbering.

Of these, overhand stoping is the most general, underhand stoping being only used in quite special cases, as when there is only a small quantity of payground to be taken below a given level. Overhand stoping can be used for veins of medium width, say up to 10 ft. on the average. Rill stoping is mainly employed in Western Australia. Magazine mining suits veins of any width, provided that they are not too flat, that the walls are fairly good, and that the whole of the veinstuff has to be extracted. Slicing and caving are used in wide veins and irregular masses when the value of the mineral is not great and where cheap methods of working are

* *Third Report of Fuel Economy Committee, Brit. Assoc.*, 1920.
† Of this amount 2*s.* 1·3*d.* goes to the colliery owners.

essential; it is largely used in the hæmatite mines of Cumberland and Lancashire. Square sets can only be used where the mineral is valuable and where large timber is abundant and cheap.

The costs of stoping vary within very wide limits, and may be illustrated by typical examples.

In Western Australia, with the contract system in force, a miner breaks 7·31 tons of ore per shift. Formerly a miner on day's pay broke only 4 tons per shift.

In eleven of the West Australian mines treating from 9,000 to 22,000 tons of ore per month with veins varying from 4–20 ft. to 6–60 ft. in width the stoping costs per ton of ore ranges from 6*s.* 4*d.* to 9*s.*, averaging 7*s.* This includes breaking ore, filling stopes, trucking, hoisting, etc. On the Rand it costs from 3*s.* 6*d.* to 5*s.* 6*d.* to stope a ton of milling ore in stopes 40 to 60 inches in height. To these figures must be added cost of compressed air, rock drill maintenance, steel sharpening and administration underground. The first three factors amount roughly to about 1*s.* per ton, while the last would not exceed 1*d.* In some Rand mines one man can break 12 tons per shift per machine, and uses one case (50 lbs.) of blasting gelatine to break 3·5 fathoms of ground. At other mines only 7 tons are broken per man and one case of explosives is used to break 2·5 fathoms.

In Nevada at the Silver Peak Mines each miner breaks 8·6 tons of rock per shift. The total stoping cost is 5*s.* per ton. Miners here receive 16*s.* per shift.

At the Braden Copper Mines native miners break 12 tons of ore per man per day with rock drills in moderately hard rock. The total cost per ton of ore broken, including superintendence and general charges, is given as 1*s.* 9*d.*

In Utah in quartzite with a stoping width of 10 ft., square set system, small air drill, the stoping cost per ton varies from 6*s.* to 8*s.*

At Douglas Island, Alaska, the ore is a mineralised igneous rock of fair hardness, the workable portions of which vary upwards from 30 ft. in width. Wages 12*s.* Machine used 3¾ inches piston diameter. The following figures are taken over a year's working :—

COST OF BREAKING GROUND AT DOUGLAS ISLAND, ALASKA.

General Details.	Ready Bullion.	700 Ft.	Mexican.	Treadwell.
Average number of drills used	10·12	11·586	14·917	39·13
Tons ore broken	151,460	238,696	232,875	830,551
Tons waste broken	2,756	—	10,509	1,670
Tons broken, total	154,216	238,696	243,384	832,221
Total footage drilled	241,679	269,990	362,519	803,542

Cost per foot of hole drilled	1 10	1 8	1 9	2 0
Cost per ton of ground broken	2 10	11	2 8	2 1
Total cost of mining, including development	4 0	4 9	4 10	4 6
Percentage of total mining cost	2 9	8	2 2	1 11

In the Granite Gold Mine, B.C., on a vein of hard quartz from 8 inches to 5 feet wide dipping 35° to 50°, the stoping costs per ton are as follows :—

	s.	d.
Stoping by hand	14	0
„ by ¾-in. piston drills	11	6
„ by 2¼-in. „ „	8	4
„ by 2-in. hammer drills	6	4

Mining costs at the Elko Prince Mine, Nevada, in 1917, stoping a 2 ft. 6 in. vertical vein of hard quartz by magazine mining, using hammer drills with 1⅛ in. cruciform steel, were as follows :—

	Per Ton of Ore
	$
Timbering, including ore shoots	0·5588
Blacksmith	0·0995
Stoping	0·8083
Tramming	0·2822
Hoisting	0·1956
Compressed air	0·1288
Explosives, detonators and fuse	0·4452
Repairs	0·0486
Drill steel	0·0570
Supervision, taxes, assaying, etc.	0·4987
Cost per ton	$3·1227 = 12s.

(*Bull. Amer. Inst. Min. Eng.*, Aug. 1918.)

For detailed costs of mining operations in various West Australian mines, see pages 2182-2185.

Drilling.

Ordinarily two men can drill double-handed 25 to 33 ft. of 1-inch holes per day in limestone, 4 to 8 ft. in granite. With double hammers 10 ft. of 2-inch holes can be drilled in medium rock.

On the Rand generally one white man and five Kaffirs run two air-drills ; in some cases one white man and seven Kaffirs run three drills. Eight 6-ft. holes is considered a shift's work for two machines ; these holes break on an average two fathoms of ground. The cost is as follows :—

	£	s.	d.	
One white man	1	5	0	
Five Kaffirs		15	0	
Powder for two machines		16	0	
Maintenance		4	0	
Total	3	0	0	per fathom.

In Chili, with native labour, contracts are let on the basis of the number of holes drilled. The rock is moderately hard.

By hand.—1,008 man-days, by single hand work, drilled 13,855 ft. at a cost of 4·1*d.* per foot. Average amount drilled per man per day 13·8 ft.

By machine.—The actual cost of drilling for one month was as follows :—164 man-days (9 hours) with two ¾-in. air drills, drilled 5,082 ft. at a cost of 1·01*d.* per foot. Average amount drilled per man-day, 31 ft.

HAULAGE.

Rails.

Mine rails weigh 10 to 40 lbs. per yard. The following table shows the least weight that should be used for the given loads (weight of 1 loaded tub) and low speeds :—

Loads, in cwts.	7	10	15	20	25	30
Weight of rails per yard, lbs.	10	12	15	18	20	22
Gauge of track, in inches	15–18	15–18	16–20	18–22	20–26	20–30

For speeds above 5 miles per hour heavier rails are to be preferred.
Weight of 1 mile of single track in tons = 1·571 × weight of rail in lbs. per yard.
Sleepers 2 ft. 6 ins. to 3 ft. 6 ins., usually 3 ft. apart.

Sleepers 8 ins. to 12 ins. longer than gauge of track, 3–4 ins. deep, 6 ins. wide. A pair of fishplates and 4 bolts for 18 lb. rails, weigh 4–8 lbs., usually 5 lbs. ; 100 dogspikes for same weigh about 14 lbs. Weight of fishplates, bolts and spikes is approximately 1 cwt. per ton of rails.

To bend rails to any curve, let l be length of rail, r radius of curve, both in feet, a the middle ordinate in the centre of the curve, b the quarter ordinate, midway between a and the end of the rail (both a and b in inches) :—

Then

$$a = 1{\cdot}56\,\frac{l^2}{r}, \qquad b = 1{\cdot}17\,\frac{l^2}{r}.$$

Width of track ¼ in. to ⅜ in. greater than gauge of wheels.

Additional width round curves :—

Gauge of track	15	18	24	30 ins.
Additional width	¼	½	⅝	¾ in.

In going round a curve with locomotive traction or on self-acting inclines, the outer rail must be elevated ; with rope haulage the inner rail may have to be elevated.

Let e = super-elevation in feet, s = gauge of track in feet, v = velocity in feet per second, r = radius of curve in feet.

For outer rail $e = \dfrac{v^2\,s}{32{\cdot}2\,r}$.

For inner rail, the elevation depends upon whether the centrifugal force due to the velocity of running is greater or less than the inward pull on the drawbar ; it will be greater at high speeds, say, exceeding 20 miles per hour, and less at low speeds ; under ordinary conditions at 15 miles per hour the elevation of the inner rail should be about 2 ins. The above formulas are based on certain theoretical considerations, which never quite obtain in practice, and therefore give the maximum super-elevation.

Colliery Tubs.

Colliery tubs carry from 7 to 40 cwts. of coals.

In North country average dimensions of tub body are about 3 ft. 9 ins. × 3 ft. × 2 ft. ; wheels 11 ins. diameter, axles 1¾ in. diameter.

Such a tub if made of wood will carry about 7½ cwts. of coals, if of iron about 9 cwts. ; wooden tubs weigh about 55 per cent. of the load, iron tubs about 50 per cent. Tubs cost approximately 15*s.* to 17*s.* per cwt., and their upkeep is about 10*s.* per annum.

Coefficient of friction of tubs on well-kept mine road (level) 1 per cent. to 3 per cent., average say 1·5 per cent. ; with tubs badly greased on roads in bad repair may be two to three times as much. Coefficient of sliding friction (wheel spragged) is from 12 to 20 per cent. ; if m be coefficient of rolling friction, m' of sliding friction, the coefficient of friction with :—

1 wheel spragged $= \dfrac{3m + m'}{4}$; 2 wheels spragged $= \dfrac{m + m'}{2}$; 3 wheels spragged $= \dfrac{m + 3m'}{4}$.

Additional friction in going round curve of radius r, where the gauge of the track $= s$ (both in feet) is $\dfrac{s}{2r}\,m'$.

Tractive effort with 18-in. wheels on good level track, 40-in. gauge, at 5 to 6 m.p.h. = 24·3 lbs. per ton with plain bearings, 12·8 lbs. with roller bearings. (*Trans. Amer. Inst. Min. Eng.*, vol. lv. p. 29.)

With ' wheel ' greasers the consumption of grease averages about ¼ lb. per tub per diem for ordinary collieries.

On the average a putter can put 10 tons of coal over a distance of 200 yards (level) in an 8-hour shift.

A horse does its best work when travelling at a speed in feet per second $= \dfrac{1}{4}\,h$, where h is the height of the horse in hands, and exerting a pull in lbs. of $\dfrac{60\,c^2}{h}$, where c is the circumference of the horse's chest in feet (*Baron*). Average pull is about 1¼ cwt.

Maximum gradient for hand putting, 17 per cent.

Maximum gradient for horse haulage, 12 per cent.

Gradient at which resistance of full tub downhill equals that of empty tub uphill :—Let W be the weight of a loaded tub, w that of an empty one, θ the inclination of the road, μ the coefficient of friction :—$\tan\theta = \mu\,\dfrac{(W - w)}{W + w}$ (usually $\tan\theta = 0{\cdot}005$ about).

Work done in hauling a tub of weight W up or down an incline of length $l = l\,(\mu\,W\cos\theta \pm W\sin\theta)$

Self-acting Incline.

Self-acting Incline.—Let the sets consist of n tubs each of weight w lbs., and capable of carrying W lbs. of mineral. Let the slope of the incline, assumed uniform, be $\alpha°$. Let l be the length of the rope (= length of incline) in feet, c its weight in lbs. per foot.

Let the rope be supported on rollers, the weight of which per foot of rope (= weight of one roller divided by the distance in feet between the centres of successive rollers) is r lbs. Let D be the diameter of the rollers, d of the spindle. Let μ be the coefficient of friction of the tub on rails (usually say about 0·015) and μ_1 the coefficient of friction of lubricated bearings (say 0·005 to 0·008). Let F be the frictional resistance of the drum at the head of the incline, including that of the rope coiled upon it—a figure that is always relatively small and may often be neglected. Then at any distance x feet from the starting point the full set is just able to move down the incline when :—

$$\tan \alpha = \frac{\mu n (\mathrm{W} + 2w) + \mu_1 l (c + r) \frac{d}{\mathrm{D}} + \mathrm{F}}{n\mathrm{W} - c(l - 2x)}$$

By putting $x = 0$ the above expression gives the angle at which the set will just start from the top of the incline.

The time occupied in descending a distance x will be :—

$$t \text{ seconds} = \sqrt{\frac{2x[n(\mathrm{W} + 2w) + (c + r) l + \mathrm{M}]}{g\left[\sin \alpha (nw - cl) - \cos \alpha \left(l (c + r) \frac{d}{\mathrm{D}} \mu_1 + n(\mathrm{W} + 2w) \mu \right) - \mathrm{F}\right]}},$$

and the velocity in feet per second v attained after travelling a distance of x feet will be :—

$$v = \sqrt{\frac{2gx\left[\sin \alpha (nw - cl) - \cos \alpha \left(l (c + r) \frac{d}{\mathrm{D}} \mu_1 + n (\mathrm{W} + 2w) \mu \right) - \mathrm{F}\right]}{n (\mathrm{W} + 2w) + (c + r) l + \mathrm{M}}},$$

where M is the weight of the drum and its fittings and g the acceleration due to gravity.

All the above expressions are approximations, but are accurate enough for practical purposes.

When the slope is not uniform, the calculations become more complicated. If H be the total vertical fall of the incline and L its horizontal length, it is usually sufficient, with the low gradients prevailing in collieries, to use the above formulas, putting $\alpha = \tan^{-1} \frac{\mathrm{H}}{\mathrm{L}}$. As the denominator of the expression given above for tan α increases with x, it is obvious that the incline should, whenever possible, flatten going downwards, or be concave, though not so much so as to cause the rope to rise too high above the rails. The exact shape of the curve is not very important; it may with advantage be a parabola, which may be set out by making the height h at any point distant y ft. horizontally from the foot of the incline $= \frac{y^2 \mathrm{H}}{\mathrm{L}^2}$. The rope will then follow the curve whenever the relations are such that $\mathrm{H} = \frac{cl^2}{4\mathrm{T}}$, where T is the tension of the rope.

Main-and-Tail Rope Haulage.

Main-and-Tail Rope Haulage.—Loaded tubs in sets up to 40 are hauled outbye by motors (steam-engines, compressed-air engines or electro-motors) at speeds up to 20 miles per hour, whilst the empty tubs are hauled inbye by means of the tail rope. The size of the engine depends upon the pull to be exercised when one set (nearly always the full set) is in its least favourable position. Let T be the tension in the rope in such position, made up of the weight of the set plus rope × sine of angle of inclination of the roadway, the friction of the set and of both ropes on the rollers and the pull required to accelerate the moving parts. Let C be the diameter of the steam cylinders in inches, one of which is alone assumed to be effective at the start, let K C be the stroke of the engine in feet (K is usually $\frac{1}{2}$ to $\frac{2}{3}$), S the steam pressure in lbs. per sq. in., z the ratio of the number of teeth in the spur wheel on the drum shaft to the number of teeth in the pinion on the crankshaft, D the diameter of the drum in feet, then

$$\mathrm{C} = \sqrt[3]{\frac{4\mathrm{DT}}{\pi \mathrm{SK}z}}$$

For any portion of the trip except the start (i.e. with set already in motion), both cylinders are effective, and the value as found above must be divided by $\sqrt{2}$.

These engines are usually small and run at a piston speed of 500 to 800 ft. per min.

Endless Chain and Endless Rope.

Endless Chain and Endless Rope.—Endless chain is now rarely used except on steep gradients and for short distances; it is less reliable than endless rope on long roads, requires more power and is rather more expensive to work, but admits of rather higher speeds; it may work up to 6 miles per hour; endless rope rarely exceeds 4 miles.

The following calculations apply to both methods unless otherwise stated :—

If Q be the quantity of mineral in tons to be transported per hour, W the weight in lbs. carried by one tub, V the speed of haulage in miles per hour, f the distance apart of the tub in feet, then

$$f = 2{\cdot}36 \frac{V \cdot W}{Q}.$$

Endless chain is always over-tub haulage, endless rope may be over-tub or under-tub. In over-tub haulage the tubs must be so near together that the rope does not touch the ground between them. Let T be the least tension in the hauling rope or chain (i.e. between the two tubs nearest the driving pulley on the empty side), let c be the weight of the rope or chain per foot, h the height of the tub, then the distance f_1 of the tubs apart is given by

$$f_1 = \sqrt{\frac{8hT}{c}}$$

If f is greater than f_1 empty tubs must be run on the full side.

The pull to be exerted by the engine driving the haulage is

$$\mu\Big[n\ (2w + W) + 2c \cdot l\Big] \cos \alpha \pm W \sin \alpha,$$

using the same notation as above, n being the number of tubs on any one side of the rope at any time, so that $n = \frac{l}{f}$; the lower sign is used when the gradient is with the full tubs, the upper one when against it. If this expression has the $-$ sign, the arrangement is self-acting.

Cost of Haulage.

Cost of underground locomotive haulage in Westphalia in 1912, including redemption of capital outlay :—

Petrol	2·51	pence	per ton-mile.
Continuous current (with conductors)	2·16	,,	,,
Alternating ,, ,, ,,	1·58	,,	,,
Continuous ,, (with accumulators)	2·65	,,	,,
Compressed air	2·12	,,	,,

So-called fireless locomotives using superheated water, and oil or coke-fired steam locomotives are also used.

Steam Mine Locomotives.

Mine locomotives (steam) usually have cylinders 5 ins. to 8 ins. diameter, stroke 1½ diameters, driving wheels 20 ins. to 30 ins. diameter, wheel base 3 ft. to 6 ft., weight complete 4 to 15 tons, drawbar pull ⅛ to ¼ weight. Boiler pressure 120 to 150 lbs. Speed with full load in miles per hour ⅓ diameter of driving wheel in inches.

When D is piston diameter, *l* length of stroke, *d* diameter of driving wheel, all in inches, and P the gauge pressure of the boiler in lbs. per sq. in., then drawbar pull = approximately $\frac{0{\cdot}85\ P\ l\ D^2}{d}$

Compressed Air Locomotives.

Compressed air locomotives are worked at 600 to 1,000 lbs. per sq. in. gauge pressure, charged from underground receivers, in which air is compressed to 50 to 100 lbs. higher. Pressure is reduced to about 150 lbs. per sq. in. before the air enters the cylinders. The formula above given for drawbar pull may be used, P being the pressure of air as supplied to the cylinders, writing 0·95 instead of 0·85.

Electric Locomotives.

Electric locomotives.—With trolley wires may use either continuous or alternating current. Weight complete is usually 7 to 15 tons, and drawbar pull ⅛ to ⅛, usually ⅛ of weight. 75 per cent. to 80 per cent. of electric input is converted into tractive effort, 1 per cent. to 2 per cent. of which will move the locomotive on the level, the remainder being available for hauling load. Speed on the level usually 6 to 8 miles per hour.

With accumulators, small locomotives are used in places for secondary haulage. The B.E.V. locomotive has a battery capacity of 193 amps. at 65 volts, and can pull or push two 3-ton trucks on the level. Their use is on the increase in this country.

WINDING

In sinking pits, the excavated material is usually hoisted in steel buckets or hoppits, usually unguided, and usually single. The load is thus wholly unbalanced, geared engines are often used, and the winding speed is slow. Such buckets have capacities of 25 to 50 cubic feet, say 30 to 60 cwts., the weight of the bucket being from ½ to ⅔ of its load. For ordinary colliery work cages carrying two to twelve tubs are used, always in pairs running on wooden, rail or rope guides ; in the Pennsylvania anthracite mines large skips are sometimes used instead of cages.

Skips are largely used instead of cages in metalliferous mines ; when the mineral has to be crushed the fact that the skip breaks the mineral up more than does the cage is no drawback. Self-dumping skips are used on large mines, whilst underground bins and loading stations at the shaft enable the skips to be filled very quickly. Skips usually hold from 20 to 100 cubic feet, say up to about 5 tons of rock ; they are made of ¼ in. to ⅜ in. steel plate.

In some Illinois collieries, where the coal is to be crushed afterwards, skips about 6 ft. × 6 ft. × 12 ft. 6 ins., holding about 12 tons of coal, are used ; the speed of winding is up to 1,600 ft. per min. ; the average power consumption is 0·485 kw. hour per ton of coal ; up to 1,000 tons of coal has been hoisted per hour from a depth of 200 yards.

On the Continent the total load lifted is about : cage 30 per cent., tubs 20 per cent., coals 50 per cent. In Great Britain the cage usually weighs 35 to 45 per cent. of the total load, or approximately as much as the useful load of coals lifted. It is carried by bridle chains, usually six in number. Their factor of safety should be at least 10, and the size of the chains may be calculated thus :

Let *d* be the diameter of the chain in eighths of an inch, and W the safe working load in tons, then $d = \sqrt{10W}$.

Slack adds greatly to strain on rope; according to numerous experiments, if the pull required to lift a given cage with rope taut be taken as 1, it requires a pull equal 1·5 to 1·7 with 3 ins. of slack, to 2–2·25 with 6 ins., 2·25 to 2·5 with 9 ins., and up to a pull of 3 with 12 ins.

The velocity of winding varies from 15 to 75 ft. per second; a rule given by O'Donahue is: allow a speed of 20 ft. per second for shafts up to 200 yards in depth, and add 5 ft. per second for every additional 100 yards.

Wooden guides are usually 3 ins. × 4 ins. to 4 ins. × 6 ins.; rail guides 50 to 70 lbs. per yard. Rope guides made of single strand of 7 to 15 wires each $\frac{1}{8}$ to $\frac{1}{4}$ in. diameter, stretched by weight of $1\frac{1}{2}$ to 5 tons; weight is often calculated at 1 ton for every 250 yards depth of shaft. The friction on the guides is but small; it usually amounts to about 0·025 of the total load on the rope with wooden or rail guides and 0·02 of the load with wire rope guides.

Size of Winding Engine.

To calculate the size of the winding engine the conditions of the wind must be known or assumed. The diameter of the cylinders must be such that (*a*) one cylinder is capable of starting the unbalanced load, and (*b*) that the two cylinders taking steam on the full stroke shall be capable of accelerating the total load to be set in motion.

If w be the weight of a cage and fittings with the empty tubs, W the weight of minerals lifted per wind, h the depth of the shaft in feet, c the weight of the rope in lbs. per foot, v the velocity in feet per second up to which the load is to be accelerated during a lift of f feet; let P be the steam pressure in lbs. per sq. in., d the diameter of the piston in ins., S the length of the stroke in feet, D the diameter of the drum in feet, M the weight of drum, pulleys, etc., and allowing 20 per cent. to cover the friction in the shaft, of the pulleys, drum, and engine, etc., then to fulfil condition (*a*)

$$d = \sqrt{\frac{\mathrm{D}\,(\mathrm{W} + ch)}{0{\cdot}589\ \mathrm{P.S.}}}.$$

To fulfil condition (*b*)

$$d = \sqrt{\frac{4\,\mathrm{D}\left[\left(\mathrm{W} + c\,(h - f)\right)f + (\mathrm{W} + 2w + 1{\cdot}5\,ch + 0{\cdot}5\,\mathrm{M})\,\frac{v^2}{2g}\right]}{3\ .\ \mathrm{P}.f.\mathrm{S}.}}$$

The larger value of d as found by (*a*) or (*b*) should be adopted.

This formula only applies to the ordinary form of winding engine with the drum carried direct on the crankshaft and the two cranks at right angles.

Usually $\mathrm{S} = \frac{d}{6}$ and the length of the connecting rod is $2\frac{1}{2} - 3\,\mathrm{S}$. Average piston speed 500 ft. per min., varying from 300 to 800 ft.

If the load is partially or wholly balanced, the formula must be correspondingly modified.

Once the load has been accelerated to its full speed, the steam admission is reduced by means of valve gears with variable cut-offs, and during the last part of the wind work must be absorbed so as to retard the load and bring it to rest gradually; powerful brakes are employed or the engine may be reversed as well as the brakes applied.

The weight of the rope may be balanced by:—

1. Chain counterbalance, suitable for slow winding only, and adding enormously to the weight to be accelerated.

2. Balance rope beneath the cages; this adds to the weight to be accelerated, but the chief objection is the additional strain put upon the cappings of the winding ropes. Some engineers use a balance rope heavier than the winding rope, so as to overbalance the latter, to help the engine to accelerate the load at start and to aid in retardation at the finish of the wind.

3. The conical or scroll drum. The ascending load is attached to the end of the rope which is at the small end of the drum, and the descending load to the end at the large end. Using the same notation as before, but calling r the mean radius of the drum, r_s the smaller radius, rd the

larger, Q_a the resistance due to the ascending load and Q_d the force derived from the descending load, and n the total number of revolutions of the drum during the wind :—

$$r = \frac{r_a + r_d}{2} = \frac{h}{2\pi n}$$

$$r_a = r\left(1 - \frac{hc}{Q_a + Q_d + hc}\right); \qquad r_d = r\left(1 + \frac{hc}{Q_a + Q_d + hc}\right);$$

$$\frac{r_a}{r_d} = \frac{Q_a + Q_d}{Q_a + Q_d + 2hc}$$

If δ be the diameter of the rope the width of the drum will be approximately $1{\cdot}5\ n\delta$.

Cylindro-conical drums, giving partial counterbalance (where most needed) are often used.

Flat ropes wound on a reel are equivalent to a spiral drum; they will counterbalance in the three main positions where

$$r_d - r_a = nt \text{ and } r = \sqrt{\frac{Q + Q_d + hc}{4\pi c}}\, t,$$

where t is the thickness of the flat rope.

The time of banking varies considerably; it may be averaged at about 10 to 15 seconds for one deck and 25 to 45 seconds for double decks. Up to 3,000 tons may be wound in 10 hours, but 2,000 tons is not often exceeded.

The consumption of coal in winding engines varies from 0·5 to 1·5 per cent. of the weight of coals wound. Steam consumption 50 to 100 lbs. per shaft h.p. hour.

The cost of a winding engine and boilers erected varies from about 3,500*l.* to about 10,000*l.*

The cost of winding, exclusive of interest and depreciation on the winding plant, varies from about 3*s.* to 10*s.* 6*d.* per 100 tons wound.

Electric Winding Plants.

Electric winding plants are coming increasingly into favour; according to Mr. Mountain (*Trans. Inst. M. E.* xxxi., p. 329) the first cost of electric winders is considerably in excess of steam winders, so that interest and depreciation of the plant form serious items in the working costs. Some of the large geared electric winders in use on the Rand raise a 3-ton load from a depth of 2,500 ft., taking 2,000 e.h.p. An electric winder at a Durham pit raises 63 cwts. of coal per wind from 1,350 ft., uses 3-phase induction motor, 700 h.p., 2,900 volts; motor runs at 230 r.p.m., geared 5·45 to 1; cylindro-conical drum 10·20 ft. diam., weighing 45¾ tons; overall efficiency 51 per cent.

A winder in a South Wales pit uses 2,000 volts alternating, lifts 55 cwts. from 600 ft., uses 174 kw. per wind; drum cylindro-conical, 8 ft. to 13 ft.; overall efficiency, 48·25 per cent.

Electric Winders on Witwatersrand.

Name.	Depth in ft.	Tons (2,000 lbs.) per hour.	Weight of Mineral.	Weight of Skip.	Maximum Rope Speed.	Drum Diameter.	Winding Rope Diameter.	Tail Rope Diameter.	H.P.	System.

City Deep . .	3,210	157·5	9,000	8,000	3,500	11	$1\frac{9}{16}$	$1\frac{9}{16}$	1,600	A.C.
Village Deep . .	4,200	152·0	10,600	7,000	3,500	11	$1\frac{9}{16}$	$1\frac{3}{8}$	1,600	A.C.
Brakpan . . .	3,800	180·0	10,000	6,000	3,500	11	$1\frac{3}{8}$	$1\frac{1}{4}$	1,450	Ward-Leonard
Village Deep, Turf Shaft	4,093	150·0	10,000	7,000	3,500	12	$1\frac{1}{2}$	—	1,600	A.C.

The last-named winder (Whiting hoist) shows an overall efficiency of 77 per cent.

(*J. F. Perry*, Trans. Nat. Assoc. Col. Man., xv. p. 299.)

Headgears.

Headgears.—Steel-framed headgears usually range from ⅝ to 1 ton per foot of height, and cost erected 12*l.* to 18*l.* per ton; headgears composed of angles and joists only, not lattice girders, weigh ⅝ to ⅝ ton per foot of height. Wooden headgears weigh about ½ ton per foot of height and cost 10*l.* to 12*l.* per ton. The size of the main legs of timber headgears is given approximately by the expression $A = 0{\cdot}03\ H^2\sqrt{W}$, where W is the total working load on the winding ropes in tons, H the height in feet of the headgear from the ground to the pulley centres, and A the area of the cross-section of the main leg; the area of the backstay = 0·64 A. (*R. Boyle*, Scott. Inst. Min. Stud. 1908.)

Pulleys.

Pulleys.—Usually 10 to 20 ft. in diameter, mostly of the same diameter as the drum. Pillow blocks may be carried on strong springs to diminish shock at starting.

If W be the weight of a pulley in cwts. and d its diameter in ft., $W = 9{\cdot}2\,(d-8)$ approximately for large colliery headgear pulleys. $W = \frac{d^2}{4}$ is a useful approximation, but is too low for pulleys under 6 ft. in diameter.

The angle of lead from the drum to the head gear pulleys should not exceed 2° on either side of the centre line; the horizontal distance between the drum and pulley centres should not exceed 150 ft., otherwise the rope is apt to surge.

The first Koepe winder, supported directly over the shaft, thus dispensing with the usual headgear and pulleys, to be erected in this country, is in operation at Plenmeller Colliery, Northumberland. The Koepe driving pulley is 11 ft. 6 ins. in diameter, driven through single reduction gearing at 200 r.p.m. by a 240 h.p., d.c. motor, fitted with Ward-Leonard control. Current is supplied by a 200 kw., 350 volt generator direct coupled to a 3-phase 50 cycle 600 volt induction motor running at 730 r.p.m. The depth of the shaft is 815 ft., and single deck cages taking 3 tubs holding altogether 48 cwts. of coal are used. The whole of the hoisting machinery is contained in a two-storied steel-framed house with corrugated iron sides and roof mounted on a tall lattice-girder framework. An overall efficiency of 60 per cent. is attained. (*Trans. Inst. Min. Eng.*, lv. p. 170.)

On the Rand, hoisting with skips costs 8*d.* to 1*s.* per ton from depth of about 1,000 ft.

ROPES FOR HAULING AND WINDING.

Weight in lbs. of rope of circumference C inches per yard :—

Of ordinary wire rope with hemp core	=	0·47 to 0·48 C^2.
„ „ „ „ „ wire „	=	0·54 to 0·56 C^2.
„ locked coil rope	=	0·76 C^2.
„ all steel guide ropes	=	0·64 to 0·65 C^2.
„ hemp ropes	=	0·18 to 0·20 C^2.
„ coir „	=	0·12 C^2.
„ aloes „	=	0·10 C^2.

The number of wires of diameter d in a wire rope of diameter D is approximately $0{\cdot}75\ \frac{D^2}{d^2}$.

The breaking load of a rope of circumference C inches in tons is approximately $\kappa\ C^2$, where $\kappa = 0{\cdot}2$ to 0·3 for ordinary hemp, up to 0·6 for best hemp, 0·4 for aloes fibre, 1·5 for charcoal iron, 1·75 for mild steel, 2·0 for best patent steel, 2·5 for best plough steel, 3·0 for special improved plough steel, and 4·0 for extra special improved plough steel.

The British Association of Wire Rope Manufacturers has adopted the following distinctive nomenclature for the steel wire ordinarily used in rope manufacture :—

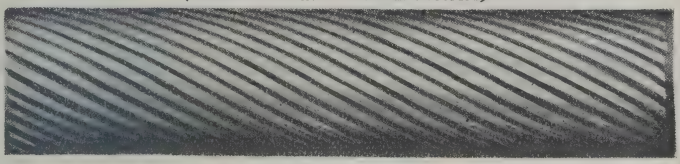
Description.	*Breaking Strain.*
Best patent steel wire	80 to 90 tons per sq. in.
Special improved patent steel wire	90 to 100 „ „
Best plough steel wire	100 to 110 „ „
Special improved plough steel wire	110 to 120 „ „
Extra special improved plough steel wire	above 120 „ „

Mild steel used for special purposes has a breaking strength of 25 to 80 tons per sq. in.

For wire ropes of 6 strands of 7 wires deduct 5% off sum of strength of wires.
„ 6 „ 12 „ „ 10% „ „ „ „
„ 6 „ 30 „ „ 15% „ „ „ „
For locked coil ropes deduct . . . 5% „ „ „ „

MEMBERS OF THE NATIONAL UNION OF MANUFACTURERS INCORPORATED

PREVENTION OF CORROSION IN LOCKED COIL ROPES.



F B I
MEMBER OF THE FEDERATION OF BRITISH INDUSTRIES

NOTE:—Users of Locked Coil Ropes—and we as manufacturers—have in the past long felt the urgent need for some more certain protection against the risks and dangers resulting from insidious deterioration of Locked Coil Ropes caused by internal corrosion, than that afforded by internal application of even the best of dressings during manufacture. The risk is present alike in Winding Shafts of Mines, due to bad water, steam or vapour, or in Aerial Ropes where the inaccessibility of standing Ropes on long spans renders any efficient operation of rope dressing almost impracticable.

It will therefore be of particular interest to all users of this type of rope to learn that we have, after much experimental work, now introduced a process by which we are in a position to offer a Locked Coil Wire Rope in which each separate wire is coated with a heavy layer of metallic covering, thus providing valuable protection against corrosion, and at the same time ensuring accuracy of section and perfect locking.

We have pleasure in introducing this type of rope to your notice, under the title of:—

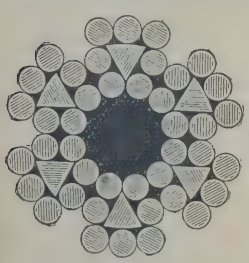
Wire ropes should never be bent round a drum or pulley whose diameter $<150D$ or $1500d$; in Belgium diameters of pulleys $>750d$ for flat ropes or $>1000d$ for round ropes are allowed.

The maximum bending stress in pounds per square inch produced by bending a rope round a pulley of diameter Δ is theoretically $E\frac{d}{\Delta}$, where E is the modulus of elasticity of the wire used; it ranges from 10,000,000 to 30,000,000 lbs. Owing to the strain not acting directly at right angles to the cross-section of the whole rope, it is found in practice that the mean stress is more correctly represented by the expression $\frac{3}{8}E\frac{d}{\Delta}$. According to R. W. Chapman (*Proc. Austr. Inst. Min. Eng.*, vol. iii., No. 3, April 1908), if a is the angle of pitch of the wires in a strand and b of the strands in a rope, the bending stress is $E\frac{d}{\Delta}\cos^2 a, \cos^2 b$.

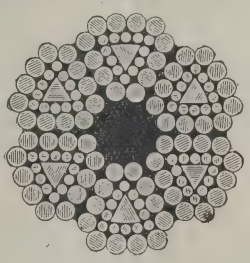
If s be the mean bending stress as above, T the breaking strength in lbs. per sq. in., m the factor of safety (ratio of total breaking load to total working load), W the total load to be carried, and A the total cross-section of steel in the rope, $A = \frac{mW}{T-s}$.

For ordinary winding ropes $A = 0{\cdot}6\ D^2$ approximately.
Factor of safety for haulages 5 to 6, for winding ropes 8 to 10.
Coefficients of friction of wire rope :—



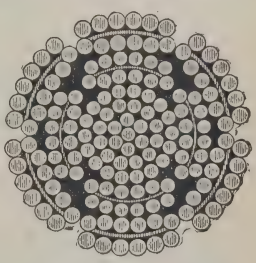
Dry rope on a grooved iron drum . .	0·120	Greased rope on a wood filled sheave	0·140
Wet " " " " . .	0·085	Dry rope on rubber or leather filling .	0·495
Greased " " " . .	0·070	Wet " " " " .	0·400
Dry rope on a wood filled sheave . .	0·235	Greased " " " .	0·205
Wet " " " " . .	0·170		

According to G. Raw (*Trans. Inst. Min. Eng.*, lv., p. 180) the coefficient of friction of a slightly oiled flattened strand rope upon an elm-filled sheave, fibres on end, is between 0·3 and 0·35.



The resistance to bending of a rope under tension T lbs. round a pulley of radius r ft. $= 1{\cdot}26 + 0{\cdot}002276\frac{T}{r}$ (*Weisbach*). The maximum admissible stress in a medium wire rope may be taken as averaging 5,000 times the weight of 1 foot of the rope.

Flattened Strand Ropes.



Flattened strand ropes are constructed of strands each of which has a flattened surface exposed for wear throughout its entire length, so that the wear due to friction in working over pulleys is distributed over a larger number of wires than is the case with ordinary round stranded

Flexible Crane Rope
(Non-rotating).

ropes. In the latter the wear is very severe on the crown wires of each strand, which are, consequently, considerably reduced in sectional area before any appreciable wear has taken place in the adjoining wires. The smooth surface of flattened strand ropes materially reduces wear and tear on drums and pulleys; owing to the wear being so light on the ropes, it is not necessary to have so large a margin between the working load and the breaking strain as in ropes of ordinary make. Being more compact, they contain a larger metallic area than ordinary ropes, and therefore a flattened strand rope is of smaller size than an ordinary rope of equal breaking

strain, and is not so liable to be forced out of shape by the crushing stress it has to sustain. When required, flattened strand ropes are made non-spinning for winding and sinking purposes. They are very suitable as balance ropes, as, being absolutely dead, they can be used with or without pulleys in the sump.

Flattened strand haulage ropes splice more effectively than ordinary ropes, as the core is slightly smaller than the strands, and there is consequently less risk of the splice drawing. This construction is of special utility in ropes used for power transmission purposes, aerial ropeways, etc., where an efficient splice is essential. The greater surface of flattened strand ropes increases the holding power of grips or clips used in haulage work. For use on cranes and lifts, these smaller ropes possess special advantages, as the construction gives greater strength than the ordinary make without increase in size or loss of flexibility. Non-rotating ropes of special formation are in great demand for crane work, particularly for cranes used in the erection of large buildings, and on quays and shipping wharves, as any tendency of the rope to spin is entirely obviated.

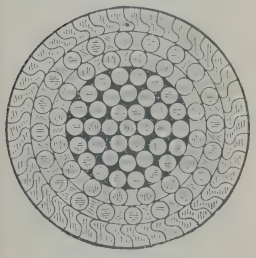
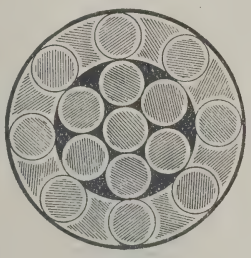
NOTE.—The figures given above are calculated on flattened strand ropes, having six strands with hemp main core, see No. 49, p. 2123.

(*John & Edwin Wright Ltd., Birmingham.*)



Locked Coil Ropes.

Locked coil ropes are in many cases advantageous where heavy loads have to be raised from great depths. Strength for strength, they are of less diameter than ordinary ropes, and consequently admit of corresponding reduction in width of drum, thus minimising lateral friction on drums and pulleys. They are absolutely free from any tendency to rotate, and are therefore of special utility in sinking operations and for winding in shafts where there is not much clearance, as the possibility of collision between the cages is obviated. Frictional wear on guides is also very much reduced by the use of locked coil ropes in winding. They are of longer duration than any other form of rope, as owing to their smooth surface the external wear is evenly distributed over the periphery of the rope, and internal friction, which is so marked a feature of ordinary ropes, is reduced to a minimum. In the event of any wire being broken in use, it is held in position and does not, as in an ordinary rope, unravel and lay across the adjacent wires, causing other fractures in working over drums and pulleys. The tendency to internal corrosion is less in locked coil ropes than in any other type of rope, as during the process of manufacture the successive annular layers of wires of which the ropes are composed are coated with a special



rust and acid proof lubricant, which cannot be worn off during work owing to the protection afforded by the interlocking wires of the outer cover. In consequence of the wear on these ropes being so light, they may be worked with a lower margin of safety than is the case with ordinary ropes, as with the latter, in estimating factor of safety required, provision has to be made for the rapid wear which takes place.

As guide ropes, the advantages of the locked coil construction may be readily understood when it is borne in mind that, in the event of a rod breaking in the ordinary twisted guide rope, it would strand out from the rope, and be caught by the cage gland with disastrous results; in a locked coil rope the broken rod would be securely held in position.

Locked coil ropes are eminently desirable as standing ropes for aerial ropeways, as their smooth surface affords very easy running for the wheels of the carrier; consequently less haulage power is required and wear and tear considerably reduced.

Steel Wire Ropes for Oil-well Drilling.

(Allan, Whyte & Co., Ltd., Rutherglen, Glasgow.)

Wire ropes are largely employed in drilling oil-wells, particularly where the American system of drilling is in use, which is known as the Californian Cable Rig. This system uses a drilling line for manipulating the tools, a casing line for manipulating the casing, and a sand line for cleaning out the wells. The two former are generally 6 × 19 construction, and the latter 6 × 7.

The Russian or Galician system employs jointed rods in place of drilling lines, but wire ropes are used for cleaning out the wells and for manipulating the casing and the string of tools. The sand, pump, or bailing lines are usually 6 × 7 construction, and the other ropes, which run up to $1\frac{1}{2}$ ins. diameter, are 6 × 19, 6 × 24, or 6 × 30.

Oil-well drilling, being exceptionally severe, calls for ropes of high quality.

Galvanized ropes are sometimes advisable on account of the corrosive action of the water in the wells.

It is a matter of general practice to have the drilling ropes left-hand lay.

Electrical Cables for Collieries.

PUMPS AND PUMPING.

Cornish pumps from 4 ft. to 12 ft. stroke, 6 ins. to 30 ins. diameter, 12 to 16 strokes per min.; piston speeds vary from 60 to 120 ft. per min. A rule sometimes adopted is that speed in feet per second $= \sqrt{l}$, where l is the length of stroke in feet. Ram pumps work at speeds of 100 to 200 ft. per minute.

If n be number of complete strokes (i.e. up and down strokes) per min., and d the diameter of the ram or bucket, the theoretical discharge G in gallons per min. is given by $G=0{\cdot}034d^2\,n.l.$ The actual discharge is less than this by the slip, which ranges from 3 per cent. to 30 per cent.

* Printed and published by H.M. Stationery Office. Price 1*s.* net; 1*s.* 2*d.* post free.

in extreme cases. In practice it is usually between 10 per cent. and 15 per cent. It must be deducted from the theoretical discharge to get the actual discharge. Maximum velocity of water in rising main 200 to 300 ft. per min., rarely exceeds 100 ft. in small pumps; maximum velocity in windbore, 40 ft. per min.

Pressure at bottom of rising main = pressure due to static head + pressure required to overcome resistance of pipe.

If v be the velocity of discharge in feet per second, H the vertical head in feet, L the length in feet of the pipe, D its diameter in inches, and P the total pressure at bottom of rising main, then,

$$P = 0{\cdot}341\,D^2\left(H + 0{\cdot}024\left(\frac{L}{12D}\right)^4\frac{v^2}{2g}\right)$$

The pressure in the steam cylinder must be capable of overcoming this pressure, allowing for the mechanical efficiency of the engine (say 0·66).

The content of a pipe in gallons of water = $0{\cdot}034\,D^2L$.

The thickness of a pipe can be calculated thus :—

Thickness in inches = 0·000125 P.D. + 0·5.

Thickness of pump-barrel = $0{\cdot}5 + \frac{P.D.}{2{,}000}$, where P is pressure in lbs. per sq. in.

Weight of pipe in lbs. = $2{\cdot}5\,L\,(D^2 - d^2)$, where D and d are external and internal diameters. The flange = weight of 1 ft. of pipe.

Horse-power in the water lifted = $\frac{g\,H}{3{,}300}$, where g is the actual delivery in gallons per min.

The 'duty' of a Cornish pumping engine is the number of millions of pounds of water lifted one foot high by the consumption of 112 lbs. of coal (before 1856 of one bushel = 94 lbs., and in America of 100 lbs. of coal) under the boilers. To convert duty into lbs. of coal burnt per h.p. in the water, divide 222 by the duty. It is always theoretical discharge that is taken in calculating duty. Cornish engines have worked with as little as 1·5 lb. coal per h.p.; 2·5 to 3 lbs. is a usual figure.

For double-acting pumps the formula for discharge previously given becomes

$$G = 0{\cdot}068\,d^2\,n.l.$$

If A be the area of the piston, n number of strokes per minute, S length of stroke, b the height of the water barometer, l the length of the windbore, a its area, h the vertical height of the suction lift, g the acceleration of gravity,

$$a > 0{\cdot}0055\,\frac{A n^2 S l}{g(b-h)}$$ for single-acting pumps, and $> 0{\cdot}00275\,\frac{A n^2 S l}{g(b-h)}$ for double-acting pumps,

or the piston will rise faster than the water can follow it, and hammering will result.

The air-vessel should have a volume = 4 times that of barrel for single-acting, and 1·6 times for double-acting pumps. (*Weisbach.*)

Centrifugal Pumps.

Let u be peripheral velocity of impeller in ft. per sec.

- r radius of the impeller in feet.
- n number of revolutions per second.
- d depth of openings in impeller in feet.
- i number of impellers in series.
- h height of total lift in feet.

$u = 2\,n\,\pi\,r$. Velocity of radial water discharge from impeller = K u, where K is a coefficient between 0·1 and 0·3, averaging 0·2. Quantity of water discharged per second = $K\,u\,2\,\pi\,r\,d = 4\,K\,n\,\pi^2\,r^2\,d$ cub. ft. $h = c\,i\,\frac{u^2}{2g}$, where c is a coefficient that varies considerably, but is mostly between 0·75 and 1.

Mechanical efficiency (m) is between 0·5 and 0·8, usually about 0·7.

Hence h.p. required $= \frac{8\ K\ c\ \pi^4\ n^3\ r^4\ i\ d}{8{\cdot}8\ m\ g}$, or taking average values h.p. = about $\frac{2}{3}\ n^3\ r^4\ i\ d$.

Direct coupled motor-driven centrifugal pumps to pump 1,500 gallons p.m. to a height of 1,000 ft. have been found to have an overall efficiency of 71·6 per cent.; electrically driven ram pumps would have a similar efficiency of 80 per cent. (*Prest & Leggat.*)

(See also PUMPS, page 1135.)

VENTILATION.

Mine Gases and Ventilation.

Normal air contains 79 vols. nitrogen, 21 vols. oxygen, carbonic acid 0·06 to 0·11 per cent. With 17·0 vols. of oxygen a candle is extinguished, but breathing is still possible; with 15·2 vols. of oxygen breathing becomes more difficult; with 10 vols. of oxygen, very difficult; and with 5 or 6 vols. practically impossible. Prussian rule for volume of air in mines is 70 cubic feet per min. per man underground, reckoning each horse as four men; it must never amount to less than 53 cubic feet per ton of daily output.

The blood in a man's body is capable of absorbing about one pint (about 20 per cent. of its volume) of either oxygen or carbonic oxide when saturated. If it be half saturated with carbonic oxide, unconsciousness sets in, and with higher proportions death follows. In air containing 0·1 per cent. of carbonic oxide the blood would become half saturated in about an hour in the case of a man at rest, and in about half an hour in the case of a man taking exercise. Anything above 0·15 per cent. of carbonic oxide must be considered dangerous; 0·16 per cent. will cause slight distress to mice in an hour, 0·2 per cent. distress in 8 minutes, 0·3 per cent. distress in 4 minutes, 0·45 per cent. distress in 2 minutes and collapse in 4 minutes, 0·57 per cent. distress in 1 minute, collapse in 6½ minutes, and death in 12½ minutes. With canaries 0·09 per cent. causes distress in one hour, 0·15 per cent. distress in 3 minutes, fall from perch in 18 minutes, 0·2 per cent. distress in 1½ minutes, fall from perch in 5 minutes, and 0·3 per cent. fall from perch in 2½ minutes.

Fire-damp.—Fire-damp consists essentially (up to 95 per cent. or more) of marsh gas or methane, CH_4, the remainder consisting of nitrogen and carbonic acid; hydrogen and some of the higher hydrocarbons have also been found in some samples. Haller and Moureu have found helium with traces of neon (0·003–0·05 per cent.), and argon with traces of krypton and xenon (0·003–0·04 per cent.) in fire-damp. A mixture of air and marsh gas will explode if the mixture contains between 5 and 15 per cent. of marsh gas by volume. The maximum of explosive violence is attained with 9 to 10 per cent. of marsh gas. The igniting point is between 650° and 750° C., and there is always a perceptible 'lag' or delay in the ignition, the amount of which depends upon the temperature. According to Taffanel and Le Floch, mixtures containing only 3 per cent. of marsh gas will ignite at 680° C. and as much as 30 per cent. at 875°. In a mixture of 6·5 per cent. of marsh gas with air, the quantity of gas burnt per second varies from 0·00075 per cent. at 535° C. to 0·05 per cent. at 640° C. According to H. Le Chatelier the igniting point of acetylene is 450° C., hydrogen 550° C., methane and carbonic oxide 650° C. The velocity of propagation of ignition of methane ranges from 0·03 m. per sec. with 6 per cent. of methane to a maximum of 0·61 m. per sec. with 12 per cent., and falls again to 0·1 m. per sec. with 16 per cent. of methane in air. The velocity of the explosive wave in a mixture of methane with pure oxygen is 2,500 m. per sec. Marsh gas has been given off in quantities up to 4,500 cubic feet per ton of coal wrought, and has been shown to exist in coal under pressures up to 40 atmospheres. It is on record that in one mine as much as four million cubic feet of fire-damp has been given off in 24 hours.

Experiments on the ignition of mixtures of methane and air by electric sparks have been recorded by Dr. Thornton (*Trans. Inst. Min. Eng.*, xliv. p. 145, and xlvi. p. 112); the most inflammable mixture is one containing about 7 per cent. of methane. With sparks between copper poles the least continuous current capable of igniting a 9 per cent. mixture was found to be:—

50	100	240	480 volts.
4·0	0·9	0·175	0·05 amps.

With iron poles slightly greater currents are required. With alternating currents of low periodicity, the current required is far greater, ranging from 3 times at 50 volts to 12½ times at 500 volts. The higher the frequency, the larger the current required for ignition.

Principles of Ventilation.

The difference of pressure producing ventilating currents in mines is measured by the water-gauge; a column of 1 in. of water corresponds to about 66 ft. of air at 60° F. and 30 ins. of baro-

metric pressure. The theoretical velocity of air due to such pressure is given by the expression $v = 66\sqrt{h}$, where v is the velocity in feet per second and h the water-gauge in inches. If the friction in the airways of a mine is taken into account, according to Murgue—

$$h = K\frac{l\,p\,v^2}{a} \text{ or } h = K\frac{l\,p\,Q^2}{a^3}$$

where l is the length of the air passage, p its perimeter, a its area, all in feet, and Q the quantity of air in cubic feet per second. Values of coefficient K: for drifts, bricked and arched, K = 0·000,0012; in ordinary rock, untimbered, K = 0·000,0034: timbered in the usual way, dimensions taken inside timbers, K = 0·000,0057. If the quantities and velocities be given in thousands of feet per minute, these coefficients become 0·00033, 0·00094 and 0·00156 respectively; some engineers use Mr. Fairley's coefficient, which is 0·002. The critical velocity of air flowing in circular pipes $= \frac{18}{D}$ feet per min., where D is the diameter of the pipe in feet.

The work required to move a quantity Q of air under a water-gauge of h inches = 5·2 hQ foot-pounds.

Mr. J. T. Storrow has found that the quantity of air flowing through material under 0·25 in. in size at a slow rate varies directly with the pressure and not with the square root.
(*Trans. Inst. Min. Eng.*, lv. 313.)

Measurement of flow of air. — In a pipe circular in section a velocity equal to the mean flow is at 0·15 of radius from the wall of the pipe. In a mine drift the mean of two measurements halfway between roof and floor and one-sixth of the width of the airway from either side will approximate to the mean velocity of the air in the drift. The mean velocity is between 0·7 and 0·85 of the maximum velocity at the centre of the drift, averaging 0·78.

With the ordinary plain Pitot tube, if v be the velocity of airflow in feet per second and h the water-gauge in inches, $v = 66\sqrt{h}$; with the double Pitot tube (one branch facing the other pointing in the direction of the flow) $v = 56{\cdot}5\sqrt{h}$.

If the pressure of air on either side of a regulator or other diaphragm with an aperture of a square feet be determined by water-gauge, and the difference of gauge pressure be d inches, the quantity of air flowing is $40\,a\sqrt{d}$ cubic feet.

Natural Ventilation and Furnace Ventilation.

Natural Ventilation and Furnace Ventilation.—If there be two shafts, the mean temperature of the air in each of which is respectively T and t (in degrees Fahrenheit), the water-gauge due to this difference of temperature will be $\frac{H}{66}\left(\frac{T-t}{459+T}\right)$, where H is the depth of the pit, assuming that the temperature of the atmosphere is 60° and the pressure 30 ins., under which conditions a cubic foot of air weighs 0·0765 lb.; under any barometric pressure of β inches and temperature $t°$ Fahrenheit, the weight of a cubic foot of air is $\frac{1{\cdot}326\,\beta}{459+t}$, by means of which formula the necessary correction can be applied. The number of heat units required to produce the above water-gauge will be $\frac{1{\cdot}326\ Q\ \beta\ (T-t)}{459+t} \times 0{\cdot}2375 = \frac{0{\cdot}315\ Q\ \beta\ (T-t)}{459+t}$ heat units per second.

The grate area is often taken $= \frac{34}{\sqrt{H}} \times \frac{5{\cdot}2\ hQ}{550}$ sq. ft.

In practice, to pass 300,000 cubic feet of air per min. with a 2-in. water-gauge about one ton of coal is burnt per hour.

Fan Ventilation.

Fan ventilation.—If u be the peripheral velocity of the fan blades in feet per second, the theoretical water gauge produced $= \frac{u^2}{68g} = \frac{u^2}{2180}$.

The manometrical efficiency of a fan ranges from about 0·45 for an open-running fan up to about 0·9 for a good modern enclosed fan.

The volumetric efficiency under given conditions is the volume of air actually passed by the fan divided by the volume of the fan × number of revolutions.

The mechanical efficiency is the horse-power required to drive the fan (or the fan and fan-engine, as the case may be) divided by the horse-power in the quantity of air moved = $\frac{5{\cdot}2\ hQ}{550}$. It varies from about 45 to about 75 per cent. in different types of fans.

The equivalent orifice of a mine $o = 0{\cdot}4\ \frac{q}{\sqrt{h}}$, where q represents the quantity of air in thousands of feet per minute, and o the area in sq. ft. The equivalent orifice of British mines is usually between 20 and 30 sq. ft.

If H be the initial water-gauge of a given fan (maximum water-gauge, produced on exhausting out of a closed vessel), the equivalent orifice of a fan, working on a mine with equivalent orifice o, should be $= o\sqrt{\frac{h}{H-h}}$. The inlet area of a fan should be about 20 per cent. greater than its equivalent orifice. The equivalent orifice of a fan should be about three times that of the mine on which it works. The velocity at which air enters the fan orifice should be between 1,000 and 1,500 ft. per min. If k be the manometric efficiency of any fan, according to Murgue—

$$u = \sqrt{\frac{g\ 68\ h}{k}}.$$

To find the horse-power of a motor or engine required to drive a fan under average mine conditions, multiply the number of cubic feet of air by the water gauge and divide this product by 4,500. Example: If a fan is delivering 100,000 cub. ft. of air at 2-in. water gauge, what should be the horse-power of the motor or engine required to drive it?

$$\text{H.P.} = \frac{100{,}000 \times 2}{4{,}500} = 44{\cdot}4. \qquad (\textit{Machinery.})$$

REGULATORS.

Regulators.—If A be the area in sq. ft. of a regulator which is required to produce as much resistance to the flow of air as a roadway of length l, perimeter p, both in feet, a area in sq. ft., K = Murgue's coefficient of friction as above when the quantity of air is expressed in thousands of cubic feet per minute and the pressure in inches of water-gauge, then $A = 0{\cdot}4\sqrt{\frac{a^3}{K\,p\,l}}$. The regulator should be placed behind the last man in the split.

Safety Lamps.

The gauze should contain not less than 784 meshes per square inch.

TABLE SHOWING AVERAGE CANDLE-POWER OF VARIOUS LAMPS (*a*) AT BEGINNING, AND (*b*) AT END OF TEN HOURS' BURNING WITH FIVE DIFFERENT OILS.

Lamp.	No. 1 Oil.		No. 2 Oil.		No. 3 Oil.		No. 4 Oil.		No. 5 Oil.	
	(*a*)	(*b*)	(*a*)	(*b*)	(*a*)	(*b*)	(*a*)	(*b*)	(*a*)	(*b*)
Marsaut	0·73	0·63	0·75	0·64	0·74	0·63	0·72	0·64	0·72	0·64
Donald	0·50	0·37	0·49	0·43	0·48	0·43	0·48	0·44	0·48	0·42

Deflector	0·96	0·90	—	—	—	—	—	—	—	—

TABLE SHOWING COST IN PENCE PER 1,000 LAMPS OF ONE AVERAGE CANDLE-POWER HOUR, WITH DIFFERENT OILS.

Oil.	Marsaut.	Donald.	Mueseler.	Davy.	'Geordie.'	Clanny.	Scotch Davy.	Deflector
No. 1	11½	22	14½	18	16	11½	17½	11½
No. 2	19½	33¾	32	19	—	—	—	—
No. 3	25½	43	43½	26½	—	—	—	—
No. 4	35	56	59½	42½	—	—	—	—
No. 5	45¼	73	75¾	43¾	—	—	—	—

The oils used were as follows :—

Oil.	Specific Gravity.	Composition, per Cent.		Cost per Gallon.
		Mineral.	Vegetable.	*s.* *d.*
No. 1	0·820	100	0	0 9
No. 2	0·841	70	30	1 6
No. 3	0·844	50	50	1 9
No. 4	0 865	30	70	2 3
No. 5	0·889	0	100	2 9

Lamps burning benzine of sp. gr. 0·765, costing 1*s.* per gallon, gave the following results :—

	Candle-power.		Cost in pence per 1,000 lamp per average c.p. hour.
	At Beginning.	At End.	
Wolf	0·99	0·94	16½
Protector	0·72	0·66	25½

Gas Caps.

Gas caps are shown in an ordinary safety lamp with the flame turned down so as just not to show any white light, when introduced into an atmosphere containing small amounts of marsh gas or methane, approximately as follows :—

2 % of marsh gas. Cap ¼ in., just visible except at extreme tip.
3 % „ „ „ ½ in., fully formed.
4 % „ „ „ ¾ in., well defined.
4½% of marsh gas. Cap 1 in., well defined.
5 % „ „ „ 2½ ins. „ „
5½% „ „ „ 4 ins. „ „
6 % „ „ „ fills the safety lamp.

Gas-testing lamps burning alcohol will show clearly as little as 0·2 per cent. of marsh gas.

Coal Dust.

Coal-dust.—Three ounces of coal-dust per cubic yard of gallery space is sufficient to produce an explosive mixture; excess of coal-dust prevents neither the initiation nor the propagation of an explosion. Coal-dust giving less than 12 per cent. of volatile matter is practically incapable of initiating an explosion. At least 50 per cent. of inert stone-dust is required to prevent the initiation of an explosion. If less than 75 per cent. of the dust passes the 200 sieve it is difficult to initiate an explosion (abstracted from the Lievin experiments).

The temperature of ignition of coal-dust is about 1,000°C. Mixed with air and introduced into a heated vessel the temperature may be as low as 590°; there is very little lag (*Taffanel and Le Floch*).

Rescue Apparatus.

There are three main types of rescue apparatus :—

(1) The supply of oxygen is maintained by means of compressed oxygen carried in steel cylinders.

(2) The supply of oxygen is obtained from liquid air.

(3) Oxygen is chemically generated from peroxides, usually sodium-potassium peroxide.

In 1 and 2 the expired carbonic acid is absorbed, usually by caustic soda. in 3 the reagent that evolves the oxygen also absorbs the carbonic acid.

Particulars of some forms are as follows :—

Apparatus.	Weight.	Oxygen Capacity.
	Lbs.	Cubic Feet.
Pneumatogen (Type II.)	14½	5·8
Draeger	36–39	8·9
Shamrock	36	9·7
Fleuss	31	8·0
Weg	About 30	5·3
Proto	37	8·5
Meco	39½	8·5
Salvus	16	3·0
Aerolith	22	?
Aerophor	30	?

It is estimated that 120 cubic inches of oxygen per min. is ample for the severest exercise; a man at rest requires about 15 cubic inches, and climbing hills 90 cubic inches per min. The Aerolith uses liquid air containing about two parts of oxygen to one of nitrogen; it is stated that one gallon is sufficient for three hours' work.

The Aerophor holds 10 lbs. of liquid air, equal to about 125 cubic feet.

The following has been found to be a man's average consumption of oxygen per minute, gas dry, at N.T.P.

Rate of doing Work.	Breathing.			
	Air.		Oxygen.	
	Litres.	Cub. in.	Litres.	Cub. in.
At rest	0·36	22	0·32	19·5
3,000 ft.-lbs. per min.	1·12	68·3	0·97	59·2
6,000 " "	1·74	106·2	1·54	95
9,000 " "	2·33	142·2	2·16	131·8

The most economical rate of walking when travelling a flat road and wearing a rescue apparatus—*i.e.* the rate at which a maximum distance can be covered for a given supply of oxygen—is about 2½ miles per hour.

('*Second Report of the Mine Rescue Research Committee of the Department of Scientific and Industrial Research.*')

When the wet-bulb temperature is much above 80°F., a man cannot remain long at work; he can stand a wet-bulb temperature of 120°F. for about five minutes. (*J. S. Haldane.*)

To Detect Carbon Monoxide in the Air.—A Technical Paper (No. 11) of the United States Bureau of Mines suggests the following simple test capable of detecting as little as 0·03 per cent. of carbon monoxide in the air. One or two drops of blood from a pricked finger are diluted with water until this assumes a buff-yellow colour. Some of this discoloured water is placed in two 100 cubic centimetre test tubes, and one of the tubes is to be taken into the mine, where one-half is to be poured away at the place where the air is to be tested, the mine air taking the place of the water poured away. The tube is then to be corked, taken to the surface, and to be shaken for about ten minutes. If the air in the test tube contains CO, the pink colour of the liquid will indicate the presence of hæmoglobin on comparing the tube with the other test tube filled with the normal fluid. Mr. Ivor Graham has shown that carbon monoxide is a normal constituent of the air of coal mines over 1,500 ft. deep, being produced by the slow oxidation of carbonaceous material at the coal face, in the roads and in the goaf; it is usually under 0·005 per cent., but in a few cases 0·012 per cent. has been found.

('*Trans. Inst. Min. Eng.*,' Sept. 1920.)

Spontaneous Combustion.

Work in the Doncaster Coal Owners' Laboratory has shown that the liability of a coal to spontaneous combustion in the goaf depends, other things being equal, upon its capacity for absorbing oxygen. It appears that a coal, 100 grammes of which ground to 200 mesh, absorbs less than 200 c.c. in 96 hours at 30°C., is only liable to gob fires when the working conditions especially favour the latter. Coals liable to fire absorb over 300 c.c. in the same time. Presence of pyrites, especially when finely divided, increases the liability to spontaneous combustion.

Fire Extinction.

Investigations have been made recently into the scientific side of mud-jet working for fire extinction in colliery workings, and it has been decided that the material of the mud, some of which should be of a lime and some of a clay character, should consist of sifted earth of 5 mm. mesh, boiler ash, dust from the cleaning of blast-furnace gas, and even combustible material, such as the refuse of coal washing, can be added to make up bulk without any risk should nothing more suitable be at hand. In the majority of instances the mud tank can be so placed as to operate by gravity, but steam or compressed air pressure can be used. It has been found that if a tank is placed at a height of, say, 15 yards, it will force the mud a horizontal distance of 150 yards, even allowing for fairly sharp bends in the conducting pipes. (*Fire.*)

Electric Signalling in Coal Mines.

A circular issued by the Home Office points out that while there is no difficulty in constructing bells and relays that will comply with the requirements laid down—i.e. which will not 'spark'—most of those in ordinary use in coal mines do not comply with the provision of General Regulation 132; and it states that in mines to which this regulation applies steps must be taken without delay to bring into compliance with the regulation any existing installations which

do not already comply, while no new apparatus must be installed except such as does strictly comply. The fact is emphasised in the report that with the usual type of bell and magnitude of battery at present employed, nearly every break-flash that occurs when the bare signal wires are separated would ignite a mixture of firedamp and air containing between 7·5 and 9·5 per cent. of methane, were such a mixture to surround the wires at the time.

Relays, although not requiring for their action so great a battery power as bells, have owing to their higher inductance a lower 'igniting-current' at which the break-flash on the signal wires becomes dangerous. At the present time, with few exceptions, the battery power used on relays is in excess of that sufficient to give a dangerous break-flash at the signal wires. The commonest kinds of relays are dangerous when used with a battery of more than four wet Leclanché cells, or with any current in excess of the current given by such a battery.

The report shows in detail how the bare wire system of electrical signalling as commonly employed can be rendered quite secure from any danger of the ignition of inflammable gases by the break-flash at the signal wires or at the contacts of the signalling instruments.

In order to secure a safe bare-wire signalling system it is necessary in the first place that the battery power employed on any one circuit should be limited, and, in the second place, that the signalling instrument, whether bell or relay, should comply with certain requirements set out in the report.

The maximum pressure allowed by the General Regulation (No. 134 (a)) for a signalling circuit is 25 volts, and from the point of view of safety a pressure of 25 volts is not excessive provided that, as is usual, wet Leclanché cells (quart size) are employed.

Systems in which the battery used consists of dry primary cells or secondary cells, or in which continuous or alternating current generators are employed, can be rendered safe if, in addition to the use of anti-sparking devices, sufficient non-inductive resistances are permanently installed in the circuit.

Both bells and relays should have flame-tight covers (preferably locked), and should be so constructed and maintained that when included in a circuit with a battery at 25 volts the break-flash produced, when bare signal wires are separated after giving a signal, is incapable of igniting an 8 per cent. methane air mixture. (*Times Engineering Supplement.*)

ORE DRESSING AND COAL WASHING.

(For details see 'The Dressing of Minerals,' by Henry Louis, from which the following is mainly abstracted.)

The operations included under the head of dressing comprise all the operations between the extraction of the crude mineral from the mine and rendering it merchantable, thus forming a link between the operations of the miner and the metallurgist. By common consent, gold milling is generally looked upon as a dressing operation, though it is doubtful whether cyanidation should also be included.

The various operations consist of :—

Hand picking or sorting.

Comminution (coarse breaking or crushing and fine breaking or grinding).

Sizing (preliminary or rough sizing and final or fine sizing).

Classifying.

Separation by differences of specific gravity, magnetism, electric conductivity, or surface tension.

Usually a more or less complicated series of operations is required, especially in the case of complex ores, and these are usually indicated by means of flow sheets.

Let the weight of feed to any concentration process be A and its assay a per cent., the weight and assay of concentrates be B and b and of tails C and c respectively, then the

$$\text{Enrichment ratio} = \frac{b}{a} = \frac{\%\ \text{Recovery}}{\%\ \text{Concentration}}.$$

$$\%\ \text{Concentration} = \frac{100\text{B}}{\text{A}} = \frac{100(a-c)}{b-c}.$$

$$\%\ \text{Recovery} = \frac{100b(a-c)}{a(b-c)} = \frac{\text{B}100b}{\text{A}a} \cdot \text{A} = \frac{\text{B}(b-c)}{a-c}.$$

$$\%\ \text{Efficiency of concentration} = 100\frac{\text{B}}{\text{A}}\left(\frac{b}{a} - \frac{100-b}{100-a}\right) = 100\frac{a-c}{b-c}\left(\frac{b}{a} - \frac{100-b}{100-a}\right) =$$

$$100\ \frac{\%\ \text{Recovery} - \%\ \text{Concentration}}{\%\ \text{Waste in feed}}.$$

(*R. T. Hancock.*)

Sorting is performed either on floors or on picking belts or tables. An ordinary picking belt may be of iron plates 4 ft. wide, 50 to 100 ft. long, travelling at 40 to 65 ft. per minute. Pickers stand on both sides, 7 ft. to 15 ft. apart; each picker can treat 1–3 tons of coals per hour.

Power required to drive, 2½ to 5 h.p. Upkeep, about 50*l.* per annum.

Rubber-covered canvas belts about 32 ins. wide are also used, and will carry 25 to 50 tons per hour at speeds of 30 to 60 ft. per minute.

Circular tables are 3 to 4 ft. wide, 10 ft. to 18 ft. in diameter, revolving with a peripheral speed of 40 to 60 ft. per minute, and can deal with 30 to 70 tons of mineral per hour.

Comminution.—Rough breaking is done by jaw breakers, either reciprocating like those of the Blake, Dodge, etc., type, or gyrating like the Gates type. The former have been built to take pieces up to 5 ft. by 7 ft., requiring 300 h.p. to drive, and breaking 300 tons per hour. Smaller breakers usually break 1 ton per hour for a consumption of 2–3 h.p. The gyrating crusher is better suited to very large outputs, but cannot take such large pieces, and appears to be rather more economical of power.

Fine Crushing.—Rolls are used for medium and fine crushing. Let r be the radius of the particle to be broken and d the radius of the particles in the crushed product (both considered as spheres); the minimum radius of the roll should be $> 25\ (r-d)$.

For fine crushing to about ¼-in. mesh the following table shows the general practice:—

Rolls.		Revs. per minute.	Horse-power required.	Cwts. crushed per hour.
Diam.	Face.			
10½ ins.	10½ ins.	130	3	25
12½ ,,	10½ ,,	110	4½	45
16 ,,	10½ ,,	90	6½	65
21 ,,	10½ ,,	75	9½	100
27 ,,	11 ,,	45	12½	145
37 ,,	12 ,,	45	16	200

The peripheral speed should be greater the finer the product required; for grinding to 40 mesh the speed should be 1,000 ft. per minute.

In large plants three or four sets of rolls are placed in series so as gradually to reduce the ore to the desired size. At Mount Morgan, such a plant consisted of eight sets of rolls in two series of four, thus:—

26 ins. diam.,	15 ins. face,	set	⅜ ins. apart,	112 revs. per min.
26 ,,	15 ,,	,,	$\frac{3}{16}$,, ,,	,,
30 ,,	16 ,,	,,	$\frac{1}{16}$,, ,,	,,
30 ,,	16 ,,	in contact	,,	,,

The total power consumption was 100 h.p. and the crushing capacity 125 tons per 24 hours crushed to 20 mesh (0·025 in.); the wear on the steel roll-shells was 0·108 lb. of steel per ton of ore crushed.

Stamps.—The ordinary gravitation stamp is used more largely for gold milling than for other purposes, but also for crushing tinstone, etc. The complete stamp consists of the head, shoe, stem and tappet, the weight of which may be up to 1,500 lbs. The relative weights are about 30, 17, 40, 13. It is lifted by a cam forming the involute of a circle; if h be the lift of the stamp, r the radius of the pitch circle of the involute, and a the angular motion of the cam during the lift, $h = \frac{\pi r a}{180}$. The speed is usually about 90 drops per minute.

If n be the number of drops per minute, h the drop in inches, s the number of stamps, and w the weight of a stamp in pounds, the power required is approximately $\frac{nhsw}{300{,}000}$. (For a more exact formula see 'A Handbook of Gold Milling,' by H. Louis.) The average crushing capacity is 2–8 tons per 24 hours for a 1,000 lb. stamp. The Husband atmospheric stamp with two heads requires 35 h.p. to work it, and can crush 40 tons of hard tinstone per 24 hours down to 0·048 in.

Steam stamps are used mainly for crushing the copper-bearing rocks of the Lake Superior Mines, down to about ¼-in. mesh. One such stamp will crush 10 tons per hour, the efficiency being about 1·75 tons per i.h.p. per 24 hours.

Ball mills have been made both for dry and wet crushing. The Krupp mill is a dry-crushing mill; the No. 5 size, which is largely used, is 86 ins. diameter by 46 ins. length, makes 20–25 r.p.m., weighs 182 cwts., and a set of balls weighs 18 cwts. At Mount Morgan these

mills require 13 h.p. and crush 22·7 tons per 24 hours to 20 mesh (0·025 in.). The balls wear at the rate of 0·725 lb. and the hunch plates at the rate of 0·681 lb. per ton of ore crushed.

Wet crushing ball mills are 60 ins. to 80 ins. in diameter and about 40 ins. long. A charge of balls for such a mill weighs about 2 tons; it is run at 25 to 30 r.p.m., takes from 25 to 35 h.p. to drive it, and will crush 25 to 100 tons down to 0·02 mesh per 24 hours; the water consumption is about 65 gallons per minute.

The tube mill is also used wet or dry, and is in effect an elongated ball mill, 3 ft. to 5 ft. in diameter and 13 ft. to 26 ft. long. A tube mill 4 ft. in diameter, 16 ft. 6 ins. long, crushed in Western Australia 38 tons of sand per 24 hours, 95 per cent. of the product being finer than 100 mesh, requiring 30 h.p. to drive it. Such mills are lined with silex, chilled iron, or hard steel bars, and are usually charged with flints. According to Mr. Davidson, the best number of r.p.m. $=200 \div \sqrt{d}$, where d is the internal diameter in inches; the weight of flints in pounds should be $N \div 44$, where N is the internal capacity of the mill in cubic feet. Western Australian practice corresponds nearly to $N \div 60$.

The Marathon mill uses rods in place of balls; a mill 3 ft. diam., 7 ft. long, charged with 7,000 lbs. of rods $\frac{1}{2}$ in. to 2 in. diam., running at 30 r.p.m., crushed 18 tons per hour with a consumption of 12·5 h.p., using 42 U.S.A. gallons of water per minute. The feed was below $\frac{1}{4}$-in. mesh and the product was ground to $\frac{1}{14}$-in. mesh, 14 per cent. being below $\frac{1}{200}$-in. mesh. The wear of the line plates was 0·14 lb. and of the rods 0·4 lb. per ton of feed.

(*Trans. Amer. Inst. Min. Eng.*, lv., p. 678; lvii., p. 355.)

The Hardinge tube mill has the form of two cones base to base. An 8 ft. Hardinge mill requires 50 h.p. to drive it, and requires about 10 h.p. hours per ton crushed to about 48 mesh.

An 8 ft. × 22 ft. mill crushed 200–250 tons per 24 hrs. using about 56 h.p., with a charge of 5 tons of Danish pebbles wearing at the rate of 2·16 lbs. per ton of feed; with steel balls instead of pebbles 360–400 tons were crushed per 24 hours.

(*Trans. Amer. Inst. Min. Eng.*, lv., p. 678.)

The Marcy mill is a short mill (5–6 ft.) with perforated diaphragm at the discharge end, from 2 ins. to 48 mesh. An 8 ft. by 6 ft. mill driven by a 225 h.p. motor crushes 550 tons per 24 hours at 24 r.p.m., carrying 30,000 lbs. chrome steel balls.

(*C. T. Van Winkle, Trans. Amer. Inst. Min. Eng.*, vol. lix. (1918), p. 227.)

The Huntingdon mill is made in three sizes, 3 ft. 6 ins., 5 ft. and 6 ft. diam.; No. 2 is most used; it weighs about 5 tons; consumes 12 h.p.; makes 60–70 r.p.m., and will crush about 10 tons per 24 hours to about 15 mesh.

The Arrastra is 10 to 20 ft. in diameter, has usually four dragstones, 6–8 cwts. in weight. At 6 to 12 r.p.m. a charge of 1 to 3 tons is ground in 2–3 hours.

The Chilian mill has 2–3 rollers, 4 to 6 ft. in diameter, takes up to 75 h.p., and crushes up to 150 tons per 24 hours.

Sizing.—For coarse screening fixed grizzlies or 'jigging' screens are used. For medium and fine screening mostly trommels, 8 ft. to 2 ft. in diameter by 12 ft. to 3 ft. long; the peripheral velocity is usually 50 to 200 ft. per minute. The slopes may vary from 5° to 14°, averaging about 7°. A set of seven trommels, 3 ft. diam., 5 ft. long, will size about 7 tons of ordinary crushed material per hour, and require up to 5 h.p. to drive it.

Classification.—This term applies to the separation into groups of equal falling particles. The terminal velocity of a particle falling freely in water is approximately $V = 2{\cdot}6\sqrt{D(S-1)}$, where V is the velocity in meters per second, D the diameter in meters of the screen mesh through which the particle just passes, and S the density of the mineral. This velocity will be attained after the particle has fallen a distance equal to $V^2 \div 4$ approximately. When V is less than 0·5 to 1, according to the substance, the law on which these formulas are based (friction $\propto$ velocity^2 and viscosity negligible) no longer holds good. The particles fall more slowly, obey a different physical law, and are known as slimes, which are incapable of classification.

Spitzkasten: the first box should be 2 ft. wide for 10 cub. ft. pulp per minute, or 1–2 cwts. of solid matter; boxes may increase in geometrical progression with factor of 1·5; length of first box about 6 ft., increasing by 3 ft. for each successive box.

Trough classifiers 10 to 20 ft. long, 1 ft. wide at narrow end, will treat 100 tons per 24 hours, with 100 cub. ft. of water per ton of crushed material.

Jigs.—The following represents the general modern practice:—

Diam. of particle .	0·25	0·50	0·75	1·00	1·25	1·50	1·75	2·00
Length of stroke .	0·4	1·2	1·55	1·8	2·0	2·15	2·3	2·4
No. of strokes per min.	200	160	145	130	125	125	125	125

Round buddle; diam. 18 ft. to 25 ft.; arms 5–10 r.p.m. Capacity 1½–3 cub. ft. per min., carrying 28 to 56 lbs. material; time of filling 3–10 hours.

Slime table; diam. 15 ft. to 25 ft.; ½–1 r.p.m. Pulp 1½–3 cub. ft. per min., carrying 4 to 7 lbs. per cub. ft. Clear water 1½–3 cub. ft. per min. Power required ½–1½ h.p.

Frue vanner; belt surface 4 ft. by 12 ft.; fall 3 ins. to 6 ins.; travel 6 ft. per min.; strokes 200 per min. Capacity 0·25 to 0·5 cub. ft. pulp per min.; 5 to 8 tons material 24 hours. Clear water ¼ of pulp. Power required ½ h.p.

Lühring vanner; belt surface 3 ft. 6 ins. by 12 ft.; travel 8–12 ft. per min.; 160–180 strokes per min. Capacity 2½–7½ tons per 24 hours; clear water 1–2 cub. ft. per min. Power required ⅓–½ h.p.

Wilfley table; 16 ft. long, 6 ft. wide, tapering to 3 ft. Will take particles up to ½ in. 240 strokes per min., ¾ in. long. Capacity 25 to 50 tons per 24 hours. Clear water 1 to 3 cub. ft. per min. Power required 1 h.p.

Coal Washing.

Coal as it comes from the mine is first screened, usually over a 2 ins. to 2¾ ins. screen; the oversize drops on to picking belts, where shale, dirty coal, etc., is picked out. The undersize is taken to a washery, especially when it is required for coke-making. A jigging screen with ¾-in. holes will screen about 1 ton per hour for each 0·75 sq. ft. of screening surface.

When the separation of the clean coal from the accompanying shaly matter is easy, or when the products are not required in the highest possible state of purity, a simple form of washer may be used. Such is, e.g., the Elliott trough washer, capable of treating 5 to 10 tons of small coal per hour with a water consumption of 1,750 gallons per ton of coal washed. The Blackett washer is similar in principle, but the fixed trough with the moving dam-plates is replaced by a revolving drum within which is a spiral baffle-plate; it will treat 10 tons of small coal per hour, requiring 3,000 gallons of water in circulation per ton of coal washed. The Robinson washer works on the principle of a spitzkasten, with upward flow of water and a revolving stirrer; it can treat 15 to 20 tons of small coal per hour.

The purity of the washed coal is usually determined by floating it in solutions of known specific gravity; coal that floats in solutions of sp. gr. 1·35 to 1·45 is considered clean coal. Most plants for such complete washing make use of jigs (bashes or boxes), and the coarser refuse is sometimes crushed and re-washed. See Flow Sheet No. I, p. 2210.

The Coppée Washery is typical of the more usual form of plant. The unwashed coal, say under 2 ins. to 3 ins., is sized before washing. The washing is carried out in two types of boxes, viz.: (*a*) Small coal feldspar boxes, which treat all the coal below ½ in.; (*b*) nut coal type of box, which treats the various sizes below 3 ins. and above ½ in. These sizes vary according to local conditions and the requirements of the market. The nut washers are 8 ft. deep, and the sieves are 5 ft. long and 3 ft. to 5 ft. wide, each washer treating 2·5 to 3·5 tons per hour per foot of width of screen. The more important data affecting the operations of nut washers are shown in the following table:—

Size of Nuts.	Depth of Layer o Shale on Sieve.	Length of Stroke.	No. of Strokes per Minute.	Mesh of Sieve.
¼ in. to ½ in.	2½ ins.	2½ ins.	80	1/10 in.
½ ,, ,, 1 ,,	3 ,,	3 ,,	75	⅛ ,,
1 ,, ,, 2 ins.	3½ ,,	3½ ,,	70	¼ ,,
2 ins. ,, 3½ ,,	4¼ ,,	4¾ ,,	65	3/10 ,,
3½ ,, ,, 5 ,,	5½ ,,	6¾ ,,	60	5/10 ,,

The Feldspar Washer is built in two compartments, each 4 ft. long, making a total length of 8 ft. by 2 ft. 6 ins. wide, the box being 5 ft. deep; such a washer can wash 7 to 10 tons of small coal per hour up to ½ in. in size. The following are the leading data:—

	1st Compartment.	2nd Compartment.
Thickness of layer of feldspar	2½ ins.	2½ ins.
,, ,, shale	2/10 in.	2/10 in.
Size of pieces of feldspar	2/10 in. to 1 in.	2/10 in. to 5/10 in.
Length of stroke	0·55 in.	0·47 in.
No. of strokes per minute	165	165
Mesh of screen	0·55 in.	0·47 in.

A plant to wash 100 tons per hour, 50 per cent. on nut washers and 50 per cent. on feldspar washers, would require four of the former, 4 ft. wide, and six of the latter. Such a plant would require in circulation about 135,000 gallons of water, and make-up water amounting to between 2,800 and 3,500 gallons per hour.

When the refuse from the nut washers contains sufficient intergrown coal to be worth treating, it is crushed, generally in a disintegrator, and the crushed material is re-washed on feldspar washers.

A coal washery may require from 1·5 to 3·5 h.p. for each ton of unwashed coal treated per hour, varying with (*a*) the total output of the washery (a large washery requiring a relatively smaller h.p. per ton); (*b*) the quantity of interstratified coal, and whether the larger size is crushed and washed together with the smaller size, or whether the smaller size only is re-washed: (*c*) the type and capacity of draining and storage bunkers, and whether apparatus is installed for mixing the various products.

Messrs. Simon-Carves, Limited, build washeries on the so-called Baum principle, in which washing precedes classification. The slack below about 2 ins. is delivered to a bash having an area of about 0·8 sq. ft. per ton per hour; the washed coal then passes to a screen of about ⅜-in. mesh; the over-size is clean coal, and the under-size goes to a second bash having an area of about 1 sq. ft. per ton of coal per hour, the product being clean coal and refuse. The dirt produced in the first washing can be further crushed and washed over again if necessary. A plant to treat 100 tons of slack per hour would, therefore, require a first bash with an area of 80 sq. ft., and a second bash with an area of 100 sq. ft.; the water in circulation would be about 130,000 gallons per hour, and the make-up water required about 2,500 gallons.

In the United States small coal is being largely washed on shaking tables of the Wilfley type; such a table will treat 5 to 8 tons per hour of coal under ⅜-in. mesh, requiring about 1 h.p.

Magnetic Separation.

Maxima of magnetic susceptibility of minerals by volume in C.G.S.

Common non-ferrous minerals, e.g. mica, quartz, felspar, calcite have susceptibilities < 0·000001. 'Strongly' magnetic minerals have susceptibilities > 0·001. 'Feebly' magnetic minerals between 0·001 and 0·0001. (After Prof. Ernest Wilson.)

Magnetic separators: (1) For minerals of high magnetic susceptibility:—

Dry working, e.g. Wenström: drum 30 ins. diam., 24 ins. face. Capacity 5–7 tons per hour; will take lumps up to 7 lbs.; 30 r.p.m. Current 15 amperes at 120 volts.

Wet working, e.g. Gröndal: 24 ins. wide, 24 ins. diam., 100 r.p.m. Capacity up to 3·5 tons per hour. Current 10 amperes at 110 volts.

(2) For minerals of low magnetic susceptibility:—

Dry working, e.g. Rowand-Wetherill. Belt 18 ins. wide, three electro-magnets taking respectively 5, 15, and 30 amperes at 110 volts. Capacity, 0·25 to 1 ton per hour.

Wet working, e.g. Ulrich.

Flotation Processes.

These may be classified as follows:—

I. *Film Flotation*, utilising differences of surface tension on particles at an air-water interface—e.g. De Bavay, Macquisten processes.

II. *Oil Flotation*, utilising differences of surface tension in an oil-water medium where the particles are buoyed up by oil—e.g. First Elmore process.

III. *Adhesive Processes*, utilising differences of surface tension between particles and oil or grease, causing differential adhesion to oiled or greased surfaces—e.g. Murex, Cattermole, greased-plate processes.

IV. *Froth Flotation*, utilising differences of surface tension at gas-water interfaces, where the particles are buoyed up by bubbles of gas:—

(*a*) Where the bubbles are produced by chemical action—e.g. Potter, Delprat processes.

(*b*) Where the bubbles are produced by releasing the air dissolved in water—e.g. Elmore vacuum process.

(*c*) Where the bubbles are produced by mechanical means—e.g. Minerals Separation, Callow, Janey, K. & K., Rork processes.

(See also 'Froth Flotation: its Commercial Application and its Influence on Modern Concentration and Smelting Practice,' Walter Broadbridge, *Bull. Inst. M.M.*, January 1920.)

Costs of Flotation Machines.

1,000	12–25	4–6	0·17	0·17

(*Ralston.*)

Reagents used:—

Gangue modifying:—Acids, alkalies, silicates, carbonates, and other salts.

Froth producing:—Soluble oils, essential oils, cresylic acid, amyl alcohol, etc.

Froth stabilising:—Insoluble oils, petroleum, etc.

Surface Tension of Liquids against Air.

		Dynes per sq. cm.			Dynes per sq. cm.
Water	(at 0° C.)	75·8	Water with 0·14 per cent. cresol	(at 23° C.)	71·5
Water	(,, 20° C.)	75·1	Water with 0·14 per cent. amyl alcohol	(,, 23° C.)	68·4
Phenol	(,, 41° C.)	37·0	Water with 0·134 per cent. saponine	(,, 23° C.)	48·7
Cresol	...	34·8	Water with eucalyptus 'solute'.	(,, 20° C.)	44·6
Olive oil	...	32·0			
Petroleum	...	27·7			
Turpentine	...	25·6			

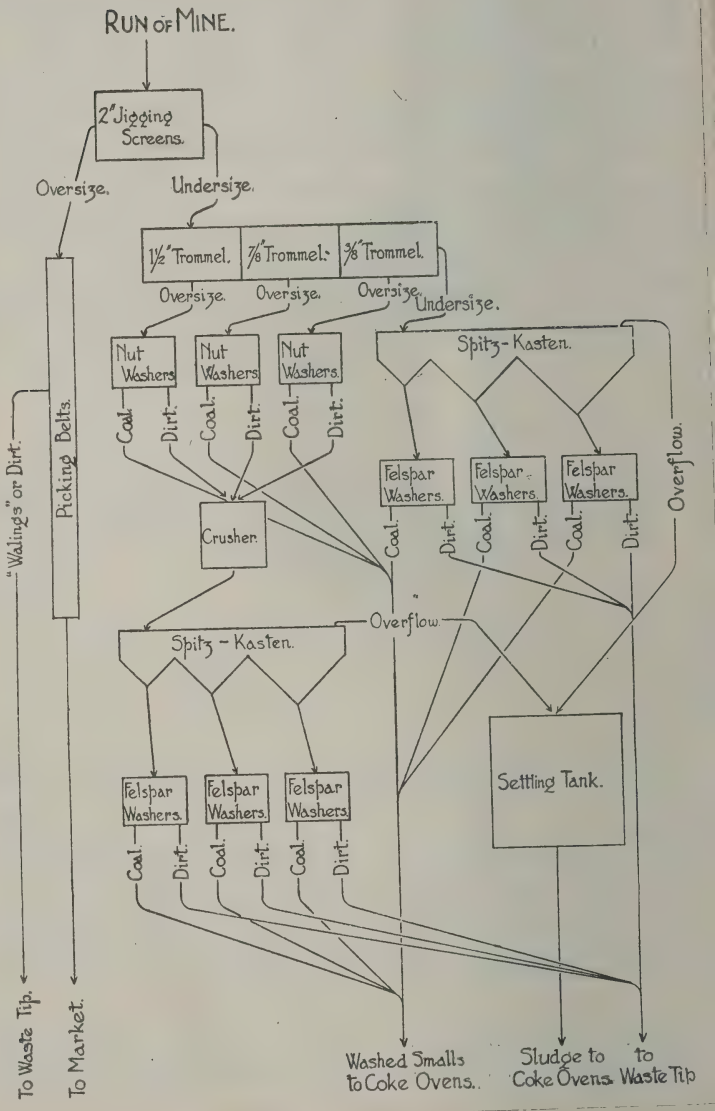
Dilute sulphuric acid reduces the contact angle and hysteresis range of that angle far more for quartz, silicates, and oxides than it does for metallic sulphides; oiling the latter greatly increases the contact angle and the hysteresis range.

(*H. L. Sulman*, 'A Contribution to the Study of Flotation,' *Bull. Inst. Min. Met.*, November 1919.)

The Inspiration Consolidated Copper Company's plant at Miami, Arizona, treats 15,000 tons in 24 hours. The ore contains 1¾ per cent. of copper, mainly in finely disseminated sulphides. Flotation reagents used, 1¾ lbs. per ton of ore. Recovery, 85 per cent. of total copper, 90 per cent. of copper present as sulphide; concentrates contain 20 per cent. of copper.

(*Trans. Amer. Inst. Min. Eng.*, lv., 1916, p. 576.)

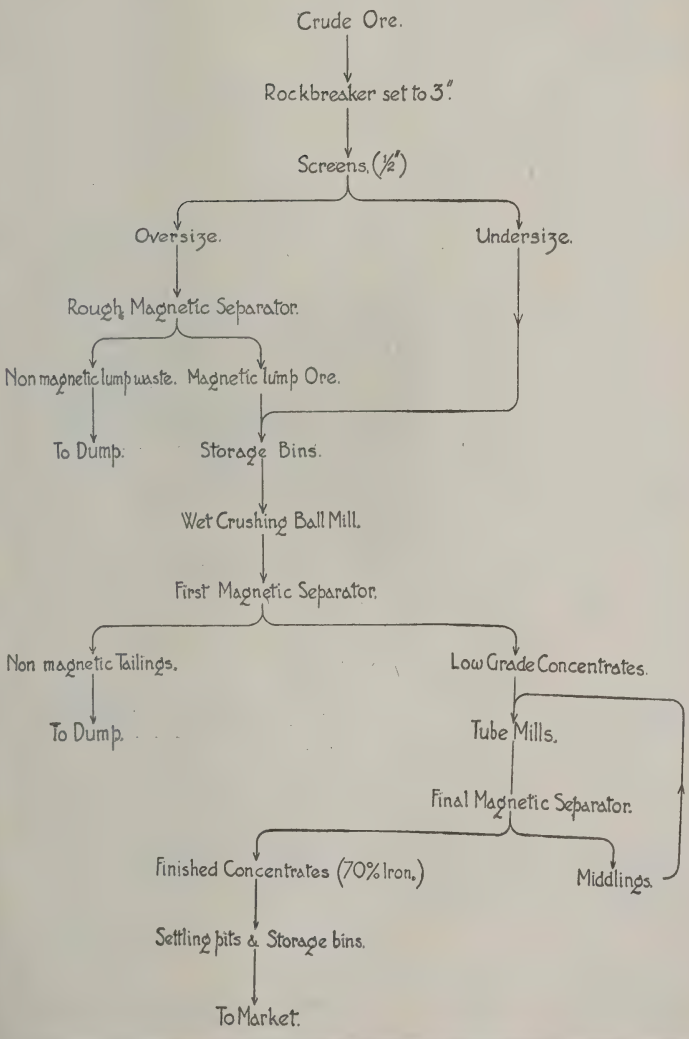
Finely-ground coal may be froth-floated from shale, using 1 lb. of cresol and ½ lb. of paraffin per ton of coaly shale; the latter contains about 65 per cent. of ash, the clean coal about 8 per cent.



Electrostatic Separation is used in some special cases—e.g. for concentrating rosin blende, molybdenite, and graphite (Blake-Marsden and Huff processes).

FLOW SHEETS.

The diagrams given on pp. 2210–2216 are specimen flow sheets, illustrating the sequence of operations in certain typical cases:—



I. Coking coal. II. Low grade magnetic iron ore. III. Quartz carrying cupriferous pyrites. IV. Lake Superior copper ore. V. Lead ore. VI. Tinstone containing wolfram. VII. and VIII. Copper ore by Froth Flotation.

GOLD MILLING.

With the improvements in the cyanide practice and also with the exhaustion of the rich free milling surface ores of various camps, which rendered such improvements necessary, have come changes in the process of treating gold ores. Instead of the simple Californian practice of crushing by 900 lb. stamps to about 40 mesh, amalgamating either in or outside the battery, concentrating the sulphides on vanners or shaking tables, chlorinating the concentrates, and sometimes treating the tailings by cyanidation, the 'all-sliming' process has come into force.

As practised on the Rand, the ore is screened through grizzlies with bars 2⅜ ins. apart the oversize going to a sorting belt, thence to a crusher. The ore passes into a feeder, thence to stamps weighing 2,000 lbs. per head, where it is crushed to pass a 10-mesh discharge screen. The pulp is classified in cones and the coarse product delivered to tube mills where it is slimed. The product of the tube mills, together with the overflow from the classifying cones, is delivered to the amalgamating tables. From the tables it is again classified, the sands being cyanided direct, and the slimes treated by air agitation, then filter-pressed or vacuum-filtered.

The most vital changes from the old practice to the new have been: the use of the heavy gravity stamp merely as a preliminary coarse crusher for the tube mills; the adoption of the tube mills for fine grinding and the employment of the tall, air-agitation tanks and of filters.

The practice is modified in each district, the modification depending largely upon the nature of the ore. In some camps silver ores are being successfully treated by fine crushing and cyaniding.

Stamps.

The duty of stamps depends upon the nature of the ore, the weight of the stamp, its speed and drop, the size of the aperture of discharge screen, and the height of the discharge. The following table gives the duty per stamp in various districts:—

DUTY OF STAMPS.

Mine or District.	Weight of Stamp.	Drop in Inches	Number of drops per Min.	Screen Aperture.	Discharge in Inches.	Tons Crushed per head per 24 Hrs.	Remarks.
California . .	900 lbs.	7	90	900 per sq. in.	4	3	Gold Quartz
Melones, Cal. .	1,000 ,,	7	104	20 mesh	—	4·41	
Tonopah Mill, U.S.A.	1,050 ,,	6½	104	slot ·04 in. wide	2½	5·09	Gold and Silver
Montana-Tonopah, U.S.A.	1,050 ,,	7	100	20 mesh	3	3·3	Gold and Silver
Tonopah Belmont, U.S.A.	1,050 ,,	6	104	24 mesh	—	3·7	,,
Goldfield, U.S.A..	1,050 ,,	7	108	12 mesh	—	6	,,
Komata Reefs Mine	1,030 ,,	6½	100	4½ holes per in.	4	5	Gold
Luipaards Vlei Rand	1,629 ,,	8½	98·6	200 holes per sq. in.	4	9·6	,,
Simmer & Jack East	1,550 ,,	8	96	200 holes per sq. in.	3½	8·3	,,
Waihi Grand Junction	1,110 ,,	7	105	5 to 10 mesh	1½	7·6	,,
Oroya Brownhill.	1,100 ,,	7¾	108	10 mesh	2	6·48	,,
Ivanhoe . .	1,192 ,,	7½	104	225 mesh	2	5½	,,
Gt. Fingall . .	1,150 ,,	8	106	12 mesh	3	7	,,
Mysore Gold Mine, Mysore, India	1,150 ,,	7·5	96	1,200, 625 and 400 per sq. in.	3	3·63	,,

It is claimed that the new 2,000 lb. stamps of the Goldfield, (S.A.) are capable of crushing 26 tons of ore per stamp per 24 hours by introducing an elimination screen to 'bypass' the fine material from the rock bins direct to the tube mill and using screens with aperture of ·284 inch.

Amount of water varies on the Rand, from 5 to 10 tons of battery water to one of ore, depending upon the duty. In Western Australia the amount of water required is 4 to 8 gallons of water per stamp per minute.

Power per stamp.—The 2,000 lb. stamp requires 5 h.p. per stamp. In Nevada, for 1,250 lb. stamp 3·5 h.p. per stamp is used. At the Goldfield Con. in Nevada with 140 stamps, fine grinding and cyaniding, 1,500 h.p. is supplied to the mill or 1·73 h.p. per ton of ore milled.

Cost of Equipment of Gold Mills.

The following is the comparative cost of gold mills, including all machinery and buildings :—

Mill.	Number of Stamps.	Cost of Machinery and Plant.	Cost per Stamp.
Rand Mill	200	£334,000	£1,670
New Kleinfontein	200	420,480	2,102
Wit Deep	200	346,210	1,731
Robinson Central Deep	100 and Tube Mill	234,013	2,340
Great Fingall	,,	193,745	1,937
El Oro	,,	160,000	1,600

In Nevada, the cost of complete plants doing fine grinding and slimes filtering is 1,400*l.* a stamp.

Tube Mills

are used as secondary crushers following the stamps. On the Rand they are most efficient when fed with ore that has been crushed through a screen the apertures of which are ·27 in. or say ¼ in. They are here 25 feet in length by 5½ feet in diameter, and one tube mill crushes the product of 10 stamps. Each tube mill requires 100 h.p. to drive it. In New Zealand tube mills are 16 ft. by 4 ft. revolving at 29 r.p.m., and driven by 25 h.p. motor. The feed is 1½ parts of water by weight to 1 part of ore. In 22 months a tube mill ground 28,500 tons of hard quartz, 50 per cent. of which passed through a 200-mesh screen.

At Pachuca 90 h.p. is used for a 5 ft. 6 ins. by 22 ft. tube mill. Output 140 tons per day through a 60-mesh screen.

At Waihi Grand Junction tube mills 19 ft. 3 ins. long by 4 ft. 8 ins. diameter require 42 h.p. Those 16 ft. 3 ins. long by 4 ft. 3 ins. diameter require 25 h.p. They consume 2·89 lbs. of flint pebbles per ton of ore crushed at stamps. They are run at 27 r.p.m.

Chilian Mills.

Chilian mills are employed either for crushing preliminary to amalgamation, in which case the gold is partly amalgamated in the mill itself, or they are used in lieu of the tube mill as fine grinders following the stamps.

For crushing ores for direct amalgamation the so-called slow speed Chilian mills are well adapted. Machines of this type are extensively employed in Russia and Siberia. They are expensive in first cost, but the power, labour, and repair cost are very low. Furthermore they are notable for their simplicity, requiring little close or skilled attention.

A slow speed Chilian mill was employed in California on hard close quartzose gold ore. It ran at 8 to 10 r.p.m. It had four runners each weighing 1,200 lbs. travelling on a steel die 3 ins. thick with 5 ins. face and 7 ft. outside diameter, 4½ tons of rock in a tank above and sustained by the axles giving additional crushing weight. Twenty tons of ore per 24 hours were crushed with a 4 in. discharge, and 88·1 per cent. extraction obtained 0·85 per cent. of the ore passed through a 100-mesh screen. One man per shift handled the mill. Cost of ore crushed 6*s.* per ton. Gasoline power was used consuming under heaviest load 2·17 gallons of distillate per hour. (*A. McLaren.*)

The standard type of Chilian mills used in Russia is 7 ft. to 10½ ft. in diameter with 2 runners 5½ to 6½ ft. in diameter, and from 7 to 12 ins. in width. The speed is 11 r.p.m. The discharge is 8 to 10 ins. Feed is about 1 in. and discharge screen slotted. The water is 6·5 to 10·1 times the ore in weight and duty is 16 to 24 tons per 24 hours. The power required is 7 to 12 h.p.

Rapid-running Chilian mills were used as fine grinders after the stamps in the Goldfield Consolidated mill in Nevada on fairly soft ore. There 140 stamps were in operation and six 6 ft. Chilian mills crushing from 4-mesh to 16-mesh were installed. These were operated at 32 r.p.m. Their capacity was 75 tons per 24 hours and the power required 35 h.p. each. The cost of crushing by these mills is given at 5*d.* per ton of ore milled. (*J. W. Hutchinson.*)

At Cripple Creek a 6-ft. Chilian mill running at 33 r.p.m. reduces 4 tons of ore per hour, 60 per cent. of which will pass a 150-mesh screen. The feed passed a ⅜-in. aperture.

Rolls.

Where a relatively small tonnage is to be crushed coarse, as for example when coarse concentration is employed or where the ore is porous and is cyanided coarse, it is the practice to use rolls. They are cheaper than gravity-stamps in first cost, repairs, labour, and power, and are not complicated by screens.

In South Dakota the ore, a hard, close-grained Cambrian quartzite, carrying from 5 dwts. to 7 dwts. per ton, is crushed by rolls. The ore is fed to two 16 by 36 in. rolls used as cracking rolls, and two others of the same size are used as finishing rolls. The final product goes through a $\frac{1}{4}$ in. mesh direct to the cyaniding vats. The rolls require 100 h.p. The milling and cyaniding cost is 2*s.* 2*d.* per ton and 14,800 tons of ore are treated monthly.

Ball Mills.

Krupp ball mills are used extensively in Kalgoorlie where 44 are at work. Size No. 5 will crush up to 45 tons of ore per day consuming 25 h.p. No. 8 will crush 90 tons per day requiring 50 to 60 h.p. About 45 per cent. of the product from a 25-mesh screen will pass 150-mesh. It is charged with 1 or 2 tons of steel balls and revolves from 21 to 25 times per minute. They work well on either wet or dry ores. The wear and tear of liners, hunch and scoop plates cost 4·64*d.* per ton milled.

Milling Costs.

The following are the milling costs of different stamp mills :—

Mill.	Stamps.	Tons Crushed Monthly.	Cost of Milling per ton.	Rate of Wages per day.	Remarks.
Tonopah, U.S.A.	100	15,000	12*s.*	18*s.*	Silver Gold ore
Goldfield Con., U.S.A.	140	29,500	9*s.*	18*s.*	
Ivanhoe	100	16,600	8*s.* 9*d.*	12*s.* to 14*s.*	Bromo-cyanide treatment of slimes
Oroya Brownhill	50	8,950	17*s.*	12*s.* to 14*s.*	
Gt. Boulder	—	14,800	12*s.* 4*d.*	12*s.* to 14*s.*	Dry crushing with Griffin mills. Roasting.
Melones, Cal.	100	12,000	1*s.* 1½*d.*	10*s.*	Cheap power, labour and supplies
New Unified (Rand)	—	10,000	1*s.* 4*d.*	—	Milling only
Simmer East	—	—	2*s.* 6*d.*	—	

On the Rand, cost of milling of those companies using tube mills varies from 4*s.* 10*d.* to 8*s.* 8*d.* per ton of ore.

In California, with free milling ores and cheap water power, milling costs average from 2*s.* to 4*s.* per ton. In Alaska, with large tonnages of soft, free milling ore treated daily and no cyaniding or fine grinding the costs are about 1*s.* per ton of ore.

Horse-Power per Ton of Ore Treated per Day.

Type of Mill.	Mesh.	Horse-power.
Stamps and vanners	20 to 40	0·75 to 1·0
Coarse concentration	10 to 20	0·5 to 0·8
Combination-stamp	16 to 30	1·5 to 1·75
Chloridising stamp (dry)	to 16	2·0 to 2·5
Chloridising stamp (wet)	to 40	4·0 to 4·5
Magnetic separator	—	0·25 to 0·5
Cyanidation (dry) roll-crushing	20 to 30	0·5 to 0·8
Cyanidation (wet), stamp crushing and sliming	to 80	0·75 to 1·5

(*J. A. Barr*, 'Testing for Metallurgical Processes.')

Standards Adopted by the Institution of Mining and Metallurgy.

1 oz. of fine gold = value 85*s.*
1 ton = 2,000 lbs. (avordupois).
1 miner's inch = a flow 1½ cubic ft. of water per minute.
1 sluice head = „ 60 „ „
1 gallon of water = 10 lbs. at 34°.

Temperatures are to be expressed in centigrade.
Screen apertures and diameters of wire are equal, giving 25 per cent. screening area.

GOLD AND SILVER TABLES.

It is the practice of Continental and South American engineers to report the values of ore in grammes per metric ton. English engineers generally employ the method of quoting values in grs. and dwts., in some cases per long ton of 2,240 lbs., in others per short ton of 2,000 lbs.

TABLE for Conversion of Grammes per Metric Ton into Grains, etc., per Long and Short Ton.

Grammes per Metric Ton.	Per Short Ton.		Per Statute Ton.		Grammes per Metric Ton.	Per Short Ton.		Per Statute Ton.	
	Dwts.	Grs.	Dwts.	Grs.		Dwts.	Grs.	Dwts.	Grs.

Alluvial or Placer Mining.

Deposits of auriferous or tin-bearing alluvial gravels are termed placers, alluvial drifts, or more simply alluvials. They are classified as shallow or superficial and deep-lying, sometimes called deep leads. Deep leads are accumulations of gravel from extinct or ancient rivers. They are mostly capped by igneous flows, as in California and Victoria, though sometimes they may be buried under recent gravels or drift, as at Lightning Creek, B.C., and the Lena Goldfields in Siberia.

The methods of mining used to exploit deposits of this character resemble pillar and stall in some cases and long wall in others. In California the gravel beds can be attacked by means of adits which also serve as drains for the large amount of water present. When the topography of the ground permits adits being used, the cost of mining is low, as at the Hidden Treasure, California, where the costs average 4*s.* 6*d.* per cub. yd. of gravel washed. In the Deep Leads of Victoria, where the pumping charges were unusually large (eleven million gallons per day being raised from one mine), the total cost per cub. yd. was 12*s.* to 15*s.* At the Lena Goldfields the total cost is from 20*s.* to 30*s.* per cub. yd. of gravel washed.

Superficial Deposits.—All gravel under 60 feet in thickness may be termed shallow or superficial gravels. Surface gravels are worked by the following methods:—

Panning.—A miner can pan ½ cub. yard to 1 cub. yd. of gravel per 10-hour shift, depending on character of ground and nearness to water; 100 pans per day is a good day's work. Gravel in place is usually estimated at 3,000 lbs. per cub. yd., and the standard sheet iron pan 16 ins. diam. at top and 10½ ins. diam. at bottom will hold 20 lbs.; 150 pans full will make a cub. yd. of dirt.

Rocker.—A man can rock ordinarily from 2 to 3 cubic yards of gravel per day, and save, in practical mining, 90 per cent. of the gold. In alluvial examinations the rocker plays a most important role, and is used in conjunction with the pan for determining the gold contents of any parcel of gravel. When used for this purpose, the design of the rocker differs slightly from that of the ordinary miner's rocker. A well-designed rocker, carefully employed, should save practically all the gold. The plans of most rockers, as published from time to time, are those of the ordinary mining rocker, which is too short and set on too great a grade for use in saving fine gold. If much fine gold is present in the gravel, it will be advisable to use a strip of common Brussels carpet, laid along the floor of the rocker. This carpet is held in place by cleats and so can be easily removed in cleaning up.

Long Tom or short sluice can handle 3 to 10 cub. yds. of dirt per day, depending on the amount of water available and the character of the dirt.

Hand Sluicing.—Capacity of a sluice box depends upon the amount of water, grade of sluice, deposition of tailings, and character of gravel. No capacity can be given. Grade of sluice varies from 2 ins. to 21 ins. per box (12 ft.). An ordinary sluice box is made from 2-in. planks, and is 12 ins. wide by 12 ft. long.

Grade and Duty of Sluices.

Grade and Duty of Sluices.—The relation of actual width to the best ratio of quantity to width may not be very significant, but there is a notable increase in efficiency in passing from the smallest widths to the larger, and boxes less than 1 ft. wide are to be avoided, especially if the gravel is coarse. Treating 30 to 40 mesh sand on a 1 per cent. grade (say 1¼ in. per 12 ft. box), one sluice head of water requires a channel 2 ft. wide to enable it to attain maximum duty. On a 2 per cent. grade, half a sluice head requires 2 ft. of width, the quantity of water required for maximum duty with a fixed width diminishing with increasing grade, but at what rate there are insufficient data to determine. Apparently the best width required for constant quantity of water varies directly as the grade. Coarser material requires a greater depth of water, and for 4 to 6 mesh gravel on a 2 per cent. grade, 1 ft. of width per sluice head is indicated. Variations up to 50 per cent. in the water make little difference to its duty, consequently the actual position of the optimum is not easily determined. Naturally the capacity of the sluice itself is correspondingly varied, and the mode of transportation and the saving are doubtless affected in any case.

The rate at which duty varies with slope is the resultant of so many variables that no law can be stated for all cases. In the neighbourhood of the best conditions the Utah experiments support the approximate rule that duty (water, width, and material being constant) varies as the 1·75th power of the grade. A single experiment with natural gravel on low grades by the U.S. Geol. Survey gave the 1·84th power. (*R. T. Hancock.*)

Good modern practice provides about 1 ft. of sluice-box width for every 2 cub. yds. of average material treated per hour, and 3,000 gallons of water per cub. yd. treated on a grade of 6 ins. to 12 ft.

Besides the ordinary feeding of sluice box by means of hand shovelling, many modified methods of feeding and disposing of tailings are employed. In Russia and Siberia the favourite method in use is to transport the gravel to and from the sluice box (here greatly modified from the plain open sluice box) by the employment of horses and small carts. This is a most expensive system and the yardage treated is small. Other variations are: the use of wheel barrows, tramming by cars, handling gravel by means of derricks, digging gravels by means of steam shovels, and loading into cars or direct into sluice, feeding sluice by means of scrapers operated by horses or steam power (drag-line scrapers).

The methods of preventing accumulation of tailings are to deposit them in running water or to remove them by means of drags, belt or link elevators, or hydraulic elevators.

HYDRAULIC MINING.

Hydraulicing proper is the method of mining by which jets of water under high pressure are thrown against a gravel bank, thereby undermining the gravel which falls, and is carried by the current into the sluice. The necessary pressure is obtained either by natural means, i.e. by conveying the water from some source having a greater elevation than the working face, or by pumping directly into the supply pipe by powerful pumps. In the former case water is conveyed to the working by means of pipes, flumes or ditches. Ditches are generally most convenient and economical for conveying water for long distances, but sometimes the nature of the ground is such (either too porous or too rocky and difficult to excavate) that a flume becomes cheaper. When lumber is abundant wooden flumes are built, but in many cases, especially in the tropics, where wood rots rapidly, sheet steel flumes are preferable. Steel flume per foot, including rivets, angle iron, etc., ready for transport, costs from 4*s.* to 1*l.*; the sizes vary from a cross-section of 1·28 sq. ft. to 20·48 sq. ft. From the ditch or flume the water is fed through a strainer into a pressure box. From here, a pipe leads to the Y's, which in turn lead to the monitors or giants.

Monitors or Giants.

Monitors or Giants.—These are appliances consisting of a base for attachment to the pipe line and a long conical reducing piece, arranged with one or more joints so that it can be rotated in any direction horizontally and through a very wide angle vertically. The smaller or conical end is fitted with a nozzle butt to which different sizes of nozzles may be attached as circumstances may require. Modern giants are fitted with deflectors, attachments on the butts whereby the giant is turned or deflected by means of the force of the water itself. The high-pressure giants also have ball-bearing joints.

Nozzles from 2 ins. up to 10 ins. are used, working under heads or pressure from 100 up to 600 ft. or more.

The amount of gravel which can be washed down will depend upon its nature, upon the volume and pressure of the stream of water issuing from the nozzle, and is also dependent in no small degree upon the skill of the operator who handles the giant.

The following gives the approximate amount of gravel washed under various heads :—

Effective Head in Feet.	Size of Nozzle.	Flow in Cub. Ft. per Minute.	Approximate amount of Gravel in 24 hours in Cub. Yds.	Weight of Giant. Lbs.	Price of Double Jointed Ball Bearing Giant.
					£
100	2 ins.	104·88	160	120	28
200		148·32	230		
300		181·61	280		
400		209·82	320		
100	4 ins.	420·06	650	225	55
200		594·00	930		
300		727·56	1,130		
400		840·12	1,300

400		5248	8,140		

(*Hendry.*)

Hydraulic Monitors and Pelton Wheel Jets.

J. J. Garrard (*Trans. I.M.M.* 1917) gives a table of discharges in cubic feet per minute for different sizes of nozzles and various heads derived from the formula : Delivery in cub. ft. per min. $= 3{\cdot}75\, d^2\sqrt{P}$, where d = diameter of nozzle opening in ins. and P = gauge pressure in lbs. per sq. in., or effective head $\times 0{\cdot}4326$. An equivalent formula given by him is $2{\cdot}468\, d^2\sqrt{h}$, where h = effective head in ft. The factor 2·468 allows for a nozzle contraction coefficient of 0·94, whereas Hendry's figures in the above table are based on the theoretical value 2·624, and make no such allowance.

Costs.

The costs per cub. yd. were at North Bloomfield 2·05*d.* per cub. yd. and at La Grange 3*d.*

In British Columbia one and a half million cub. yds. were mined and washed at a working cost of 0·97*d.*

In Northern California placer ground containing only 1·26*d.* per cub. yd. has been profitably worked. The amount of gravel washed was 1,251,399 cub. yds., yielding 6,330*l.* The profit obtained was 821*l.*

Hydraulic and other Elevators.

When a hydraulic mine possesses an insufficient slope of bed rock for moving material (the lightest grade permissible being 220 ft. to the mile) other methods of disposing of the gravel 'piped' must be employed. Where water under pressure is cheap and abundant the hydraulic elevators are employed. They are of the pipe type—either Hendry, Evans or Campbell and the Giant Elevator.

The pipe elevator operates on the principle of an injector. Water under pressure is discharged through a nozzle set within a steel jacket, creating a vacuum, and causing water and sand and gravel fed into intake to rise to a height corresponding to 10 per cent. of the head under which the water is applied.

Three sizes are made: 10-inch throat 3½–4½ inch nozzle, using 300 to 500 ins. of water; 12-inch throat 4½–5 inch nozzle, 500 to 750 ins. of water; 15-inch throat, 750 to 1,000 ins. They weigh about a ton and cost 250*l.*

In South Oregon, U.S.A., at the Weimer placer mine, two hydraulic elevators are employed to handle the gravels. One of them has a lift of 39 ft., and operating with a head of 330 ft., uses 11 cub. ft. of water per sec., besides taking all water from two No. 2 Giants. The second elevator has a lift of 9 ft., a head of 125, and uses 18 cub. ft. of water per sec. besides all the water from the first elevator. This makes a final discharge of 40 cub. ft. per sec.

Giant Elevators.

Giant Elevators.—Besides undermining and cutting the gravel it has been discovered that gravel can be effectively 'driven' up a slope or incline to a raised line of sluices by means of the power of water under pressure. An elevator based on this principle is termed a 'stacker.'

In California a stacker was operated as follows: A chute was built sloping upwards at 30°. This was 4 ft. wide by 24 ft. long and constructed of 1½-inch planks. Riffles 2 ins. apart and with a drop of 2½ ins. between were laid across the bottom. These were covered by an iron grizzly. At the foot of this chute a 3-foot sump was dug in which was set up a hydraulic elevator with a 12-inch throat and worked by a 5-inch giant. This elevator, working under a 90-foot head, elevated to 16 ft. vertically the seepage, fine and water from two field-giants.

Twenty feet in front of the stacker was installed the 3-inch drive giant. Two 4-inch field-giants wash the gravel to the chute and the drive giant forces it up the stack, the fine material falling through the grizzly and down the riffles to the elevator, which raises it to the sluice-boxes.

The field-giants handled 600 cub. yds. per 24 hours, and the gravel could easily be raised to 25 ft. vertically by means of the drive giant. The cost of handling material exclusive of equipment was under 2½*d.* per cub. yd. (*S. S. Smith.*)

Ruble Elevator.

Ruble Elevator.—The Ruble elevator is constructed on the above principle, but it is more portable and does away with the hydraulic elevator. It is also self-contained, as the sluice-box is part of the machine.

In Idaho, U.S.A., this elevator has been tried with excellent results (*see* Porter, T.A.I.M.E., 1909, for a detailed description of this elevator). The following points are claimed to its merit: 1. It handles larger rocks with less water than other types of elevators. Handles boulders up to 1 ton in weight. 2. It dispenses with the boulder crew, either at the mine, ground, sluice-box or dump. 3. It saves the gold and the gold-saving department may be protected by lock and key. 4. The gravel is picked up in close proximity to the giants, the gold immediately extracted, and the boulders and other waste material dropped back on bedrock previously worked off, instead of being transported a long distance to the dump. It makes its own dump.

Mechanical Elevator.

Mechanical Elevator.—In regions where water is neither cheap nor abundant, in handling gravel or tailings, resort must be made to some form of mechanical elevators. A mechanical elevator was erected some years ago on Bonanza Creek, Alaska. This was made of a frame of steel, 49 ft. high, mounted on wheels. The gravel was elevated by a bucket line of the close-connected type, 76 buckets in all, each with a capacity of 3 cub. ft. each. These discharged at a rate of 26 per min. directly into a sluice-box. The pit was drained by means of a 12-inch centrifugal pump, assisted by a hydraulic jet. The power was 200 h.p. in all, 35 for the bucket line and 165–175 for the pumps. The actual capacity per day was 1,500 yds. (*T. A. Rickard*). The first cost of this machine was high, and in actual running it proved costly in operation and repairs. Another machine of the same type, but employing a heavy dredge bucket, is being erected in Eastern Canada. No results of actual working are yet to hand.

Centrifugal Pumps.

Centrifugal Pumps as a means of elevating gravel and tailings have been extensively employed in Australia. It is claimed that with wood fuel at 7*s.* per ton of 50 cub. ft. and European rate of wages paid, to elevate tailings with pumps should not cost more than 2½*d.* per cub. yd. of solid. Thompson & Co., of Victoria, are the makers of gravel pumps suitable for this class of work. Their pumps vary in size from 3½ ins. to 16 ins. The capacity of solids per hour from 7 to 150 cub. yds. The indicated horse-power from 2½ to 583. The combined suction and delivery head from 10 feet to 100. An installation of this kind possesses the advantage of being cheaper to erect and easier to move than the belt or bucket type of elevators mentioned. However, where there is an undue amount of large stones present in the gravel, the latter type is preferable.

Dredging.

The most important form of alluvial mining is dredging. In 1913 there were 70 dredges at work in California alone, 55 in Russia and Siberia, and 30 in New Zealand. When all conditions requisite for successful working are present, when the ground has been properly proved and well designed and effective dredge installed, then this type of mining is the safest and surest of all forms of mining investment.

Dredging properties call for certain conditions, and unless these exist the success of the enterprise suffers. The conditions are: 1. The presence of gold, which should be evenly distributed throughout the gravels. 2. Sufficient gravel to warrant the installation of at least one dredge. 3. Soft even bedrock. 4. Absence of boulders. 5. Absence of permanently frozen ground. 6. Absence of great amount of clay. 7. Absence of floods. 8. Surface should be of an even contour—not rough and broken. 9. The ground should retain sufficient water to float dredge (50 miner's ins.). 10. The economic conditions, i.e. labour, transport, climate, vary inversely with amount of gold in gravel.

Broad flood plains or ancient lake gravels form more suitable dredging ground than does deposit, situated in narrow rocky gulches. Frozen ground cannot be dredged without preliminary thawing. Dredging of gravels lying in rapid rivers is risky as there is always danger of losing the dredge by sudden floods. Gravels from 10 ft. to those 60 ft. below water and 20 ft. above have been successfully dredged.

The modern gold dredge consists of a hull or pontoon of wood or steel upon which is mounted the digging device, a line of buckets capable of being raised or lowered; the washing plant; the gold-saving tables; the stacker or elevator which disposes of the tailings, the sand-pump and the motors or engines. The dredge digs the gravel, washes it, extracts the gold and disposes of it in the form of tailings. It digs its own pit. Suction dredges are used at times. There are two types of bucket dredges, the New Zealand and the American type. The latter has been evolved from the New Zealand dredge to suit conditions existing at Oroville, and it now forms a distinct type and is used on all properties controlled by American capital.

Both types have their advocates and both their utility.

Briefly, the New Zealand type of dredge is a lightly constructed, light-powered boat of steel pontoons, with open connected buckets, and employs a headline in digging. Its first cost is low, its capacity small, and it is better adapted to work in ground of a loose, easy-digging nature. It is too lightly built for heavy ground.

The Californian or American dredge is costly, very heavily built, with close-connected buckets, digs with spuds, and till lately built with wooden hulls.

For properties where the transport is high, as in parts of Siberia, and where heavy repairs are difficult, a well-built New Zealand type of dredge, with ample stock of spares, is preferable. Indeed, its choice is imperative in some cases, for the high transport costs to some properties exclude the use of the ponderous American type of dredge. On the other hand, cheap transport, access to machine shops, and with heavy or stiff semi-cemented gravel, or large deep deposit of fair digging gravel (the latter permitting the handling of enormous daily yardages) are conditions favourable to the use of the American dredge.

The following figures relate to both the Californian and New Zealand types of dredge. In the former case the dredges quoted are of the Standard American type, i.e. built with wooden hulls, the stacker of the rubber-belt type and the dredges electrical equipped throughout. The cost includes erection in America. The yardages given, while estimated, have been actually accomplished in Oroville ground.

CALIFORNIAN TYPE.

Size of Buckets.	Estimated capacity per month. In cub. yds.	Digging Depth below Water Line.	Weight exclusive of Hull.	Price Erected.	Horse Power.
Cub. Ft.		Ft.	Tons.	£	
3	45,000– 60,000	36	350	12,000	180
5	90,000–110,000	36	520	16,000	220
7	110,000–150,000	35	576	19,000	300
8½	150,000–185,000	48	1,000	36,000	560*
13	250,000–280,000	40	1,100	50,000	415

* This includes 100 h.p. for pump for two monitors or giants.

In the following figures of New Zealand type the dredges referred to are built in England, and the price is f.o.b. London. The weights include steel hull. The capacities are over-estimated in this case, as the yardage given has never been accomplished in actual practice. For actual capacity the yardages quoted should be reduced from 25 per cent. to 50 per cent. according to conditions of ground.

In Siberia the following yardages were realised by this type during a season of seven months : 4½ ft. dredge, 165,100 cub. yards ; 5 ft. dredge, 190,500 cub. yds. ; 6 ft. dredge, 228,600 cub. yds. ; 7 ft. dredge, 254,000 cub. yds.

These dredgers are equipped with an open connected bucket line and a pan stacker, except the first, which has no elevator but discharges from a sluice in the rear. They are all steam driven.

NEW ZEALAND TYPE.

Size of Buckets.	Estimated Capacity. In cub. yds.	Digging Depth below Water Line.	Weight including Hull.	Price, f.o.b. London.	Horse Power.
Cub. Ft.		Ft.	Tons.	£	
3	30,000	20	100	3,000	35
4	40,000	20	180	7,000	—
5	50,000	26	220	8,000	56
6	60,000	40	280	9,100	—
7	74,000	32	350	11,500	180
3½	—	20	235	4,400	50
5	—	20	250	4,625	60

Note.—The figures for two last dredges are for machinery only. The hulls of these were of wood.

Cost of Dredging.

The Cost of Dredging depends on the character of the ground, the climate, transport, labour, power, yardage treated, make of the dredges, and the personal equation of the management. It varies greatly. In countries where seasons are short and labour and supplies high, i.e. in the Far North, Alaska and Siberia, the costs are highest. In Alaska 2,300,000 cub. yds. were dredged at a cost of 1*s.* 4*d* per cub. yd. This included thawing charge amounting to 7½*d.* per cub. yd. In Siberia the cost with one 5-ft. open connected dredge averages about 6*d.* per cub. yd.

In California a dredge having 3½ ft. bucket digging in ordinary loose gravel and sand had an average working cost for six years of 3·9*d.* per cub. yd. The new 16-ft. cub. ft. dredge in California, handling 300,000 cub. yds. a month, is working at a cost of 1*d.* per cub. yd.

DATA ON OPERATION OF CALIFORNIAN DREDGES.

Capacity of Buckets.	Period of Observation.	Actual Operating Time.	Gravel Dug per month.	Depth of Gravel.	Cost per cub. yd.	Character of Ground.
Cub. Ft.	Months.	Per Cent.	Cub. Yds.	Ft.		
3	12	82·3	38,200	27	3·50*d.*	Favourable
3½	12	83·7	38,400	35	3·66*d.*	Compact
5	12	—	67,600	36	3·32*d.*	Medium
7	12	79·0	84,700	28	2·20*d.*	Compact
7½	12	73·2	113,900	70	2·08*d.*	Medium
8	6	72·2	97,000	42	1·96*d.*	Light
13½	8	77·7	225,000	19	1·15*d.*	Fine and light

At Waipoi, New Zealand, 212,000 cub. yds. of soft ground were handled in 45 weeks at a cost of 3·3½*d.* per cub. yd.

In Victoria, during 2,006 weeks 14,927,269 cub. yds. of material were handled by 50 dredges at a cost of 2·67*d.*

Thirteen dredges operating in California for the Natomas Consolidated in 1914 handled 25,850,000 cub. yds. at a total cost of 5·8 cents per yd. Of these one handled nearly 2,000,000 at 2·5 cents and another over 2,000,000 at 7·14 cents. Ten dredges of the Yuba Consolidated operating in California in the same year handled 17,000,000 cub. yds. at a cost of 4·40 cents per cub. yd., varying from 3·29 to 6·86 cents. The Conrey Company in Montana, between 1906 and 1915, treated 32,000,000 cub. yds. at 5·91 cents, the cost ranging from 9·79 cents in 1906 to 5·99 cents in 1915. The gradual reduction in total costs was mainly due to the increasing yardage as larger and more powerful dredges were installed, the increased yardage lowering the indirect or overhead charges. Direct operating charges did not vary much, averaging 5·91 cents. The dredges of a company operating in Colorado handled in 1914 3,000,000 cub. yds., at 5·9 cents. One dredge in Idaho in 1914 handled 4,670,000 cub. yds.—a world's record—at a total cost of 2·77 cents per cub. yd. In Colombia, South America, the Pato dredge in 1914 handled 920,000 cub. yds. at an operating cost of 18·4 cents and a total cost of 23·2 cents per cubic yard. This was an 8-ft. bucket dredge. The 5-ft. Gumaos dredge in the Philippines handled 1,850,000 cub. yds. in twenty-seven months at a cost of about 12 cents per cub. yd. In Alaska in 1917 seven dredges of the Yukon Gold Co. operated 151 days at Dawson, handling 4,583,326 cub. yds. at an average cost of 25·81 cents per cub. yd. Sixty-five acres, or 60 per cent. of the ground, was frozen and required thawing by steam. At Idatarod the company's dredges operated 192 days, handling 871,045 cub. yds., at 48·1 cents. The company's five dredges in California handled 6,161,941 cub. yds. at an average cost of 3·71 cents per cub. yd. Hydraulicing operations treated 2,143,444 cub. yds. at 11·8 cents, the duty of the water being 4·18 cub. yds. per miner's inch. (*Bull.* 121, *U.S. Bureau of Mines.*)

SECTION XXXVI

PART II

MINERAL VALUATION.

(By Professor Henry Louis, M.A., D.Sc., A.R.S.M., M.Inst.C.E., etc.)

General Principles.

Under the head of Mineral Valuation are included two somewhat different valuations, namely, that of a mineral property, whether worked or not, and that of a mine as a going concern ; the difference arises from the fact that the proprietor of the minerals does not as a rule work them himself, but disposes of them, usually for a royalty, to the mine-owner who works them. In cases where the mine-owner is also the proprietor of the minerals, it is generally more convenient to value the mine, the royalty derivable from the ownership of the minerals being included as a part of the profit derivable from the mining operations.

In either case it is necessary to determine the present value of a number of annuities, the latter being the annual revenue derived from the royalties or the profits, as the case may be.

The amount of the royalty per ton is generally known or can be closely approximated, being the price paid or to be paid for the mineral in its unsevered condition as it lies in the deposit.

The profit per ton must be estimated from the probable cost of working and the probable value of the mineral in its marketable condition.

The tonnage to be wrought annually must be estimated, having due regard to all the conditions of the deposit, and should be taken to be the amount that can be extracted, so as to produce the maximum total profit over the period under consideration. It is obvious that a deposit worked out with excessive rapidity will yield no profit when the interest on the capital outlay required to so work it exceeds the profit derivable from working ; on the other hand, if worked excessively slowly, the standing charges may exceed such profit. Between these extremes lies the rate of economic working ; it will generally be found that there is a considerable range of working rate, within which the economic results are practically uniform, and the best rate within that range is usually determined by market conditions or other purely commercial considerations.

The probable total quantity of mineral that can be economically produced from the property must next be calculated, meaning thereby the amount which is as likely to be exceeded as to be fallen short of ; it is obvious that the quantity that can actually be produced from any property can never be known until the property has been exhausted, when the information is naturally valueless. Hence the question becomes one of probabilities, never one of actually ascertained figures, and must always be considered as subject to the laws of probability in the mathematical sense. The quantity thus estimated divided by the estimated or proposed annual output determines the probable life of the property ; if the latter is held under mineral lease, the period of which is less than the probable life, the length of the lease is substituted for the probable life in the calculations.

In the following formulas, the annual income = annual tonnage × royalty per ton, or annual tonnage × profit per ton, as the case may be, will be designated by a.

The number of years of life of the property or of the lease will be designated by n.

The problem then becomes that of determining in the first instance the present value (P) of a series of annuities of £a for a term of n years.

Generally the ordinary compound interest formulas apply, which show that X pounds invested at a rate of interest i per unit will amount in n years to $X(1+i)^n$, and conversely the present value of Y pounds payable at the end of n years, allowing interest at rate i, is

$$\frac{Y}{(1+i)^n}$$

(See page 3.)

The main difficulty in all mineral valuations lies in determining the proper rate of interest to allow. The rate of interest in operations in which there is practically no risk, that is to say where the probability of the payment of capital and interest in full is practically unity, may be taken to be the rate obtainable by investment in such securities as Trustee Stocks. In all mining operations the risk is always greater, or in other words the probability of payment is less, hence a higher rate of interest is demanded to cover the risk. If i be the safe rate of interest the risk rate may be expressed by ri, where r is a number greater than unity, depending upon the conditions of the case, and which may conveniently be described as the risk factor; it may also be defined as the reciprocal of the fraction representing the probability of success, and is therefore greater the more hazardous the nature of the enterprise. In practice the risk factor ranges from 2 to 5, being lowest in well-proved bedded deposits, the uniformity of which has been determined by experience, and highest in veins or masses in which values are known to be very irregularly distributed. It is less where money is invested merely in the purchase of a mineral property than when it is invested in a mining enterprise, because royalties form a first charge on revenue and are almost invariably secured on the assets of the mining enterprise, whereas the latter can take only remainder profits, which are totally unsecured.

The determination of a proper risk factor is the principal problem that the mining engineer has to solve in valuations.

Present Value.

Let $ri=s$, so that s is the rate of interest *per unit* that is required in any given case.

Some writers call i the 'accumulative' and s the 'remunerative' rate of interest; the term 'risk rate' will be adhered to here in order to emphasise that the high rate is required in compensation for the risk that the investor runs. Of course i is governed by the money market, and is the rate of interest paid on investments in Government stocks and similar first-class securities; it will be noted that s varies directly with i.

The value of the mineral property or mine *at the moment of commencing profitable operations* is therefore P, the present value of n annuities of $£a$. This should obviously be equal to the present value of sums of $£a$ payable at the end of each of the first, second, third, etc., years up to the end of the nth year, and this sum

$$=\frac{a}{s}\left(1-\frac{1}{(1+s)^n}\right).$$

It is sometimes useful to remember that, if A is the present value of $£a$ due at the end of n years,

$$\mathrm{P}=\frac{a-\mathrm{A}}{s}.$$

The expression for present value given above is often spoken of as Inwood's formula. Calculations are easily made by this formula; the table on page 6, which gives the present value of an annuity payable at the end of each year for a varying number of years and at various rates of interest, obviates this calculation, as it is only necessary to multiply the present value taken from the table by the amount of the annuity. The table gives the values of

$$\frac{(1+s)^n-1}{s(1+s)^n}$$

for different values of n and s; in the headings of the table the rates of interest are given per cent. and not per unit. Again, the sum of n annuities of $£a$ payable at the end of each year up to the end of the nth year is

$$\frac{a}{s}\left((1+s)^n-1\right),$$

and the present value of this sum is

$$\frac{a}{s}\cdot\frac{(1+s)^n-1}{(1+s)^n}$$

as before. Again, the annuity may be looked upon as part interest on the present value, the remainder being applied annually to the reduction of the capital, interest being paid each year on the unredeemed portion of the capital. If calculated on this basis the same result is obtained.

There is yet another method of looking at the problem. The annuity exceeds the simple interest on the present value by an amount equal to $a-Ps$ in each year; if this difference be allowed to accumulate at rate s for n years it will amount to

$$\frac{a}{s}\cdot\frac{(1+s)^n-1}{(1+s)^n}=\mathrm{P},$$

that is to say, to the original capital, as it obviously should do, because the purchaser of an annuity, spending each year only the interest on the capital invested, should get back his capital at the end of the period, because this operation would be equivalent to investing the capital at the given rate of interest during the given term of years.

This last method of looking at annuities has given rise to another method of calculating them, known from its originator as Hoskold's method. He considers that the risk rate of interest s should be allowed upon the capital, but that the difference between the annuity and the interest $(a-Ps)$ should be looked upon as accumulating at a safe rate i because it is not necessarily invested in the risky mining operation. This view gives rise to the formula

$$P=\frac{a-is}{\frac{i}{(1+i)^n-1}+s}.$$

This value may be taken out from any ordinary tables as follows:—

$$\frac{(1+i)^n-1}{i}$$

is the amount of £1 at interest i for n years, and the reciprocal

$$\frac{i}{(1+i)^n-1}$$

is the sinking fund for the repayment of £1, i.e. the sum to be set aside annually and allowed to accumulate at interest i in order to amount to £1 in n years. These values are obtained from tables (see pp. 3 and 9). The denominator of the fraction in Hoskold's formula can be taken out by adding the risk rate to the sinking fund for £1 at interest i for n years.

This method is often used, but is not one that fairly answers all the tests of a true annuity formula. Nevertheless, it is used by valuers on the grounds that the difference between the annuity and the simple interest cannot, in fact, be invested at the risk rate s, but must be invested at the safe rate i, and that this method, therefore, more correctly represents what would obtain in actual practice.

Hoskold's method depends upon considering only one out of the various methods in which the true annuity formula may be looked at; obviously the two can be made to give the same result by selecting suitable risk factors in each case. Thus if r is the risk factor in Inwood's formula, and r' in Hoskold's method, the present values will be the same whichever formula be used, when

$$r'=\frac{r(1+ri)^n}{(1+ri)^n-1}-\frac{1}{(1+i)^n-1}.$$

It follows that r' must be greater than r; in other words Hoskold's method allows a rate of interest higher than the stipulated risk rate, and hence puts a lower present value on a given annuity. It need hardly be said that both his method and the ordinary method provide equally for the replacement of the original capital, if suitable sums are set aside in each case out of the annuities received.

Increasing and Decreasing Values.

The above methods of valuing mineral properties tacitly assume that the mine will forthwith commence to produce at its full rate of output and will continue to do so until the mineral is worked out; this is, of course, not the case in practice, a mine only reaching its full output after several years, and this gradually declining again as the deposit approaches exhaustion. There would be no difficulty in allowing for this in the valuation, but as a rule it is neglected; as has already been pointed out, the figures on which the valuation is based are only probable, not actual figures, so that there is no use in endeavouring to attain minute accuracy in these computations.

There is obviously no difficulty in introducing these refinements if it is considered desirable; the computation is made as above for the estimated period of full production deferred during the period of production at a lower rate than the full output; the income expected in each year of output less than full output is calculated and its present value is determined, and all these present values are added together to obtain the total present value of the property.

If preferred, calculations can also be made directly, whether the annuity increase or decrease in arithmetical or in geometrical ratio. Let c be the income in the first year and let it increase or decrease by b each year, so that the income for the second year is $c \pm b$, for the third year $c \pm 2b$, etc., during n years. Then the present value of this annuity on the Inwood method is :—

$$c\left(\frac{(1+s)^n-1}{(1+s)^n s}\right) \pm \frac{b}{s}\left(\frac{(1+s)^{n-1}-1}{(1+s)^{n-1}s}\right) \mp \left(\frac{(n-1)b}{s} \cdot \frac{1}{(1+s)^n}\right).$$

These values can be taken out from the tables: the first expression is, as before, the present value of £c for n years at rate s; the second is the present value of £$\frac{b}{s}$ for $(n-1)$ years at rate s, and the third is the principal which will amount to £$\frac{(n-1)b}{s}$ in n years at rate s. (See Present Value Table, p. 11.)

If Hoskold's method be used, the present value is :—

$$\frac{c+\frac{b}{i}}{\frac{i}{(1+i)^n-1}+s} \mp \frac{nb}{i-s+s(1+i)^n}.$$

The first part of this expression is the present value of an annuity of £$\left(c+\frac{b}{i}\right)$ calculated for n years by Hoskold's method; in the second expression $s(1+i)^n$ is the amount of £s at interest i for n years (see table, p. 3).

Again, let c be the income for the first year and let it increase geometrically by a ratio k, so that the income for the second year is ck, for the third ck^2 . . . etc., during n years. Then the present value of the annuity on Inwood's method is

$$\frac{c}{(1+i)^n} \cdot \frac{k^n-(1+i)}{k-(1+i)}, \text{ or, if } \frac{k}{1+i} = f, \text{ it is } \frac{c}{1+i} \cdot \frac{f^n-1}{f-1}.$$

On Hoskold's method the present value becomes :

$$c \cdot \frac{(1+i)^n-k}{1+i-k} \cdot \frac{i}{i+s[(1+i)^n-1]}.$$

All the above calculations are based upon the hypothesis that the annuity is paid at the end of each year; in practice royalties are mostly paid quarterly, and mining dividends at least half-yearly. To meet this point, for n substitute $2n$, and for s substitute $\frac{s}{2}$ when payments are made half-yearly, these becoming $4n$ and $\frac{s}{4}$ respectively when payments are made quarterly.

Dead-rent.

In computing the present value of mineral royalties 'certain rent' or 'dead-rent' has sometimes to be taken into account. Mineral leases usually stipulate for a definite dead-rent, which may be in addition to the variable royalty, or may be a merging dead-rent, that is to say that the amount of royalty to be paid is determined by the tonnage which is in excess of that which corresponds to the dead-rent at the agreed royalty rate. As the dead-rent is payable in full, whatever the results of the mining operations, its present value must be calculated not on the mining risk rate of interest, but on a rate obtained by multiplying the standard safe rate by a factor depending only on the financial stability of the lessee. This consideration may be neglected when the dead-rent is very small compared with the expected annual royalty, but must be taken into account when it is considerable, the present value of the whole royalty, in the case of an additive dead-rent, or of the excess of royalty, in the case of a merging dead-rent, being computed as above and added to the present value of the dead-rent.

Relinquishment.

When, as is often the case, the lessee has power to relinquish the lease after a given number of years or at stated intervals, there is a risk that the lease may be cancelled because the mine proves unprofitable or because the deposit is exhausted, and the rate of interest applicable to the

dead-rent during the definitely fixed period is estimated as above, but it must be multiplied by a risk factor representing the probability of such relinquishment in computing the present value of the dead-rent during the successive periods. Here, again, the difficulty of the problem consists entirely in determining the proper probability factor.

Deferment.

In opening a mine there is always a period of development during which no mineral is produced, or at any rate none is produced profitably, whilst the main capital expenditure in the way of shafts, adits, plant, machinery, etc., is incurred. The present value at the commencement of the profit-producing period as found above must therefore be looked upon as deferred for the requisite number of years and the actual value determined. If V be the actual value at the commencement of mining operations and d the number of years occupied in development

$$V = \frac{P}{(1+s)^d}.$$

The risk rate of interest must be taken, because the capital is being spent and is subject to the full risks of the mining operation.

The annuity formula and deferred value formula may be combined, thus :—

$$V = \frac{a}{s} \cdot \frac{(1+s)^n - 1}{(1+s)^{(n+d)}}.$$

It is, however, better as a rule to make the computation in the two stages, as above.

The table on page 11 facilitates calculation of actual values; it gives the present value of 1*l.* due at the end of a varying number of years at varying rates of interest; the present value taken from the table and multiplied by P gives the value of V. This table gives the values of

$$\frac{1}{(1+s)^d}$$

for different values of d and s, rates of interest being expressed in the headings as percentage rates.

Mr. O'Donahue has proposed a method of calculating deferments that has some analogy with Hoskold's method of computing the present values of annuities, being also a two-rate method. He considers that simple interest at the risk rate s should be allowed on the actual value V, whilst the interest assumed to fall due accumulates at the safe rate i, whence

$$V = \frac{P}{1 + \frac{s}{i}\left[(1+i)^d - 1\right]}.$$

Since interest is never in fact paid nor payable on the actual value, this method cannot be recommended. This formula and the ordinary deferment formula may be connected as follows :— Let r be the risk factor in the ordinary method and r' the risk factor when O'Donahue's method of deferment is employed ; then

$$r' = \frac{(1+ir)^d - 1}{(1+i)^d - 1} \text{ and } r = \frac{\sqrt{1 + r'[(1+i)^d - 1]} - 1}{i}.$$

In some cases, however, where two different rates are involved, another method must be adopted. In the most general case, it is required to determine the present value, V, of a mine that will take d years to develop, during which time no profits are earned, and which will then yield a profit of £a per annum during n years, it being a condition that the original capital shall bear interest at the risk rate s, but that all accumulations can only be invested at the ordinary investment rate i. At the end of the n years the investor is entitled to receive back his capital plus the accumulations of interest (Vs per annum) at the rate i or

$$V + Vs\,\frac{(1+i)^n + \quad - 1}{i}.$$

This must be equal to the amount of an annuity of a per annum for n years, or

$$\frac{a}{2}\left[(1+i)^n - 1\right].$$

Equating :—

$$V = \frac{a\left[(1+i)^n - 1\right]}{i + s\left[(1+i)^{n+d} - 1\right]}.$$

This is the same result as follows from the method of calculating deferred annuities, published by Mr. George King in his 'Theory of Finance.' Further, if $d = 0$, the above formula becomes the ordinary Hoskold formula given above.

Capital Expenditure.

From the present value, V, as determined by any of the above methods, the capital necessary to bring the mine into full work must be deducted in order to obtain the value of the mineral property ; if the capital expenditure is spread over several years, the present value of this deferred expenditure must be computed at the ordinary investment rate i, and the sum thus found deducted from V.

Deferred Development.

It occasionally happens that the valuation is required of a mineral property which it is not intended to commence to develop for a number of years ; in this case the present value must be calculated as the present value of a sum V, the payment of which is deferred for the given period at a rate of interest i per unit. The risk rate of interest must not be taken into account, because there is no mining and therefore no mining risk. If the value of V has been properly determined, making all due allowance for mining risks, the problem resolves itself into determining what capital sum must be invested in safe securities in order to produce the sum V at the time when mining operations are to be commenced. Special attention is drawn to this point, because mistakes are often made in confusing the rate of interest required during the development period and the rate required during the period preceding development, the latter depending on ordinary acutarial considerations and not on the risks incidental to mining.

Investment Value.

Finally, in comparing investments in mines or in minera properties with other investments of capital, the effect of Income Tax as well as of Mineral Rights and Increment Value Duties must be taken into account. Mines and minerals both constitute wasting assets, but income tax is charged upon the gross revenue derived therefrom, hence not only on the true revenue, but also on that portion of the gross revenue that ought to be looked upon as forming a sinking fund set aside to replace the original capital at the end of operations ; mineral rights duties specifically affect only mineral properties and thus constitute an additional charge upon these. In both these respects, therefore, these investments are at a disadvantage compared with ordinary investments, a fact that requires due consideration in computing mineral valuations as a basis for the investment of capital.

METALLURGY

By Owen W. Ellis, M.Sc. (B'ham.), A.M Inst.C.E.

(With contributions by A. H. Allen, M.I.E.E., F. J. Cook, Frank Foster, M.Sc., L. C. Harvey, Colin Livingston, D. Richardson, Wh.Exh., A.M.I.M.E., Dempster Smith, M.Sc., M.I.Mech.E., and others.)

UNITED BRASSFOUNDERS & ENGINEERS LIMITED.

UBEL UBEL

The demand for definite standards of uniform quality in special alloys led to the production of the world-favoured STELLA BRAND.

STELLA ALLOYS are known the world over for their unfailing reliability, their freedom from impurity and their uniformity.

MANGANESE COPPER
PHOSPHOR TIN
PHOSPHOR COPPER
FERRO COPPER
FERRO ZINC
SILICON COPPER
METALLIC MANGANESE

EXTRUDED BRASS & BRONZE BARS

UBEL Extruded Brass & Bronze Bars possess these advantages :—

1.—They are of uniform density and strength.
2.—Surfaces are smooth—there are no surface blemishes, flaws or blow-holes.
3.—Each part is of extreme accuracy, close to size and highly finished all over.
4.—Made by standardized processes that permit of larger production, lower selling prices, and speedy delivery.

Makers of all Sections of high-speed Turning and Screwing Extruded Brass Bars, Extruded Bars in Naval Brass, Naval and Manganese Bronze, Yellow Metal, Red Metal, etc., for Turning, Stamping and Forging. Brass Bolts and Nuts and General Turned Work from the Bar.

METALLURGY

By Owen W. Ellis, M.Sc. (B'ham.), A.M.Inst.C.E.

(With contributions by A. H. Allen, M.I.E.E., F. J. Cook, Frank Foster, M.Sc., L. C. Harvey, Colin Livingston, D. Richardson, Wh.Exh., A.M.I.M.E., Dempster Smith, M.Sc., M.I.Mech.E., and others.)

FURNACES.

CLASSIFICATION OF FURNACES.

Furnaces in which the Charge and the Fuel are Intermingled.

1. Hearth Furnaces.

(*a*) With blast. Forge for smithing. Grate for zinc-white manufacture.

(*b*) Without blast. Heap and stall for coking and roasting. Trough for liquation and drossing.

2. Shaft Furnaces.

(*a*) With forced draught. Blast furnaces for smelting ores of iron, copper, lead, etc. (see p. 2236). Cupolas for iron-foundry practice (see p. 2251).

(*b*) With induced draught. Only rarely employed.

(*c*) With natural draught. Furnaces for smelting readily fusible ores. Kilns for calcining, roasting, etc.

Furnaces in which the Charge and the Fuel are Separate.

1. Reverberatory Furnaces (Radiation).

(*a*) With forced draught. Furnaces for the refining of metals and the smelting of ores.

(*b*) With natural draught. Furnaces for the roasting of ores. Furnaces for the manufacture of wrought iron, etc.

2. Crucible, Retort, Muffle, etc., Furnaces (Conduction).

(*a*) With solid, liquid or gaseous fuel (see p. 2254).

(*b*) With electricity (see p. 2259).

Furnaces in which the Charge Supplies its own Fuel.

(*a*) Preheated furnaces with solid charge. Kilns for ore-roasting. Beehive coke ovens.
(*b*) Preheated furnaces with liquid charge. Converters for refining, etc.
(*c*) Non-preheated furnaces with solid fuel. Blast-roasting furnaces with up and down draught.

Electric Furnaces Heated by Resistance Effects.

(*a*) The charge is included in the electric circuit. Héroult aluminium furnace. Kjellin induction furnace (see p. 2259).
(*b*) The charge is heated by means of an electrically-heated conductor (see p. 2259).

Electric Furnaces Heated by Arc Effects.

(*a*) Direct heating. The charge forms one or both poles of an electric arc (see p. 2259).
(*b*) Indirect heating. The charge is enclosed in a space heated by an electric arc (see p. 2259).

Electric Furnaces Heated by Combined Resistance and Arc Effects.

Girod, Greaves-Etchells, Héroult, etc., steel furnaces (see p. 2259).

(Charles Reitell.)

A blast furnace should be designed to suit the materials used in smelting; successful designs can best be accomplished by keeping in view the best practice with particular materials. No general formula for the design of all blast furnaces, for a given output, is possible. The following points are common to all successful blast furnace plants, and should be kept in view, in new construction :—

The aim of all blast-furnace work is the production of a good marketable iron at the lowest cost. Low costs rest chiefly on low fuel consumption; low fuel consumption is governed by the quantity of fuel, dryness and temperature of blast, with correct furnace lines for the ores smelted.

Blast temperature is entirely one of stove capacity; it is essential that stove capacity should be on the generous side.

Output will depend on capacity of furnace, diameter of hearth, and will vary according to materials used, quantity and pressure of blast, dry or wet blast, temperature of blast; blast pressure should be able easily to penetrate to centre of furnace.

Bosh line angles are found to vary very little; short steep bosh lines are a decided advantage with most materials. Leading American blast-furnacemen attribute some of their remarkable results, in part, to low steep boshes and large hearths.

Furnaces with hearths 20′ 9″ in diameter are in successful operation.

TABLE VI.—CONDITIONS WHICH NORMALLY RESULT FROM VARIATIONS IN HEARTH DIAMETERS.

(*a*) Hearth Diameter in Ft. and number Tuyeres.	(*b*) Hearth Area in Sq. Ft.	(*c*) Air needed per Minute per sq. ft. of Hearth consuming 6,000 lbs. Coke in 24 hours.	(*d*) Air needed by Furnace per Minute.	(*e*) Number of Revolutions of Engine with Air Cylinder 84 × 60.	(*f*) Total Heating Surface required in Stoves combined.	(*g*) Pig Produced and Coke Consumed at Fuel Consumption of 2,240 lbs.	(*h*) Boiler Capacity required at 8 per ton coke.	(*i*) Diameter of Tuyeres.	(*j*) Minimum Diameter of Bustle Pipe.	(*k*) Bosh Diameter.

(*Forsythe.*)

In general practice, furnace shafts should have a batter of at least ·625 in. in 12 ins.; where fine ores are smelted this could be considerably increased with advantage. Diameter of bell should be 4 ft. to 4 ft. 6 ins. smaller than diameter of throat.

The furnace should be entirely enclosed in a strong steel shell, from the hearth level up.

All parts of furnace top work should be securely fixed to main shell structure.

In designing blast-furnace details the main considerations should be (1) efficiency, (2) strength, (3) simplicity.

The number of gas offtakes should be such that the gas leaves furnace as slowly as possible, so as to avoid carrying dust over to flues.

The height of furnace varies from 80 to 100 feet; with the materials used, each district has come to fix the height found most suitable for its particular conditions.

Sufficient relief area, by bleeders or explosion doors, should be provided on top of furnace to prevent injury from slips; the relief should, if possible, be directly upwards.

For hearth well and boshing nothing but the best quality of fire-brick should be used. The bricks should not be too large, so that they may be thoroughly burned.

For the upper lining a fire-brick with more wear resisting qualities can be used.

Care should be taken that all bricks when laid are properly bedded and tight built, with fire-clay joints as thin as possible.

In relining a furnace, the bear in old hearth need not be removed, but simply levelled to start building well on.

This will save much hard work and expense—experience will prove that nothing better for a hearth can be put in.

Some means should be taken to preserve the upper lines of furnace from wear where stock from bell strikes brickwork; a satisfactory way of doing this is to insert with brickwork alternate layers of cast iron or steel plates. In normal working, the stock level should be kept just high enough to allow bell to swing freely when full open.

The number of tuyeres is not so important (if sufficient area for output is provided) as equal distribution and penetrative power of blast.

There should always be a reserve of blowing power available after providing for normal maximum requirements.

Where blast-furnace gas is fully utilised and gas economy a necessity, the blowing should be done by gas engines. Where there is a surplus of gas the turbo-blower can be installed with advantage, and will prove an ideal blowing engine. Reciprocating steam-blowing engines are still being installed, but only in cases where conditions make it unsuitable or inconvenient to discard existing plant.

Cooling.—Apart from tuyeres, jumbos, and hearthcooling, any cooling appliances provided for the bosh or upper lining should be carefully considered; external or spray-cooling has the great advantage that leakage of water into the furnace is prevented, or rather more easily detected. The trouble caused by water leakage from blocks inserted in the building is considerable, and can never be fully known; it is often when the damage is done the leak is located. The latest practice is to spray-cool the bosh and sometimes the entire outside shell; by this means a much thinner brickwork can be used, the furnace preserves its original lines longer, and the lining has a longer life. Table V. illustrates the saving in labour costs with modern methods.

Stoves.—Should be as simple in design and equipment as possible, with ample facilities for cleaning and inspection, and have a good chimney draught.

Using unwashed gas, chequers should not have less than 9-in. by 9-in. openings; with washed gas smaller chequer openings can be used, giving greatly increased heating surface for same size of shell, and higher blast temperatures and lower chimney temperatures for same gas consumption. Openings 3½ ins. × 3½ ins. with 2-in. thick walls have proved satisfactory in practice.

In latest practice for heating stoves the gas and air is forced by special fan into combustion chamber, the stove burns more gas, which gives higher and more regular temperatures, with a saving up to 25 per cent. in stove construction for a given production.

Preheating the blast before entering the stove proper is in successful operation with increased average temperatures.

It is decided economy to clean blast-furnace gas, as better results are obtained.

It is no advantage to go beyond 1,550°F. in stove heats, any fuel economy being more than off-set by stove repairs.

Better results with certain ores will sometimes be obtained by running on lower blast heats; this may seem to conflict with theory, but in blast-furnace work it is often the case that sound theory follows successful practice.

Uniform ore mixtures and quality of fuel and flux should be kept in view, rather than frequent changes of ore mixture, with varying qualities of fuel and flux. It is an advantage to break hard dense ores, especially magnetites.

The approximate saving in lbs. of coke per ton of iron by increase in blast temperature is as follows:—

1,000°	to	1,100° F.,	50 lbs.
1,100	,,	1,200° ,,	40 ,,
1,200	,,	1,300° ,,	30 ,,
1,300	,,	1,400° ,,	20 ,,

Dry Blast.—Average results with dry blast give a saving of 10 per cent. in fuel consumption with 10 per cent. increase in output, more regular grade of metal, and more regular working conditions.

A blast furnace in its working and results responds readily to improper treatment; proper regulation of flux has much to do with this, and the formation of a correct slag is all important.

The slag should not be too basic or limey; this causes the furnace to become stocky and gob up. If the slag is too acid the furnace will drive harder, but trouble is sure to result with grade and quality of pig.

When the lime content of slag is high it will prove profitable to make such slag into cement; the slag form from furnaces making Bessemer iron will generally be found suitable for this purpose. Most blast-furnace slags can be easily made into first-class building bricks.

The slightest indication of irregular furnace working should be promptly attended to and put right; irregular conditions will probably show first in change of slag or irregular settling of stock. The appearance and degree of fluidity of the slag is the furnaceman's best indication of working conditions.

Irregular working at tuyeres is generally caused by water leakage from jumbos and tuyere blocks. It is quite possible for tuyeres to be shut by water leakage, in spite of very careful watching.

No tuyere in a regular working furnace will close while the blast is on except by water leakage.

Irregular working at tuyeres is sometimes caused by an alteration in burden; in this case every tuyere will give trouble, which will continue till the trouble has been put right.

The best way to open tuyeres that may have been hard closed by slips, irregular working, or water leakage, is by the application of oxygen; the apparatus used is simple and cheap: the worst stuck tuyere can be opened in a few minutes.

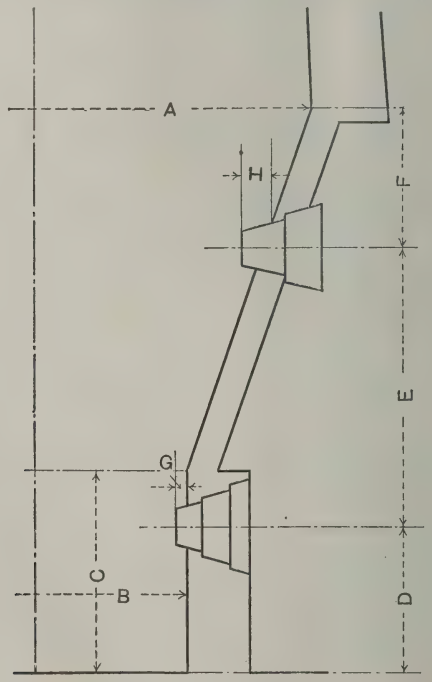

FIG. 20.—Bosh Tuyere.

Bosh tuyeres it is claimed increase the output of a furnace 20 per cent. with a slight increase in fuel consumption and more regular working. Fig. 20 and Table VII. give sizes and position of bosh tuyeres from actual practice.

(*J. S. Hollings.*)

Flue Dust.—The treatment of flue dust has developed into a distinct branch of blast furnace work; the true solution of the problem is to keep the dust in the furnace, thereby increasing production and reducing costs. Flue dust is caused chiefly by (1) fine ores; (2) soft fuel; (3) hard driving; briquetting or sintering gets over the first, but furnace design will need to be adapted to surmount the second and third. Table III., page 2239, gives some striking figures of the production of flue dust per ton of iron in a modern furnace. The recovery of potash from the flue dust and gases has now passed from the theoretical to the practical stage.

'HEENAN' BLAST-FURNACE GAS CLEANSERS.

We are informed by Messrs. Heenan & Froude, Ltd., Worcester, that they have developed a new type of cleanser for dealing with blast-furnace gas. This is capable of dealing with heavy volumes of dust, and is so arranged as to extract a large percentage of the water vapour contained in the hot crude gas.

CUPOLAS.

BLAST-QUANTITY AND PRESSURE IN CUPOLA WORKING.

An average of 120—in terms of quantity of air in pounds, multiplied by $\sqrt{}$ pressure in ounces—is required to melt one ton of ordinary phosphoric iron.

The maximum output of metal melted per hour is more nearly comparative to diameters of cupolas than areas of same.

The maximum output of a cupola will be obtained when the pressure and quantity of the blast in ounces and pounds per minute respectively are so adjusted that $\frac{W\sqrt{P}}{D} = 330$, D being the diameter of the melting zone in feet. Any further increase in the product $W\sqrt{P}$ results in excessive oxidation of the metal in the cupola.

Iron melted in a cupola is affected in hardness directly as the pressure of blast used, so that the total area of the tuyeres employed should be regulated according to the class of iron being melted, small areas being used when greater hardness is required.

The height of the cupola from the top tuyeres to the charging-door sill should *not be less* than two and a half to three times the diameter across the melting zone.

The coke consumption in a well-designed cupola need not be more than 0·075 lb. to 0·09 lb. per pound of ordinary phosphoric iron melted, when the coke contains from 90 to 92 per cent. of carbon. (*F. J. Cook.*)

CENTRIFUGAL FANS FOR CUPOLAS AND SMITH'S FIRES.

To give the high pressure required to supply air to Cupolas and Smith's Fires the fans must be of the 'centrifugal' type and suitably designed. They usually have smaller inlets and outlets than those used for ventilating, as pressure, not volume, is the essential feature.

Care is required in the choice of a suitable fan, as the efficiency varies within wide limits with the design.

CENTRIFUGAL FANS FOR CUPOLAS, SMITH'S FIRES, ETC.

9	60	10	1,600	35	60	1,250	24
10	66	13	1,450	42	80	1,080	32

The duct to the cupola or fires should be made at least as large as the fan outlet; in long lengths it should be made larger, so as to reduce friction, which increases the power to no purpose. If the ducts are below ground cast iron is the best material; sheet-steel ducts $\frac{1}{8}$ in. thick, with flanged joints, are also very suitable, especially if carried above ground. If earthenware pipes are used great care must be taken to lay them straight, with good, sound, and permanent joints.

(Sturtevant.)

MUFFLE FURNACES.

Heat Treatment of Metals in Coal-gas Furnaces.

Furnaces of the oven and muffle types heated by several different systems—natural draught, air blast, 'Lopress'—are manufactured for annealing, normalising, case-hardening, tempering, forging, and other heat treatments of iron, steel, and the non-ferrous metals.

Fig. 23 shows an oven furnace heated by the 'Lopress' system, in which gas at ordinary main pressure is used in conjunction with air at approximately 4-in to 6-in. water gauge. No compressor is necessary, the requisite air supply at this pressure being derived from a fan. Very rapid heating and much higher temperatures can be obtained compared with natural-draught heated furnaces. The 'greasy' flame so essential to annealing work on a large scale can be produced to perfection, while economy is ensured by regeneration of the air supply to the burners.

It is difficult to give comprehensive figures, as heat treatments differ so much, both in duration and intensity.

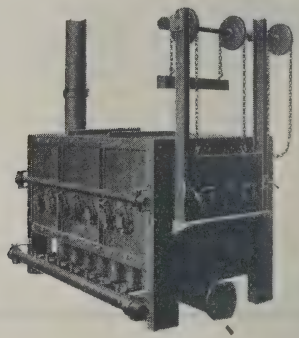

FIG. 23.

The following are figures from actual practice :—

Operation.	Load.	Duration.	Cub. ft. ton.
Annealing H.S. steel . . .	3½ tons	8 hrs.	3,000
,, steel	3½ tons	15½ hrs.	6,000
,, C.I. parts packed in filings in boxes	2,000 lbs.	3 hrs.	3,360

High-speed Tool Steel.*

In no heat treatment of metal is uniformity of furnace temperature more important than in the treatment of high-speed steel. Tool makers nearly always state the exact temperature required for various processes.

The furnace shown in fig. 24, page 2255, enables any temperature to be quickly reached and regularly maintained down to the very narrow limits frequently required by particular steels.

F. 2255

Whatever the composition of the steel, this furnace enables the operator to produce good tools giving the maximum of service and avoiding the waste of expensive material and time due to under, over or irregular heating, etc.

The upper chamber is heated by waste heat from the lower, and serves to preheat the tools, etc., before they are put into the lower chamber, thus raising them to a medium temperature preparatory to the final rapid heating necessary to bring them to the hardening temperature.

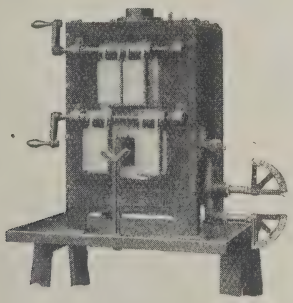

FIG. 24.

CRUCIBLE MELTING FURNACES.

(L. C. Harvey.)

Numerous types of melting furnaces have been designed to meet the wide scope of demand for such plants, and some of these patterns are referred to hereunder.

'Lift-out Crucible' or Pit Type Furnaces.—These are supplied where requirements of molten metal are small, or in cases where it is preferable to melt in relatively small capacity crucibles. *Natural Draught Coke Furnaces* can be either connected up to one main flue and chimney or can be provided with smaller collecting flues, each flue having a chimney to serve a small number of fires, or again, each fire can have its own small stack.

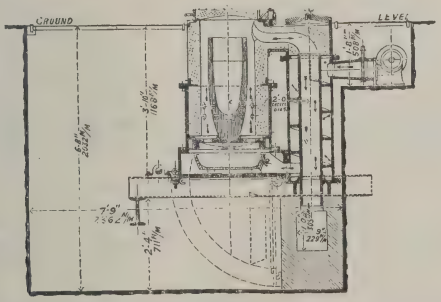

FIG. 25.—Furnace for Coke and Forced Draught. Sectional view, showing ground level.

Forced Draught Coke Furnaces (fig. 25) can be similarly arranged as regards provision for exhausting the waste gases, and as they are not dependent upon chimney pull the heights of stacks are considerably less than those required for natural draught furnaces.

MELTING FIGURES FOR COPPER.

Fuel.	Types of Furnaces and Range of Crucible Capacities.	Most useful Sizes for General Work.	Melting Times, etc., for the larger of the more useful Sizes mentioned.		
			First Heat.	Subsequent Heats.	Fuel Consumption by Weight for full Working Day.
			H. M.	H. M.	
Foundry Coke. 12,960 B.T.U. per lb.	Pit Furnace :—				
	Natural draught . 40 to 400 lbs.	150 to 200 lbs.	1 30	1 0	40 per cent.
	Forced draught . 40 to 350 lbs.	200 lbs.	1 20	0 50	24 „
	Tilting Furnaces . 200 lbs. to ½ ton	400 to 600 lbs.	2 0	1 30	16 „
Fuel Oil. 19,700 B.T.U. per lb.	Pit Furnaces . 40 to 350 lbs.	150 to 200 lbs.	1 10	0 45	20 „
	Tilting Furnaces . 250 to 800 lbs.	250 to 600 lbs.	2 30	1 30	12 „
Producer Gas. 140 B.T.U. per cub. ft.	Pit Furnaces . 100 to 300 lbs.	100 to 200 lbs. (multiple type 6–12 crucibles)	2 0	1 30	30 cub. ft. per lb. of metal.
	Tilting Furnaces . 250 to 800 lbs.	400 to 600 lbs.	2 30	1 30	20 cub. ft. per lb. of metal.

It is usual to supply air from a blower or fan of sufficient capacity to feed any number up to the whole of the plant. Forced draught offers the advantages of (*a*) independence of atmospheric conditions, and, therefore, absence of variation in chimney pull; (*b*) quicker heating qualities of furnaces; (*c*) a greater degree of heat intensity than is possible under all conditions in natural draught furnaces.

Oil-fired Furnaces.—These can be fitted with burners to work with compressed air at 20-30 lbs. per square inch, depending to a large extent upon the temperature desired, the higher pressure effecting a more perfect atomisation of heavy grades of fuel, or with low pressure burners which run with a pressure of only $\frac{3}{4}$ lb. per square inch for all temperatures up to that necessary for melting mild steel and nickel.

The former require an air compressor, which is a relatively expensive machine, and may develop 5 to 10 h.p. per burner, whereas the latter needs only the ordinary open high-speed fan, and the burners will take $1\frac{1}{2}$ to $2\frac{1}{2}$ h.p. according to size of the furnace, etc. Almost any grade of commercial fuel oil can be used with either type of burner, and this is fed to the burners by gravity.

The 'Radiation' Gas or Oil-Fired (Pit Type) Crucible Furnace.

(*Radiation, Ltd.*)

This furnace (for use with air blast) is specially suitable for melting copper, brass, nickel, aluminium, and other non-ferrous metals. The furnaces are made in sizes for melting from 60 lbs. to 300 lbs. of brass (or equivalent bulk of other non-ferrous metals) and they embody all improvements suggested by modern experience; they contain many exclusive and patented features.

60	$11\frac{3}{4}$	$7\frac{7}{8}$	47	56	33	1
100	14	9	47	58	35	$1\frac{1}{4}$
150	$16\frac{3}{4}$	$10\frac{1}{4}$	48	63	36	$1\frac{1}{2}$
200	18	10	50	63	41	$1\frac{1}{2}$
300	$20\frac{1}{2}$	$12\frac{3}{4}$	53	66	43	$1\frac{1}{2}$

Only one burner is used to operate, except in larger sizes, and quadrant cocks on gas and air connections are fitted, and are easily adjustable to give complete combustion and high efficiency.

The following are typical results obtained :—

MELTING OF COPPER—Pouring temp. 1200° C.		
Average per lb.—	C. feet.	B.Th.U.
For 5 Melts . .	3·70	1,924
„ 6 „ . .	3·50	1,820
„ 7 „ . .	3·35	1,742

MELTING OF BRASS—Pouring temp. 1000° C.		
Average per lb.—	C. feet.	B.Th.U.
For 6 Melts . .	2·25	1,203
„ 12 „ . .	1·92	1,031
„ 15 „ . .	1·86	996

Exceptional economy in gas (or oil) consumption is insured by means of the patented pre-heating arrangements for both metal and air supply.

The material saving effected is shown by the following summary. The figures given are for melting yellow brass.

	Gas Consumption per Pound of Metal melted.	
Number of consecutive melts	4	6
With no pre-heater	3·10 cubic ft.	2·91 cubic ft.
Brass only pre-heated	2·72 „ „	2·48 „ „
Brass and air pre-heated	2·42 „ „	2·17 „ „

At a foundry using a 100-lb. crucible, the following results were obtained, covering a full week's working under ordinary foundry conditions: Charge, electric bronze (ingots and scrap); nature of work, sand castings; gas consumption (per 100-lb. melt), 300 cu. ft.; No. of heats per 8-hr. shift, 11; Average time per melt, 42 mins.; life of crucible, 34 melts per pot.

In one day consisting of 12 working hours, 1011 lbs. of electric bronze were melted and cast, also one pot of aluminium. But for loss of heat during meal hour, a still greater output would have been attained.

Producer Gas can be applied to lift-out crucible furnaces if these are made in the multiple form, viz. several crucibles in one common melting chamber, or several crucibles in separate chambers, but exhausting into one air or gas heating regenerator.

For ordinary low-power producer gas, 135 to 175 B.Th.U. per cubic foot, it is essential to preheat the air or gas supply to about 300° C. for efficient melting of copper alloys; for iron and higher temperature melting, both the gas and air should be supplied at about this temperature.

When using high-power gas, such as water gas of roughly 280 B.Th.U. value per cubic foot, no preheating is required for melting temperature up to about 1,400° C.

Tilting Furnaces *for Coke Fuel* are always of the forced draught pattern, for one of their chief features, quick heating, would be greatly impaired if worked on natural draught. This type of furnace is more efficient than the pit type, and it has the important advantage of melting in greater bulk than can be handled in a lift-out crucible—up to ½ ton of metal at one charge—and the further advantage of making it possible to mechanically tilt the furnace on a fixed front trunnion, so that the metal can be poured direct into ladles or moulds. In the portable pattern the body portion holding the crucible can be transported by means of an overhead crane to the point at which the molten metal is wanted.

Furnaces for Oil Fuel.—The remarks made above in connection with pit furnaces apply also to the tilting pattern. The economy in oil when melting, say, ½ ton of metal in one crucible with one burner, will be very marked, compared with, say, five burners for five 200-lb. size pit furnaces, and the consequent saving in power for air blowers is equal in proportion.

Producer Gas can be applied to tilting furnaces as for pit furnaces, but tilting furnaces being of greater capacity than the latter it becomes possible to run single furnaces with producer gas, the heat in the waste gas being utilised to warm the incoming air or gas supply. For copper alloys it is usual only to preheat the air.

The table on page 2257 gives an indication of the melting times, etc., for copper. Calculations can be readily made within approximate limits for metals of other known melting points.

ELECTRIC FURNACES.

(A. H. Allen, M.I.E.E., and Owen W. Ellis, M.Sc.)

The classification of electric furnaces has already been dealt with (pp. 2235–2236). It remains to treat in detail of these furnaces and their application industrially.

Electric Furnaces Heated by Resistance Effects.

Those furnaces of this type in which the charge is included in the electric circuit (fig. 26) are of indirect interest only to the engineer. They are employed largely in the manufacture of aluminium, carborundum, calcium carbide, etc.

Those furnaces of this type in which the charge is heated by means of an electrically-heated conductor find extensive employment in laboratories, and are coming into more general use for the annealing and thermal treatment of steel and the melting and heat treatment of non-ferrous alloys.

The smaller furnaces, such as are used in laboratories, are often made after the style of gas-heated muffle furnaces, but in place of gas jets, wire of platinum or incorrodible alloy, heated by the passage of an electric current, is wound round the body of the chamber. Another type consists of a tube of carbon, cut into a spiral or helix, through which the current flows.

Discussing furnaces of the larger type, T. F. Baily states that a 150-kw. annealing furnace heating 1,000 lbs. of steel to 900° C. in one hour consumes 300 kw. hours per ton. With regard to melting in a shop working 24 hours per day, the following costs were recorded :—

	s.	*d.*
Electricity, 400 kw. hours per ton at ½*d.*	16	8
Metal loss, 1 per cent. zinc at 5*d.* per lb.	8	4
Labour, 1 man per 600 lbs. per hour at ⅛*d.* per hour .	5	0
Renewals and repairs	4	2
Total per ton of brass melted	£1 14	2

These furnaces are provided with separate heating elements of carbonaceous material, which do not come into contact with the charge, but are made incandescent by the current passing through them, and thus heat the interior of the furnace chamber.

Induction furnaces (figs. 27 and 28), which may be classed under this head, find employment in the manufacture of steel. They are able to hold their own against other types of steel-melting furnaces on account of their steady current consumption and low power consumption in the melting of cold stock, but suffer from certain disadvantages of a well-defined character. The heat being generated in the metal and only conducted to the slag renders it impossible to work a fluid basic slag, with the result that desulphurisation of the charge is not so efficiently carried out as in the case of furnaces of the resistance or arc-resistance type. Nor can dephosphorisation be so perfectly attained, since the design of these furnaces militates against ready and complete removal of the oxidising slag needed for the removal of phosphorus. A further disadvantage arises as a result of the continuous circulation of the molten metal in the bath which leads to the erosion of the lining. This, in addition to the corrosive effect of the slag, leads to high figures for lining repairs.

Were the induction furnace of more flexible character and efficient design, it should find wide application in the melting of brass containing as high as 50 per cent. zinc. At present this type of furnace is being experimented with in the direction of non-ferrous alloy melting.

Electric Furnaces heated by Arc Effects.

Only furnaces in which indirect heating of the charge (fig. 29) is carried out, are of interest in this connection. The Stassano furnace is the most striking example of this type. The power consumption of arc furnaces is high, and fluctuations in the value of this factor are, when the furnace is being employed in the fusion of cold stock, of high magnitude.

In the melting of copper alloys the indirect arc furnace may be employed economically in large units. For melting brass containing not more than 10 per cent. zinc it has also been used.

Electric Furnaces heated by Combined Resistance and Arc Effects.

By far the largest number of electric furnaces in use industrially are of this type. In this class of furnace an arc is struck between the extremities of vertical electrodes and the liquid or solid furnace charge (fig. 30). In many furnaces of this type negative electrodes are built into the furnace bottom or sides so that current is forced to flow through the bath (fig. 31). In both cases the bath is heated by (i) the heat of the arc and (ii) the heat produced by the resistance of the steel and slag to the passage of electric current.

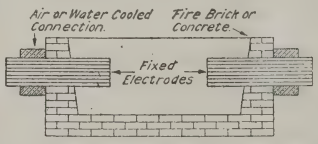

FIG. 26.

Cross Section of Resistance Furnace. Current passes from one electrode through the charge to the other electrode.

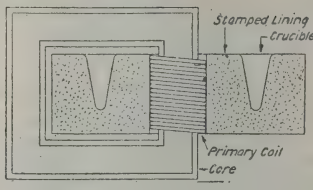

FIG. 27.

Cross Section of Single Ring Induction Furnace.

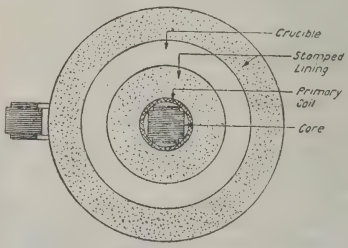

FIG. 28.

Cross Section in Horizontal Plane of Single Ring Induction Furnace.

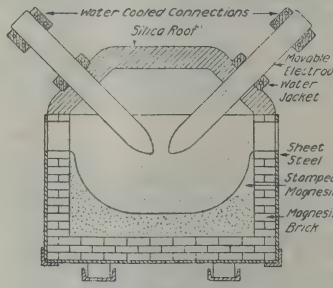

FIG. 29.

Cross Section Indirect Heating Arc Furnace. Current arcs from one electrode to the other above charge.

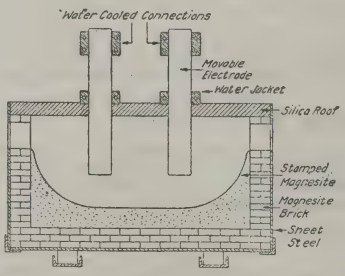

FIG. 30.

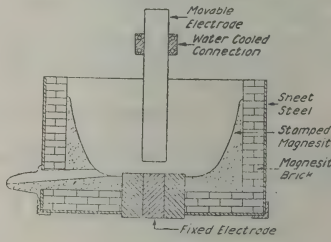
Cross Section Direct Heating Arc Furnace. Current arcs from one electrode to charge and from charge to other electrode.



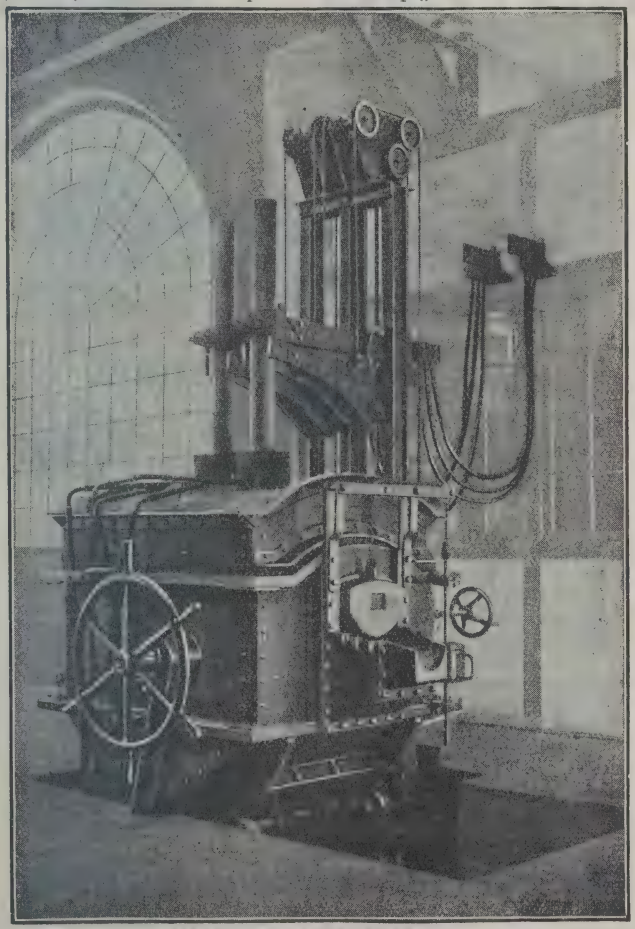


FIG. 31.

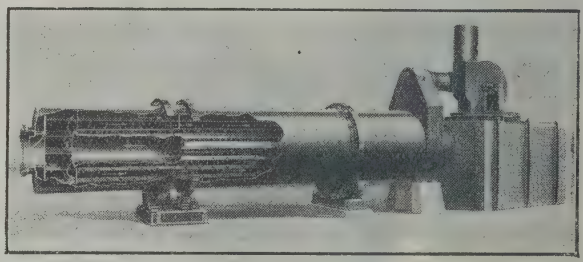
Cross Section of Smothered Arc Furnace. Current arcs from the electrode to the charge in which the electrode is plunged and the current passes through the charge to the lower fixed electrode.

ELECTRIC FURNACES

For the manufacture of all kinds of steel, from the cheapest scrap, and for the production of pig iron from ore.



HALF TON STEEL FURNACE.

ELECTRO-METALS, LTD. —56 Kingsway,— London, W.C. 2.

F. 2260

DRYING PLANT

OUR DOUBLE-SHELL ROTARY DRYER

has a high thermal efficiency, is inexpensive to operate and has a simple robust construction. Due to the several different designs and sizes in which it is made, it is applicable for drying a very wide range of materials.

ELECTRO-METALS, LTD.

Head Office: 56 KINGSWAY, LONDON, W.C.2.

The electrodes, which are of graphite or amorphous carbon, are capable of movement in a direction parallel to their axis and are controlled, either by hand or by electrical device, so as to retain the arc at as constant a length as may be desired either for melting, refining, heating, etc., of the metal. In certain cases the practice of completely immersing the electrode in the molten charge—thus utilising the resistance effect of the electric current only—is in vogue.

For making steel the arc resistance type of furnace is that chiefly used, the charge generally consisting of scrap steel. The composition of electric steel can be very accurately controlled, and the proportions of sulphur and phosphorus in the final product can be reduced to mere traces. An improvement in quality is, therefore, to be expected. The most widely used arc-resistance furnace is the Héroult, of which, according to the Society for Electrical Development, 181 were in operation on January 1, 1917, 84 of these being in the United States and Canada. These and similar furnaces are largely used for making small castings in steel, malleable iron, and cast iron, their capacities ranging from 1 to 20 tons ; 6-ton furnaces are very common. Other well-known furnaces of this class are the Girod, Nathusius, Keller, Grouwall, Electro-metals, and Greaves-Erchells. Each of these furnaces is possessed of special characteristics which appeal to individual users. While steel melting and refining, and the production of steel and iron castings, occupy the vast majority of electric furnaces, all the foregoing types can be, and have been, used for melting brass, copper, etc., though it is questionable whether their use for such purposes can be considered as expedient.

Arc-resistance furnaces for steel melting are most frequently lined with basic refractory materials. Acid-lined furnaces are, however, employed, chiefly to melt down high-grade raw materials. The necessity for utilising such materials, for which high prices must be paid, renders the mere melting process a costly one. Further, as the treatment of molten steel on an acid hearth leads to an appreciable gain in those elements, sulphur and phosphorus, most to be avoided, the process is still further limited in its application.

The process employed for the production of steel in basic-lined arc-resistance furnaces is determined by (*i*) the stock on hand and (*ii*) the product desired.

Should the stock on hand be of fair quality, i.e. containing contents of sulphur and phosphorus not above 0·06 per cent., the process may consist of (*i*) the application to the charge of a basic oxidising slag and (*ii*) the conversion of this slag, by means of suitable additions of coal dust and lime, into a reducing slag, which is allowed to remain in contact with the molten steel during the operations of teeming from the furnace and of casting from the ladle. Such additions of ferro-alloys as are required to bring the steel up to the standard required are made when the slag is as completely reducing in character as is possible under the conditions imposed by practice.

If the stock on hand is of poor quality, i.e. should it consist of scrap containing high (from 0·06 to 0·20 per cent.) sulphur and phosphorus, or if it is desired to specially refine stock of fair quality, the first slag—the basic oxidising slag—is removed from the surface of the steel in the furnace. The removal of this slag implies the removal of the major portion of the phosphorus from the steel, and unless the removal be very complete a return of phosphorus to the steel may be expected, the content of phosphorus returning to the steel under these conditions being roughly proportional to the amount of slag allowed to remain upon the charge. Occasionally it may be necessary to apply a further oxidising slag to the metal in the bath ; generally, however, one slag only is made. The first slag having been removed, deoxidation and desulphurisation are effected by the medium of a slag composed largely of calcium silicate. The 'physic' required to provide for carbon, manganese, etc., in the finished steel may be added immediately after the first slag has been removed. Generally speaking, the additions are made at a later stage in the process. The complete deoxidation of the metal is made evident by the appearance of the slag, which, the above conditions prevailing, decrepitates spontaneously and is practically white when cool.

Melting and refining carried out on a basic hearth results in a practically complete loss of carbon, silicon and manganese, and a very appreciable loss of sulphur, phosphorus and such elements as chromium, molybdenum, etc.

The possible uses of the electric furnace in the steel foundry have been tabulated by J. H. Hall :—

Melt scrap . . .	Impure : eliminate phosphorus and sulphur. Pure : get hot and cast. Alloy steels.
Melt pig and more or less scrap. Eliminate C, Si, Mn.	Impure : eliminate phosphorus and sulphur. Pure : get hot and cast.
Treat hot metal . .	From cupola : eliminate C, Si, Mn, S and P. From acid Bessemer or open hearth : eliminate S and P. From basic open hearth : eliminate S and P.
Melt pig and scrap and treat cupola metal	Eliminate C, P and S without loss of Mn and Si. (Greene's process.)

The arc-resistance furnace proved to be of value during the war in the preparation of high-grade pig iron to replace the Swedish pig iron so much sought after for the preparation of high-grade steels.

According to E. K. Scott, a 10-cwt. steel-melting furnace running 9 charges a day will do as much as 36 crucible-steel furnace holes, each accommodating two 56-lb. pots, and can be operated by one man and an ammeter boy, whereas the crucible furnaces require 15 men, most of them skilled. The electric furnace, with its transformer and switch-gear, occupies one quarter as much space as the crucible plant, and costs half as much to instal. It can deal with a charge consisting entirely of turnings, millings, etc., whilst in the crucible-steel process only a very limited quantity of turnings can be used. The renewal of the furnace linings costs less than that of crucibles for the same output. Consequently the electric-steel furnace has been largely adopted in Sheffield in place of crucible furnaces.

The chief **losses** in electric furnaces are due to radiation from the walls and conduction through the electrodes. Since the radiation losses increase as the square and the capacity as the cube of the linear dimensions of furnaces, it is obvious that large installations are more economical than small ones. Conduction losses can be reduced to a minimum by suitably designing the electrodes.

Although, with coal at 14*s.* per ton and electrical energy at ½*d.* per kw.-hour, the latter costs twenty-eight times as much as the former per British thermal unit purchased, the efficiency with which the electrical energy is applied is so much higher that the difference is largely neutralised, and in the case of crucible steel is completely wiped out. In addition, the labour cost is greatly reduced with electric furnaces and there is a considerable economy of space and buildings, while the steel produced is of higher quality and uniformity than by any other method.

A useful method of calculating heat flow through the furnace walls, etc., has been developed by Carl Hering on the lines of Ohm's law. If—

W = heat flow in watts,
T = drop in temperature in degrees C.,
R = thermal resistance in 'thermal ohms.' Then—

$$W = T/R.$$

A thermal ohm is that thermal resistance which requires a drop of temperature of 1° C. to produce one watt of heat flow and = 4·2 gramme-calorie units; 1 gramme-calorie unit of thermal resistance = 0·24 thermal ohm.

Assuming that the electrodes are of uniform section, and that no lateral loss of heat takes place—conditions which are only approximately fulfilled in practice—Hering finds that the total loss of heat through the cold end of the electrode equals the sum of the loss by heat conduction alone (i.e. when no current is flowing) and half the T^2R loss. This combined loss is least when the loss by heat conduction alone equals half the T^2R loss; the total loss then equals the T^2R loss, and no heat will be conducted out of the furnace by the electrodes. This minimum loss is dependent only on the material of the electrodes, the current, and the temperature, but not on the absolute dimensions: it fixes the ratio of cross-section of electrode to length. In the case of a furnace working at 1,400° C., the cool end of the electrode being at 100° C., the length of the electrode 20 ins., and the current 10,000 amperes, the following dimensions were given by Hering's method of calculation: –

Carbon, 12·5 ins. diameter, loss of power in electrode 23·4 kw.
Graphite, 7·1 ins. diameter, loss of power 15·1 kw.
Iron, 4·8 ins. diameter, loss of power 4·6 kw. (*Stansfield.*)

F. T. Snyder states that in the case of a furnace melting 1,000 tons of steel a month, the cost of renewing the electrodes, plus the cost of the heat conducted out of the furnace by them, represents an expenditure of some 1,200*l.* a year per electrode. Hence the type of furnace having the fewest electrodes has an advantage in this respect. By using the metal bath as one terminal of the arc, a furnace can be operated with one carbon electrode per arc. The furnace lining becomes conducting at very high temperatures, and this fact limits the voltage between two electrodes passing through the same roof to a maximum of 110 volts to avoid serious leakage of current. The bulk of the cost of renewing refractory linings is due to roof wear round the

electrodes, and for the size of furnace above mentioned can be kept down to 800*l.* per annum per electrode. The higher the power input the quicker is the heating and the greater the efficiency of the furnace. With three electrodes the limit of power is soon reached, owing to lack of room to space the electrodes sufficiently far apart to prevent current leakage through the roof lining, but with a single electrode there is no such limit to the power input.

The power, etc., provided in connection with Héroult furnaces used by the United States Steel Corporation are given in the following table, which applies to cold charges; if the charge is put into the furnace in a molten condition about half this power suffices :—

POWER REQUIRED FOR ELECTRIC FURNACES.

Size of Furnace, tons.	Transformer capacity, kva.	Amperes, per phase.	Square inches Copper, per phase.
1	375	2,250	3
2	600	3,600	5
3	750	4,500	6
4	900	5,400	7
6	1,200	7,200	9
10	2,000	12,000	16
15	3,000	18,000	24

The voltage used in arc furnaces depends upon the current and the length of the arc. In three-phase furnaces it ranges between 75 and 100 volts, and in single-phase furnaces between 150 and 200 volts. In resistance furnaces the voltage at starting, with a cold charge, may be 400 volts, decreasing as the charge heats up to 35–60 volts. The consumption of the electrodes varies widely according to the conditions obtaining, from 3½ to 20 lbs. per ton of steel produced. The furnace bottoms last from 1 to 3 years, the walls from 100 to 300 heats, and the roof from 50 to 200 heats. To make ordinary carbon steel of crucible quality with a 6-ton furnace requires from 550 to 750 kw.-hours per ton, starting cold. In smaller furnaces the input per ton is greater. The following figures for a Rennerfelt furnace are due to C. H. Vom Baur.

ENERGY REQUIRED IN TREATING VARIOUS METALS.

	Kw.-hours per ton.
Melting red brass	168
„ pure copper	197
„ white iron	290
„ gray iron	325
„ 80 per cent. ferro-manganese	441
„ and refining steel scrap on a basic bottom	700

The power factor of the arc resistance furnace varies from 85 per cent. to more than 90 per cent.: that of the resistance type from 90 to 97 per cent.; that of the induction furnace varies from 50 to 60 per cent. only.

The efficiency of a Héroult furnace was tested with a charge consisting of 5,733 lbs. steel scrap, 430 lbs. iron ore, 346 lbs. lime. The input was 215 kws. for the first hour, at 110 volts, and afterwards 342 kws. The total time taken to melt the charge was 5⅛ hours, and the total energy input for melting was 1,680 kw.-hours. The ratio of heat utilised to heat supplied (the efficiency) was 76·5 per cent. The time required for the purification and carburisation of the steel was 3 hours, and the result was 5,161 lbs. of tool steel. The total consumption of energy was 2,580 kw.-hours, or 0·171 e.h.p.-year per ton of steel.

The leads from transformers to electric furnaces should be as short and direct as possible, and close together, as the voltage drop due to their self-inductance and the very large currents is considerable, resulting in a low power factor. The conductors should be wide thin bars, or tubes, to prevent loss of energy due to the tendency of alternating current to flow in the skin of the conductor.

ELECTRICAL RESISTIVITY OF MATERIALS, OHMS PER INCH CUBE.

Material.	Cold.	Hot.	Temperature ° C.
Graphite	0·00034	0·00031	100–2000
Carbon	0·0018	0·0014	100–2000
Silicate slag	∞	1 to 2	Molten
Fire bricks (various)	∞	8 to 24	850
		24 to 300	815

(*Stansfield.*)

FURNACE CONSTRUCTION.

The following are points requiring special attention in the construction of furnaces :—

1. Sections of furnaces such as are exposed to differing physical and chemical actions should be united in such a manner as to allow of free and independent movement and as to be subject to independent condition.

2. Such sections as are exposed to high temperatures should be made thin and should, when possible, be water-cooled; such sections as are exposed to low temperatures should be made of such a thickness as will reduce thermal losses due to radiation and conduction to a minimum.

3. The interiors of furnaces should be constructed so as to resist mechanical, physical and chemical wear. With this end in view choice must be made of suitable materials of construction and of efficient design. In this connection note should be made of the following factors :—

(*a*) The action of heat.
(*b*) The erosive and corrosive actions of flame, slag, etc.
(*c*) The mechanical wear due to abrasion by the solid charge, etc.

4. The exteriors of furnaces should be supported and strengthened in such a way as to allow of the free expansion and contraction of the body. The foundations of all furnaces must be of a strong and rigid character.

MELTING POINTS OF REFRACTORY MATERIALS.

	° C.
Alumina (pure)	2010†
Bauxite	1820†
Bauxite brick	1565 to 1785†
Bauxite clay	1795†
Chromite	2180†
Chromite brick	2050†
Fireclay brick—Highest grade	1843*
General grade	1650 (average)*
Ditto	1649 (average of 41 samples)†
Ganister	1700 to 1800
Kaolin	1735 to 1740†
Magnesia brick	2165
Silica—Pure	1750†
Pure	1830*
Pure, with 14·5 per cent. alumina	1690*
Pure, with 63·0 per cent. alumina	1890*
Brick	1700 to 1750†

The melting points have been considered to be those temperatures at which the material in question was first seen to flow easily.

* Boudouard.
† Kanolt—'Iron and Coal Trades Review,' vol. lxxxv. p. 309.

FURNACE EFFICIENCY.

The thermal efficiency of furnaces may be stated either absolutely or relatively :—

$$\text{Absolute furnace efficiency} = \frac{\text{Net thermal effect produced}}{\text{Calorific power of the fuel}}.$$

$$\text{Relative thermal efficiency} = \frac{\text{Net thermal effect produced}}{\text{Actual calories realised}}.$$

Owing to the large variation in the actual number of calories realised in individual furnaces it is general to employ the former of the above ratios. In order that a determination of the absolute efficiency of a given furnace may be made, a knowledge of the heat-absorbing and the heat-producing factors that are likely to be encountered in practice, of which a number are tabulated below, is required.

(*A*) Heat-absorbing Factors.

1. Heat absorbed by fume, gases, etc.
2. Heat removed by such solids and liquids as are periodically or continuously removed rom the furnace.
3. Heat lost by radiation and conduction.
4. Heat absorbed owing to endothermic reactions within the furnace.

(*B*) Heat-producing Factors.

1. Heat supplied to the furnace by the combustion of fuel either inside or outside the furnace.
2. Heat added by such solids and liquids as are periodically or continuously charged into the furnace.
3. Heat gained owing to exothermic reactions within the furnace.

The thermal efficiency of the furnace is represented by the ratio of the heat-absorbing factors to the heat-producing factors.

Latent Heat of Fusion of Metals.

The latent heat of fusion is the number of gram calories required to convert one gram of substance from solid into liquid without change of temperature :—

Mercury	2·8 calories.	Platinum	27·1 calories.
Lead*	5·5 ,,	Sodium	31·7 ,,
Bismuth*	10·2 ,,	Palladium	36·3 ,,
Cadmium*	10·8 ,,	Manganese*	36·7 ,,
Tin*	13·8 ,,	Antimony*	38·9 ,,
Potassium	15·7 ,,	Copper	41·0 ,,
Gold*	15·9 ,,	Nickel*	56·1 ,,
Iron	(See note).	Cobalt*	58·2 ,,
Silver*	26·0 calories.	Aluminium*	94·0 ,,
Zinc*	23·0 ,,		

* Values after Wüst. ' Stahl und Eisen,' 1918, 38, 177.

NOTE.—The latent heat of fusion of iron as determined by Campbell (and confirmed by Desch) from freezing-point depression data is 20·1. C. Brisker (1908), as a result of an examination of Carpenter and Keeling's freezing-point determinations of the iron-carbon system, has arrived at the value 31·6 for this element. Grumer gives values of 23 and 33 for gray and white cast iron respectively. Wüst obtained the value 49·4 for this factor.

Heat and Electrical Energy required for Fusion of Metals.

The following table (after Stansfield) gives the heat and electrical energy required to melt various metals, per lb. :—

	Calb.*	Watt-hours.		Calb.*	Watt-hours.
Tin	28	15	Copper	162	85
Lead	16	8	Cast iron (gray)	245	129
Zinc	68	36	Tool steel (1 % C.)	300	158
Aluminium	258	136	Wrought iron	343	181
Brass	130	69			

(See also p. 2263.)

* *Calb.*—The amount of heat required to raise one pound of water through one degree Centigrade.

Calorie.—The amount of heat required to raise one gram of water through one degree Centigrade.

TEMPERATURE CONTROL OF FURNACES—PYROMETRY.

Determination of Calorific Intensity.

The calorific intensity of a substance is the theoretical maximum temperature attained during the perfect combustion of the same in air at 0° C. and 760 mm. pressure, and is inversely proportional to the time occupied in attaining to this temperature. The calorific intensity of a substance may be determined by calculation or by experiment.

Calculation.

Let C = the calorific power of the substance.
T = the rise in temperature during combustion.
$w, w', w'', — =$ the weights of the products of combustion.
$s, s', s'', — =$ the specific heats of the products of combustion.

Then

$$T = \frac{C}{ws + w's' + w''s'' + \text{etc. etc.}}$$

for the fuel at 0° C. and 760 mm. pressure.

The calorific intensity of a fuel (by formula) will be seen to be directly proportional to the calorific power of the fuel and inversely proportional to the weights and the specific heats of the products of combustion.

The calorific power can be raised by

(*a*) Superheating the fuel.
(*b*) Superheating the air needed for the combustion of the fuel.
(*c*) Using a minimum of excess air.
(*d*) Increasing the proportion of oxygen in the air.
(*e*) Reducing the proportion of incombustible material in the fuel.

Experiment.

The calorific intensity of a fuel may be determined by experiment. For the purpose in question a variety of instruments has been designed, almost every thermal property of matter having been employed as a basis for the construction and calibration of these instruments, which are generally known as pyrometers.

Reference may be made to the Bulletin of the United States Geographical Survey, No. 54 (1889), where the following classification of the properties on which the construction of pyrometers has been founded is given :—

1. Dilatation of solids:
   (*a*) A single solid.
   (*b*) Two solids acting differentially.
2. Dilatation of liquids.
3. Dilatation of gases:
   (*a*) Expansion measured in volume, manometrically.
   (*b*) Expansion measured in pressure, manometrically.
   (*c*) Expansion measured in volume, by displacement.
4. Vapour tension.
5. Dissociation.
6. Fusion.
7. Ebullition.
8. Specific heat.
9. Heat conduction.
10. Heat radiation.
11. Viscosity:
    (*a*) Of solids.
    (*b*) Of liquids.
    (*c*) Of gases.
12. Spectrophotometry and colour. Rotary polarisation.

Expansion Type Thermometers.

The mercurial thermometer is most important for use at about atmospheric temperatures, largely on account of the wide range of temperatures through which mercury is liquid, —39° C. to 357° C. If a high-grade mercurial thermometer has been calibrated at the National

Physical Laboratory, it is possible to measure temperatures throughout its range to an accuracy of 0·001° C. By the use of inert gases (nitrogen or carbon dioxide) under pressure in the tube of a thermometer, the boiling point of the mercury may be raised to allow temperatures up to 540° C. to be determined, at which temperature the glass softens. Quartz thermometers containing mercury under pressure can be used up to 700° C. By using tin instead of mercury the maximum limit may be raised to 1000° C. Steel tube mercurial thermometers, in which the capillary is attached to a form of a Bourdon pressure gauge, are not easily broken, and may be relied upon up to 540° C.

Fusion Pyrometers.

Observations of the fusion of metals, alloys, salts or mixtures of salts enable the observer to judge the temperature reached in a furnace at the moment of fusion, given that the temperature of fusion of the material employed is known prior to its introduction into the furnace. Fusion pyrometers are most suitable for the registration of maximum temperatures, after the attainment of which the source of heat may be eliminated and the furnace or heated object allowed to cool.

Metals.

The base metals have the disadvantage of ready oxidation; the precious metals offer only a limited number of definite temperatures.

Alloys.

Only eutectic alloys (see p. 2272) and solid solutions (see p. 2272) are of value. Base metal alloys being subject to oxidation, only precious metal alloys remain as suitable fusion pyrometers. Both the alloys of silver and gold and those of gold and platinum have been employed for pyrometric work, the latter, according to Séger, being satisfactory up to a temperature of 1200° C. only.

Salts.

The following are the melting points of a number of metallic salts that have found use in pyrometric work :—

Salt.	Melting Point
Calcium nitrate	561° C.
Strontium nitrate	570 ,,
Barium nitrate	593 ,,
Potassium iodide	705 ,,
Potassium bromide	750 ,,
Potassium chloride	790 ,,
Sodium chloride	800 ,,
Sodium carbonate	849 ,,
Sodium sulphate	880 ,,
Barium chloride	960 ,,
Potassium sulphate	1050 ,,

Mixtures of Salts.

Under this heading may be included two important types of fusion pyrometers :—

(*a*) Séger cones.
(*b*) Sentinel pyrometers.

Séger Cones.

These are small three-sided pyramids, each about 2½ ins. high and about ½ in. wide at the base. The term 'cone' is rather misleading, as they are more pyramidal than conical. They are made of a finely ground mixture of felspar, china clay, and flint, the composition of the mixture depending on the temperature to be indicated. For the lower members of the series other mixtures are used.

These cones were invented by the late Dr. Séger of Berlin, in order to provide some means of recording the effect of heat on various porcelains. Their shape and composition are such that when heated to their indicating temperature at a reasonably slow rate and under suitable conditions they bend over slowly from the upright position possessed by them when placed in the kiln or oven and gradually form an arch. When the top has almost reached the same level as the base the indicating temperature is reached. A further rise in temperature will cause the cone to collapse and form a shapeless, glazed mass.

It is customary to employ three different cones at a time; the first will indicate a temperature about 20 degrees Cent. below the one required to be known, the second cone will indicate the desired temperature (such as the finishing temperature of a glaze) and the third cone will serve as an indicator that the required temperature has not been exceeded by 20 degrees. The composition of the cones is such that the difference in temperature shown between two successive cones is about 20 degrees, though they are not quite regular in this respect.

It is important to remember that Séger cones do not serve as strict indicators of temperature in the sense that a thermometer does. If heated too rapidly a much higher temperature may be reached than is normally required to bend a cone, and which they are supposed to indicate. Under ordinary conditions of use, however, it is easy to find which cones correspond to the temperatures or conditions of heating which it is required to control, and Séger cones are, therefore, invaluable when they are rightly used. They serve as excellent indicators of the effect of heat on pottery and similar materials, and as it is this, rather than the mere momentary temperature which is important, they have advantages not possessed by a pyrometer or high temperature thermometer.

They were originally made only at Dr. Séger's laboratory in Berlin, but since 1914 they have also been made at the Pottery School, Stoke-on-Trent, and sold by Messrs. Keeling & Walker, Sutherland Mills, Stoke-on-Trent.

Owing to their cheapness and the difficulty of ensuring their accuracy when made by amateurs it is usually better to purchase the cones rather than to attempt to make them.

The following temperatures are those nominally associated with Seger cones, but, as explained above, it is preferable to refer to the number of the cone rather than to the temperature.

SÉGER CONES AND TEMPERATURES.

The chemical composition of the older Séger cones Nos. 1 to 36, together with the ingredients used in the manufacture of the same, are given in the following table for the convenience of those unable to obtain cones readily, but who may have raw materials available. The ingredients are finely divided before mixing. Dextrin is employed as a binder. The materials as employed by Dr. Séger, and considered to be sufficiently pure for the purpose in question, gave the following analyses:—

	Rostrand Feldspar.	Zettlitz Kaolin.	Norwegian Quartz.	Carrara Marble.

Silica . . 52·50 per cent.	Magnesia . 0·54 per cent.	Potash and soda . traces	
Alumina . 45·22 „	Lime . . 0·50 „	Loss on ignition . 0·78 per cent.	
Iron oxide . 0·81 „			

SENTINEL PYROMETERS.

These are small cylinders, measuring about ¾ in. by ½ in. and manufactured from salt mixtures of definite melting points. Only such mixtures can be utilised as are formed of salts that neither dissociate nor corrode when in the molten state. Brearley states that 'mixtures of salts, after being melted together and ground to a very fine powder, may be made into an adhesive paste with vaseline, and applied to many purposes for which no ordinary pyrometer is available. In the smith's hearth, for example, a tool may be heated to low redness and smeared near the point with a small portion of a paste whose melting point is, say, 770° C. The tool is then reheated directly in the fire or protected from the coke by a piece of scrap, wrought or cast iron piping, until the white mark left by the thin layer of the salt mixture disappears. This indicates that the steel itself has nearly reached the desired temperature and may be quenched.' Following are the melting points of a number of mixtures of salts.

Salt.	Parts by Weight.	Salt.	Parts by Weight.	Deg.
Potassium carbonate .	50	Potassium chloride	50	580 C.
Sodium chloride . .	30	Ditto	70	625 C.
Ditto	42	Ditto	58	655 C.
Potassium sulphate .	20	Sodium sulphate	80	825 C.
Ditto	30	Ditto	70	830 C.
Ditto	50	Ditto	50	850 C.

Heat Radiation Pyrometers.

In this type of instrument the relation between the effect of radiant heat on suitably chosen thermal elements and the temperature of the radiating body is observed. The Féry Radiation Pyrometer (Cambridge Scientific and Paul Instrument Co.) is an example of this class of instrument.

In this pyrometer the rays from the hot body are received on a concave mirror, which can so be adjusted that the rays form a heat image which covers a small sensitive element permanently fixed on a line through the axis of the mirror. The sensitive element consists of a delicately adjusted thermo-couple, which delivers current to a millivoltmeter, calibrated, if desired, to read the temperature of the body, whence the heat rays are emanating, directly. In both cases suitable means are provided for ensuring that the sensitive element is completely covered by the image of the radiant body.

In order that correct results may be obtained when using pyrometers of the radiation type it is necessary that the hot body sighted should be enclosed within a vessel whose walls are approximately at the same temperature as the body itself. If this precaution is not observed the reading obtained will be lower than the true temperature of the body, the degree of inaccuracy being dependent almost entirely on the nature of the surface of the body in question.

Optical Pyrometers.

Approximate estimations of the temperatures of incandescent bodies may be made by visual observation. Numerous colour scales have been proposed, but those due to Howe and Taylor and White are generally accepted as the most accurate. The following table (based on one by Howe) is of value in this connection.

Taylor and White.		Howe.	
Name of colour.	Degree C.	Name of colour	Degree C.
—	—	Lowest visible red in the dark	470
—	—	Lowest visible red in daylight	475
Dull red, blood red, low red	566	Dull red	550–625
Dark cherry red	635	—	—
Cherry, full red	746	Full cherry	700
Light red, bright cherry, light cherry	843	Light red	850
Orange	899	—	—
Light orange	941	—	—
Yellow	996	Full yellow	950-1000
Light yellow	1079	Light yellow	1050
White	1205	White	1150

The design of optical pyrometers is dependent on the fact that the intensity of the light rays emitted from an incandescent 'black body' is directly proportional to the temperature of the 'body.'

The Mésuré and Nouel Pyrometric Telescope consists of two suitably mounted Nicol prisms, so adjusted that their planes are at right angles to one another when the scale of the instrument is at zero and between which is placed a quartz plate cut perpendicularly to its axis. When the incandescent body is observed through the instrument it is necessary to rotate one of the Nicols in order to extinguish the emitted light. The angle of rotation is proportional to the thickness of the quartz plate, which is a constant for any given instrument, and inversely proportional to the square root of the wave length of the observed light. The wave length of the observed light being proportional to the intensity of the light, the angle of rotation of the analyser or polariser is a measure of the temperature of the incandescent body.

The Cornu-Le Chatelier Photometric Pyrometer is designed to measure the intensity of the light emitted by an incandescent body by reducing this intensity until it corresponds to that of the light emitted by a standard lamp. The reduction required is inversely proportional to the temperature of the hot body.

The Wanner Photometric Pyrometer likewise compares the intensities of the lights emitted by the incandescent body and a standard body respectively. In this instrument, however, spectra of the two sources of light are, firstly, broken up into two polarised planes at right angles to one another; secondly, adjusted so that only the narrow red bands of each spectrum are transmitted

further; and, thirdly, so brought into vision that the intensity of either field, both being in visual contact, can be strengthened or weakened, until they are equally intense, by rotation of a Nicol prism. The amount of rotation, which can be observed on a suitably situated scale, serves to measure the intensity of the emitted light, and hence to define the required temperature.

The Cambridge Optical Pyrometer is, in principle, the same as the foregoing, and is invaluable for temperature measurements between 700° and 4000° C.

Thermo-Electric Pyrometers.

This type of pyrometer is dependent for its action upon the fact that a current is produced within a closed circuit formed of two dissimilar metals when the junction between the two metals is heated, the current being proportional to the absolute temperature of the junction.

The essential features of this pyrometer are two thin insulated rods or wires of dissimilar metals coupled at one of their ends and connected at their other ends to separate leads. The connection between the two metals and the leads, which is known as the 'cold-junction,' is enclosed within suitably designed apparatus that can be retained at a known constant temperature. The leads from the 'cold-junction' pass to some form of electrical instrument capable of registering or recording changes in the P. D. produced in the now closed circuit when the thermo-couple is heated or cooled.

The number of metals and alloys available for the manufacture of thermo-couples are few. The following are among those most generally employed :—

Couple.	Range.
Platinum—platinum rhodium	Up to 1400° C.
Platinum—platinum iridium	„ 1000 „
Nickel—nickel chromium	„ 800 „
Silver constantan	„ 600 „
Copper constantan	„ 500 „
Iron constantan	„ 500 „

For the estimation of temperatures above the melting-point of platinum the iridium-iridium-ruthenium couple has been suggested, but it is considered unlikely that the same would prove efficient, on account of the known volatility of iridium at such temperatures.

Union between couple *wires* is effected by fusion in the electric arc or oxyhydrogen flame in the case of couples having a platinum base, by soldering or brazing in the case of base-metal couples or by twisting. Union between the wires and the leads can be effected as above or by means of electrical clamps.

The couple wires, when in use, are generally protected by tubes of nichrome, fireclay, silica or glazed porcelain, the last being particularly useful when it is desired to defend the wires against the deleterious action of hot gases. When necessary, protection is afforded these tubes by enclosing them in steel jackets.

Heavier types of thermo-electric pyrometers consist of a *rod* of one metal fitted tightly into one end of a cylinder concentric with the rod and of another metal and insulated from the same by suitable means.

Calibration of thermo-electric pyrometers is effected by immersing the protected couple in substances or the vapour of substances whose melting or boiling points are known. The couple, being subject to like thermal changes as the substance, causes a fluctuation in the current flowing within the closed circuit, which fluctuation is registered by the instrument within the circuit. For example, while solidification of a metal in which the protected couple is immersed is in progress a constant reading is obtained on the instrument. This value is observed, and is recorded on a graph against the melting point of the metal as ordinate. A series of such points may be obtained by employing a number of metals in similar manner to that already described, and, these points being united, a curve is obtained from which the temperature corresponding to any given reading of the instrument may be abstracted.

The following are the melting points on the thermo-dynamic scale used by the Washington Bureau of Standards as standard temperatures in the standardisation of thermometers and pyrometers :—

Mercury	−38·9° C.	Antimony	630·0° C.	Nickel	1452° C.
Tin	231·9 „	Aluminium	658·7 „	Iron	1520 „
Cadmium	320·9 „	Silver	960·5 „	Palladium	1549 „
Lead	327·4 „	Gold	1063·0 „	Platinum	1755 „
Zinc	419·4 „	Copper	1083·0 „	Tungsten	3000 „

At temperatures of 1000° C. the error is of the order of 0·1° C., at the melting point of platinum 5° C., at that of tungsten 100° C. A further table of other standard temperatures is given in which the following are included :—Normal boiling-point of oxygen 180·0°, sublimation of carbon

dioxide in an inert liquid 78·5°, normal boiling point of water 100°, of naphthalene 217·96°, of benzophenone 305·9°, of sulphur 444·6°, freezing point of sodium chloride 801° C.

In the *Physical Review* the melting point of rhodium is estimated to be at 1907 or 1968° C. and that of iridium as 2292 or 2388° C. That of silicon is placed at 1434 or 1452° C. and that of palladium at 1548 or 1576° C. The reason for the two figures is due to the fact that the calculations are based on different estimates of the melting-point of platinum, which has been placed at 1745° C. by some experimenters and at 1789° C. by others.

Electric Resistance Pyrometers.

In these instruments advantage is taken of the change of resistance of a wire with temperature. Platinum wire is generally employed. The essential features of the commercial apparatus are a coil of fine platinum wire, enclosed in a suitably designed protecting tube, a cell or accumulator for the supply of current to the wire and an indicator or recorder on which the temperature may be read off directly.

In the original type of this instrument errors due to the residual strain and impurities in the lead wires entered, but later instruments are designed with 'compensating wires,' whose component parts are equal in resistance to and are so arranged that they are heated to the same temperature as corresponding parts of the lead wires. Changes in resistance in the lead wires are compensated by equal changes in the 'compensating wires.'

The resistance pyrometer (after Callendar) is represented diagrammatically in fig. 32.

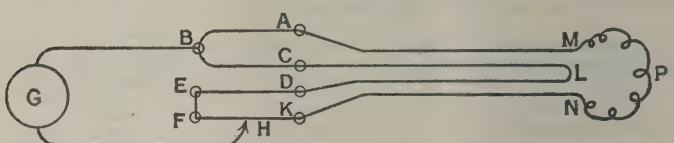

FIG. 32.

P represents the pyrometer coil; AM, KN the lead wires; CL, DL the 'compensating wires'; FK a bridge wire with scale, so arranged that 1 cm. length of the same corresponds to 1° C. rise or fall of the temperature, H the sliding contact piece, and G a galvanometer. AB and BC are wires of equal resistance. DE represents a set of resistance coils. In practice AB, BC and DE can be replaced by a post office box. Balance is obtained by the adjustment of the resistances in DE and the sliding of the contact piece H. The resistance of the pyrometer coil is given by the sum of the coils DE and the bridge wire scale reading.

Resistance pyrometers are accurate from 0° C. to 1000° C., and are employed industrially wherever reliable measurement is essential. They suffer owing to their high first cost and their fragile character. There are, however, large numbers of this type of pyrometer in use commercially.

METALS AND ALLOYS.

ALLOYS.

There are three well-recognised types of alloys:—

(i) Conglomerates of metals, or of metals and non-metals.
(ii) Homogeneous mixtures of metals, or of metals and non-metals.
(iii) Inter-metallic compounds, or compounds of metals with non-metals.

(i.)

In this type of alloy the component elements or their compounds crystallise out from the molten alloy in a practically pure state, and the addition of one component to the other results —within certain limits—in a lowering of the solidifying point of the resulting alloy. The alloy having the lowest solidifying point in such a series is called the 'eutectic.' Lead-tin alloys are of this type.

(ii.)

In this type of alloy the component metals do not crystallise out from the molten alloy in the pure state, but contain on freezing more or less of each other in solid solution. Copper-nickel alloys are of this type.

(iii.)

Inter-metallic compounds behave similarly to pure metals, crystallising in like manner. Copper and zinc form a compound $Cu_2 Zn_3$, which is extremely hard and brittle.

IRON.

IRON (FERRITE).

Chemically pure iron is not an article of commerce at the present time. Iron has been obtained by electrolytic deposition of a degree of purity greater than 99·9 per cent. iron, while the American Rolling Mills Co. manufacture a commercial product (American Ingot Iron), which they claim to contain 99·94 per cent. of iron. The Skelton Iron Co. have produced by the basic open-hearth process iron with as little as 0·13 per cent. of impurities.

Stead, by extrapolation, has arrived at the following figures for the approximate mechanical properties of pure unworked iron :—

Yield point	9 tons per square inch.	Elongation .	51 per cent. (length/area = 8).
Maximum stress	17 ditto.	Reduction in area	84 per cent.

The term 'ferrite' is applied to pure iron when it is considered as a microscopical constituent of iron or steel. Pure iron is composed of polyhedral crystallites of ferrite.

Commercial iron is always contaminated by the presence of the following elements—carbon, manganese, silicon, sulphur, and phosphorus; also arsenic, molybdenum, etc. All these elements have effect on the iron in which they occur and are frequently added with a view to obtain alloys having more or less definite physical and mechanical properties.

WROUGHT IRON.

Wrought iron is iron low in carbon content, which in course of production is in a pasty condition, owing to the fact of its being worked at a temperature too low to render it fluid. It contains a relatively large percentage of non-metallic impurities in the form of slag, which may be readily seen when the iron is examined microscopically, and which, therefore, serves, among other features, to distinguish this product from steel. The percentage of carbon in wrought iron rarely exceeds 0·15 per cent., and the total of other elements present in the metal is generally less than 0·25 per cent. Wrought iron is not appreciably hardened by quenching.

The fracture of wrought iron is fibrous in appearance and is occasionally characterised by the presence of somewhat large proportions of non-metallic inclusions.

WROUGHT-IRON (*or Mitis*) CASTINGS.

If a small amount of aluminium is added to a charge of wrought iron which has been heated until pasty, the iron immediately liquefies, and can be poured into castings having all the properties of wrought iron except fibre, and as sound as if of cast iron. These castings are called 'Mitis' castings because of their softness in contrast with cast-iron castings.

The best results are obtained by using Swedish scrap iron or English hematite iron, that is, materials containing less than 0·1 per cent. of phosphorus, which is a very injurious ingredient if present in much larger quantity. Using a mixture with poorer quality of iron, with phosphorus running up to 0·15 per cent., good results may still be obtained—that is, the castings still compare favourably with ordinary malleable castings. The following mixture for melting has been used :—Mitis scrap, 35 per cent.; hematite muck bar, 35; wrought-iron punchings, 12½; soft steel scrap (0·1 per cent. carbon), 12½, white pig iron, 3; ferro-silicon (10 per cent. silicon), 1; ferro-aluminium (6 per cent. aluminium), ½.

In general it may be said that if iron free from impurities is used very good castings are obtained; if iron is used with a large percentage of phosphorus, proportionately brittle and unsatisfactory castings result.

The ferro-aluminium used should be, for similar reasons, free from any considerable amount of such impurities as generally injure wrought iron.

PIG IRON.

Typical Analyses of Pig Iron, etc.

The following list of analyses is taken from Dr. W. H. Hatfield's book, 'Cast Iron in the Light of Modern Research.' It is published with the kind permission of the author and of the publishers, Messrs. C. Griffin & Co. Ltd.

CAST IRON.

Foundry Practice.

1.

The physical and mechanical properties of the products of the cast-iron foundry are almost entirely dependent on the condition of the carbon in these products. The carbon in cast iron can occur either in a free state, as graphite, or in combination with iron, as a carbide of iron, Fe_3C, or with iron and manganese, as a double carbide $(Fe, Mn)_3C$. Foundry practice consists almost entirely of the control of the degree of graphitisation of the carbides present in the cast iron produced.

The graphitisation of these carbides tends to increase—

(*a*) With the temperature.
(*b*) With deceleration of cooling.
(*c*) With the content of silicon, nickel, or aluminium.
(*d*) With the number of graphite nuclei in the iron.
(*e*) With the total content of carbon.

Graphitisation is prohibited—

(*a*) By the presence of sulphur, oxygen, vanadium, or chromium.
(*b*) By the presence of manganese under certain conditions.
(*c*) By acceleration of cooling.

It will be seen that by the variation of the above factors an immense number of conditions can be obtained. It is in the scientific control of these that much of the success in foundry practice lies.

2. The Influence of Carbon on Cast Iron.

The strength, hardness, density of structure, etc., of cast iron are dependent almost entirely on the relative quantities of carbide and graphite in the same.

An increase in the ratio $\frac{\text{Carbide}}{\text{Graphite}}$ leads to—

(*a*) An increase in hardness, brittleness, and density of structure.
(*b*) A decrease in machinability and ductility.

The strength of cast iron reaches a maximum when the combined carbon content is between 0·80 per cent. and 1·00 per cent.; if the combined carbon content given above is exceeded a reduction in strength, which only terminates when the carbon is entirely in the form of carbide, is witnessed. The following figures, given by Howe, are of value in this connection :—

As the tensile strength increases	From less than 20,000 lbs. per sq. in.	To more than 35,000 lbs. per sq. in.	Or by more than 15,000 lbs. per sq. in.
The total carbon content decreases .	from 3·69 per cent.	to 2·98 per cent.	or by 0·71 per cent.
The graphite content decreases . .	from 3·12 „	to 2·22 „	or by 0·90 „
The combined carbon content increases	from 0·57 „	to 0·76 „	or by 0·19 „

The above table classifies the results of an examination of 180 samples of cast iron taken without selection.

According to Dr. Stead (British Foundrymen's Association Proceedings, 1915), an increase of each 0·1 per cent. of graphite may reduce transverse strength by 2 cwts. and tensile strength by 0·8 ton per square inch.

The fusibility of the iron carbon alloys increases as the total carbon content increases up to about 4·30 per cent.; beyond this point the melting points of the alloys are raised by additions of carbon. Other effects of increased total carbon are decreased tensile strength, increased machinability and decreased chilling power. The last phenomenon is occasioned by the difficulty of retaining carbon as carbide, which naturally increases as the amount of carbon to be thus retained increases. Given suitable means for preventing graphitisation, every increase in the content of total carbon leads to an increase in the hardness of the chilled surface of the alloy in question.

The machining of cast iron containing more than 0·80 per cent. of combined carbon is practically impossible.

3. The Influence of Silicon on Cast Iron.

Silicon varies from 0·20 to 4·00 per cent. in cast iron, but rarely exceeds 3·50 per cent. or falls below 0·50 per cent. It is present in cast iron, in all probability, as silicide of iron (FeSi), which is dissolved in the pure iron, or ferrite, of the alloy. The presence of this compound tends to strengthen and harden the ferrite. Silicon, however, has the effect of rendering cementite unstable, with the result that there is a tendency towards the formation of ferrite and graphite. Starting with white cast iron, the addition of silicon up to 1·00 per cent. results in an almost proportional decrease in the chilling power of the iron. Again, the addition of silicon to white cast iron leads to an increase in the strength of the resulting irons; this factor reaches a maximum when the content of combined carbon in the alloy is between 0·80 per cent. and 1·00 per cent. As the silicon percentage is further raised so are the combined carbon content and the strength of the cast iron lowered. When the silicon content is above 2·00 per cent. its hardening effect on ferrite is noticeable, iron relatively hard to machine being occasionally improved by a reduction of the silicon content.

The presence of silicon leads to a depression of the melting-point of cast iron; in similar manner the percentage of carbon in the eutectic alloy is reduced from 4·30 per cent. to 3·40 per cent. as the percentage of silicon increases up to 3·00.

Silicon has the effect of reducing the shrinkage of cast iron.

As a means of determining the correct proportions of carbon and silicon in cast iron, the following formula has, according to Mr. F. J. Cook, been used with marked success in practical working :—

$$X = \frac{C}{4{\cdot}26 - \frac{Si}{3{\cdot}6}},$$

where

C = *total* carbon in percentage;
Si = silicon in percentage.

The elements carbon and silicon are in the best proportion when the value of X is as given below :—

For Ordinary work such as pans, grates, easily machined casting and pipes	X = 0·9 to 1
Locomotive cylinder (maximum transverse strength)	„ = 0·83
Steam, gas Diesel and hydraulic cylinders (maximum tensile strength)	„ = 0·76 to 0·82
Chilled castings	„ = 0·75 to 0·8
Acid resisting	„ = 0·85

4. The Influence of Sulphur on Cast Iron.

Sulphur combines with iron to form a sulphide having a low melting-point, which occurs in steel in the form of ovoids, oval laminæ or membranes enveloping the ferrite grains. The presence of this sulphide is the cause of red shortness.

In cast iron this sulphide may modify the properties of the alloy owing to its manner of aggregation, but it is deleterious chiefly on account of its tendency to segregate and its powerful effect on shrinkage, which it increases. Sulphur tends to restrain graphitisation, hence it increases the chilling power of cast iron and may, therefore, be termed a hardening agent. This element should, however, be employed with great caution, if at all, in this capacity, on account of the objectionable properties previously stated. The presence of sulphur makes the molten metal thick and sluggish, giving rise to blowholes, yet this element in fair proportions, say 0·12 per cent., adds considerably to the wearing properties and strength of the metal. In every case, however, sulphurous iron *must* be cast as hot as possible if trouble is to be avoided.

Manganese and silicon are employed to counteract the evil effects of sulphur. Manganese reacts with iron sulphide, with resulting formation of manganese sulphide and liberation of iron. Under certain circumstances manganese sulphide is removable from cast iron, but even when retained its effects are not so deleterious as are those of iron sulphide. Silicon, owing to its strong tendency to induce graphitisation, resists the effect of sulphur in tending to retain carbon in the combined condition; it does not remove sulphur, nor does it prohibit the shrinkage due to sulphur or reduce the tendency towards cracking.

Sulphur is frequently limited by specification to 0·05 per cent., but in the hands of experienced and careful workers as much as 0·20 per cent. can be allowed without ensuing unsoundness. If the sulphur content of an iron is to be low the conditions under which it is prepared must be such that sulphur tends to be eliminated. Hence, coke low in sulphur must be used and suitable fluxes should be employed in the furnace for removing sulphur from the metal, e.g. lime, fluor spar or manganous oxide.

5. The Influence of Manganese on Cast Iron.

Manganese and iron unite to form a series of solid solutions whose freezing-point curve lies entirely between the freezing points of the component metals. The freezing points of all the alloys of pure iron and pure manganese are below that of pure iron. The freezing point of cast iron is depressed by the addition of manganese, not only on the above account but also owing to an increase in the degree of solubility of carbon in cast iron, which is brought about by the fact that the affinity of manganese for carbon is greater than that of iron for carbon. The depression of the freezing point reaches a maximum when the percentage of manganese is about 13.

The alloys of iron and manganese (pure) are harder than pure iron. Manganese therefore would, normally, have the effect of hardening the ferrite of cast iron were it not for the fact that its affinity, firstly for sulphur, and secondly for carbon, prohibits its solution in the ferrite.

Manganese, when added to cast iron, combines in the first place with such sulphur as is present in the iron; any excess above that required for the formation of manganese sulphide unites with iron carbide, with the formation of a double carbide of iron and manganese.

The quantity of manganese required to effect the entire conversion of the iron sulphide in the alloy into manganese sulphide is considerably more than that indicated by the equation—

$$FeS + Mn = MnS + Fe.$$

Manganese sulphide is characterised by the following physical properties:—

(1) High melting point[2]–1400° C.;

(2) Insolubility in molten iron;

(3) Low specific gravity;

all of which assist in bringing about the separation of both manganese and sulphur from the molten alloy. Rapid cooling of the molten alloy leads to the more or less complete retention of manganese sulphide in the resulting solid alloy; slow cooling assists in separating the sulphide and bringing it into contact with the slag found on the surface of the alloy when the same is, for example, in the ladle. When the metal does not remain long enough in the ladle, or is not hot enough for the above to take place quickly, the manganese sulphide will be found on the top part of the casting in the form of hard spots, which are difficult to tool. Iron sulphide is deleterious in its action upon iron and steel. Manganese sulphide, though not beneficial, is of a somewhat neutral character. Manganese is, therefore, valuable as a desulphuriser.

Such manganese as is present in cast iron in excess of that required for the transformation of iron sulphide into manganese sulphide combines with the carbide of iron to form a double carbide, as stated above. Manganese is generally considered to induce the retention of the carbon in combination. This is true, but this effect does not make itself felt until the manganese content is well above that usually found in foundry irons. Hence, though hardness is increased by the addition of manganese, the cause is not usually the retention of carbon as carbide.

On the whole it may be said that, owing to (1) the tendency of manganese to produce brittleness and coarse crystallisation, and (2) its activity as a deoxidiser, it is inadvisable to add manganese to cast iron for the sole purpose of increasing hardness and chilling power.

Manganese increases the shrinkage of cast iron.

6. The Influence of Phosphorus on Cast Iron.

Phosphorus combines with iron to form a number of compounds, of which one, that containing three molecules of iron to each molecule of phosphorus, is of common occurrence in cast iron. The presence of phosphorus effects a reduction in the melting-point of cast iron and a reduction in the total carbon content of cast iron.

As the phosphorus content of cast iron is increased up to about 0·40 per cent, so is the strength of the cast iron increased. Further additions of phosphorus appear to have but slight effect on the strength of cast iron until the percentage reaches about 0·75 per cent. Above this point the alloys are liable to be brittle, and unless fluidity is more important than strength 0·75 per cent. of phosphorus should not be exceeded. For thin castings in general, which are not required to be strong, the phosphorus can be increased to 1·5 per cent. or more, but in thin castings such as automobile cylinders, which are required to withstand wear and tear, not more than 0·30 per cent. of phosphorus should be allowed, owing to the slight tendency towards segregation of high phosphide irons.

Semi-Steel.

Semi-steel is simply cast iron made from a furnace charge of cast iron to which **mild steel or wrought iron** has been added. Additions of **from 10 to 25 per cent. of steel** are usual, but 30 and occasionally 40 per cent. are not unknown. As steel is low in carbon, silicon and phosphorus, the final cast iron (for it is still a true cast iron) is low in these elements. The steel should be added as sheared clippings or other small pieces, but not as borings, which take up too much sulphur. Iron appears not to take up sulphur from gases, but only by direct contact with the coke, hence the air furnace gives irons lower in sulphur than the cupola and is specially suited for melting steel with pig irons. **Perfectly good results are,** with care, obtainable from the cupola. There is, however, a tendency for the more fluid portions of a cupola burden of cast iron and steel to run first. Hence the first tap from the cupola is generally higher in carbon content than succeeding taps.

(*The above note on semi-steel is based on a paper read before the Manchester Association of Engineers by Mr. Frank Foster, M.Sc.*)

Tests for Cast Iron.

(Abstract of paper read by Mr. F. J. Cook before the Staffordshire Iron and Steel Institute, January 20, 1917.)

Important tests which are of use as a guide to foundrymen are :—

(1) Keep's shrinkage test ;
(2) Transverse test ;
(3) Hardness test ;
(4) Casting temperature or fluidity test ;
(5) Impact test.

(1) **Keep's Test** consists of casting ½ in. square bars between iron yokes, the ends of which are 12 ins. apart. When the bars have cooled down the shrinkage is shown by the difference between the length of the bars and the gap in the yoke in which they were cast ; this is usually measured by inserting a taper graduated wedge in the gap and measuring off the dimension of the space.

This test is quite a comparative one, and when the amount of shrinkage which is associated with the most satisfactory castings has been arrived at, any deviation can be rectified by a little addition of silicon if the shrinkage becomes too high and *vice versa* when it is too low.

Under normal conditions a shrinkage of 0·183 in. = 1 per cent. silicon, and, to take the other extreme, 3·5 per cent. silicon is associated with 0·123 in. shrinkage.

(2) **Transverse Test.**—The following table gives average particulars of shrinkage, deflection and breaking load obtained with various classes of iron :—

Class of Material.	Shrinkage.	Deflection.	Breaking load.
	in.	in.	lbs.
Tough strong Iron	0·160	0·25	550
Hard „ „	0·168	0·22	630
Soft Iron	0·123	0·18	423
Mottled Iron	0·207	0·11	375
White Iron	0·226	0·08	250

from which it will be seen that to obtain a big deflection strong irons are necessary.

(3) **Hardness.**—The most handy and reliable form of test is the 'drill test,' as all other methods deal with surface hardness only. The test may be made as follows :—Cast the metal into bars 1½ in. diameter, ½ in. being shaped off one side to give a flat surface to work upon, and

move the outside skin. Drill four holes $\frac{3}{4}$ in. diameter, to a depth of 1 in., then the number of revolutions required to drill to this depth (the mean of the four holes being taken) indicates the general hardness. The angle of the drill should be ground exactly the same for each test, by means of a suitable guide on the grinding machine. It is also essential to keep the same drill for the purpose, and preferably, two drills should be used and two holes drilled with each, which minimises many discrepancies which otherwise might come in. The efficiency of drills is materially affected by the sharpness of their point, and as cast iron is often not homogeneous and may contain more or less hard spots a false result may be obtained owing to the point becoming unduly dulled by striking a hard spot in the early stages of the test. To avoid this a hole $\frac{1}{8}$ in. diameter should be first drilled, which affords clearance for the point of the drill and ensures the full cutting edge coming into operation. It is obviously necessary that the same weight be attached to the drill and also that it runs at the same number of revolutions per minute for each test.

(4) **Casting Temperature.**—Low silicon cast iron is very prone to the effects of casting temperature, and some irons employed for such purpose are also liable to liquid contraction. A handy workshop test for casting temperature with this class of iron consists in making bars of the general dimensions shown in fig. 33. When cold the bars are broken through the line AB, the condition of the fracture giving an indication of the temperature at which

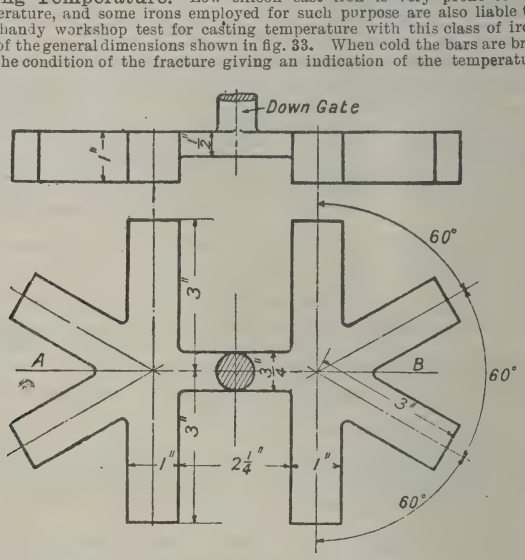

FIG. 33.

the metal was poured. Passing from the correct temperature (which is usually as hot as can be obtained from the cupola) to very low, the following fractures will be observed—perfectly solid and homogeneous, then slight whitish centre, then brown centres of varying sizes and depth of colour as temperature is lowered and then black centre; with the latter is always associated open cavities, and immediately above them is invariably found a gas hole.

For softer cast iron, which can be cast at a lower temperature without suffering the same effects as low silicon irons, a test bar in the form of a wedge is a very useful guide as to the fluidity of the metal. Dimensions of such a test-bar used by the British Chuck and Piston Ring Co. are length 9 ins., width 1 in., $\frac{3}{8}$ in. thick at the largest end tapering to $\frac{1}{32}$ at the smaller, the bars being run from the thick end.

(5) **Impact Test.**—A satisfactory test is on bars 40 mm. square (1·57 in.) supported on knife edges 160 mm. (6·3 ins.) apart, and by dropping a weight of 12 kilos (26·5 lbs.) from a height of 30 cm. (11·8 ins.) increasing the height of drop by increments of 5 cm. (1·9 in.) until such times as the sample breaks, the height at which the bar eventually fractures being taken as the impact figure. Attached to the weight, in such a manner as to strike the bar parallel to the supporting knife edges, and the centre of same, is another knife edge. The face of all the knife edges should be rounded $\frac{1}{16}$ in. radius.

A result of 55 cm. (21·5 ins.) is none too high for the work named, although this is quite a severe test. The maximum attained, as far as is known, has been 80 cm. (31·3 in.).

E—modulus of elasticity.

The above is taken from the practice of a large German engineering firm as published in the German technical press in 1908. The test bars are round, of the varying diameters stated: all cross-breaking loads being on one metre (39·37 ins.) span.

STEEL.*

The term 'steel' is applied in a general sense to those alloys of iron and carbon whose carbon is present entirely, or almost entirely, in the combined condition and whose total carbon content does not exceed 2·00 per cent. In a special sense the term is applied to alloys of iron and carbon with elements which are generally in excess of the carbon and whose presence considerably modifies the resulting alloys; such alloys are generally named 'special steels.'

The pure alloys of iron and carbon are unknown commercially. Steel is always contaminated by some or all of the elements—manganese, silicon, sulphur and phosphorus. The effect of these elements on steel is considered below.

1. THE INFLUENCE OF CARBON ON THE PROPERTIES OF STEEL.

Carbon exists in steel in various forms and combinations, the following being those most generally recognised:—

(*a*) Free Carbon.

1. GRAPHITIC CARBON.

Rarely found in steels, as it is generally produced only when the alloy has taken up more carbon than it can retain in solution on solidification—about 2 per cent.

2. TEMPER CARBON.

Present in steels containing upwards of 1·0 per cent. carbon, which have been heated to redness. It is mainly found in white pig irons that have been subjected to annealing and tempering.

(*b*) Cement Carbon.

The carbide Fe_3C, which is known as 'cementite,' when considered as a microscopical constituent of steel. It exists in unhardened steels. The carbide is soluble in nitric acid of 1·20 sp. gr., giving a brown solution, which is of value in the estimation of the carbon percentage of steels.

(*c*) Hardening (Solution) Carbon.

Occurs in quenched steels, of which the tenacity, hardness and brittleness increase, within limits, as the percentage of hardening carbon in the steels increases.

* See also 'Tool Steel,' p. 980.

Stead states that 'the influence of carbon on the properties of normalised steel,' i.e. steel that has been heated to a temperature above that of all its critical points and cooled in air 'containing less than 0·90 per cent. carbon, approximates to the following average :—

EFFECT OF 0·1 PER CENT. CARBON.

Yield point is raised	1·78 tons sq. in.
Maximum stress is raised	4·18 ,,
Elongation is reduced	4·33 per cent.
Reduction of area is reduced	7·27 ,,

The figures represent material with only small quantities of manganese.'

Sauveur suggests the following formula for the average maximum stress of hypo-eutectoid (containing less than 0·83 per cent. carbon) steel, containing from 0·20 per cent. to 0·80 per cent. manganese :—

$$T = 22{\cdot}3 + 4{\cdot}02\ C \text{ (tons sq. in.).}$$

where T = Maximum stress.
and C = Carbon content.

For hyper-eutectoid steel (containing over 0·83 per cent. carbon) he suggests the following :—

$$T = 63{\cdot}4 - 9{\cdot}2\ C \text{ (tons sq. in.),}$$

which formula must, however, be employed with considerable judgment. (See also p. 2284.)

The maximum degree of hardness of steel is reached when the carbon content is 0·90 per cent.

2. THE INFLUENCE OF SILICON ON THE PROPERTIES OF STEEL.

Iron and silicon combine to form a compound, iron-silicide (FeSi), which, in all probability, forms a series of solid solutions with iron. It is, then, in the form of a solid solution that silicon occurs in steel.

The influence of silicon on the properties of steel increases with the percentage of carbon. In the case of low carbon steel silicon up to 1·75 per cent. increases the yield point and tensile strength without reducing the ductility; beyond this percentage increase of tenacity is accompanied by a serious loss of ductility. The silicon content of carefully manufactured mild steel rarely exceeds 0·20 per cent. Generally speaking, high carbon steels are benefited by the presence of silicon.

Silicon produces soundness in cast steel and is largely used in the manufacture of basic open-hearth steel. The effect of silicon on the mechanical properties of steel is somewhat variable and no definite figures are, therefore, quoted in this connection.

3. THE INFLUENCE OF MANGANESE ON THE PROPERTIES OF STEEL.

Manganese is present in steel owing to its premeditated addition—made with a view to deoxidise the decarburised metal in the steel furnace. It also acts as a 'desulphuriser,' in the sense that it modifies the action of sulphur on steel. Provided the manganese content of a given steel is sufficient to retain the sulphur therein almost entirely, if not entirely, in the form of manganese sulphide, the deleterious effects of sulphur will be avoided. This statement does not mean, however, that the quantities of manganese and sulphur that may be present in a given steel are unlimited.

Manganese combines, in the first instance, with the sulphur in the steel (see note on Manganese in Cast Iron). Any excess of manganese over the amount required to form manganese sulphide combines with some of the carbon to form manganese carbide (Mn_3C).

The effect of manganese on the physical properties of steel is not known with certainty. Harbord considers that for mild steel and rail steel the less the content of manganese above that required to ensure solid ingots and freedom from red shortness the better. The manganese content of mild steel for boiler plate and structural work should be limited to 0·60 per cent. The presence of 1·00 per cent. of manganese in medium high carbon steel does not induce brittleness; in high carbon tool steels not more than 0·50 per cent. should be permitted, owing to the liability to fracture during the process of quenching incurred thereby. It seems likely that the mechanical properties are varied too slightly and too vaguely as to be of note if manganese be present in quantities of less than 1·25 per cent.

4. THE INFLUENCE OF SULPHUR ON THE PROPERTIES OF STEEL.

Sulphur occurs in steel in combination either with manganese or with iron. The compound of manganese and sulphur has a high melting point, low specific gravity, and occurs almost always in the form of globules or ovoids (*Arnold*). It may seriously affect the properties of steel if present in large quantities, but its presence is not nearly so deleterious as is that of iron sulphide. The latter compound has a low melting point and can occur not only in the form of globules or ovoids

but as meshwork surrounding the crystals of ferrite in steel. The low melting point of this compound is generally considered to be the cause of the red shortness of sulphurous steels, which red shortness is, of course, considerably aggravated when the iron sulphide surrounds the crystal grains.

The above serves to show that manganese modifies the effects of sulphur and, since manganese has a greater affinity for sulphur than has iron, the manganese content of steel is frequently adjusted with these modifying effects in view.

Sulphur appears (i) to reduce the yield point, maximum stress and percentage elongation of steel, (ii) to increase the percentage reduction of area and the resistance to shock, and (iii) to increase the cutting freedom of steel during machining. Certain steels specially noted for the last feature are known having a content of sulphur of 0·15 per cent. Such a sulphur content is out of the question for steel that is to be welded or to be manufactured into rails or material for structural purposes. Steel that requires to be welded should contain not more than 0·06 per cent. of sulphur, while such as is to be employed for rails or constructional work should have an upper limit of 0·08 per cent. of sulphur. It is advisable when consideration is taken of the sulphur content of a steel to take note also of the percentage of manganese in the same.

5. The Influence of Phosphorus on the Properties of Steel.

The small amount of this element usually present in steel is held in solid solution by the iron as phosphide of iron (Fe_3P). Phosphorus is supposed by some to enlarge the grain of steel, thus inducing the dangerous characteristic of cold-shortness to steel.

The effect of phosphorus becomes more noticeable as the carbon content of steel is raised. In low carbon steels not more than 0·10 per cent. is, as a general rule, allowable, while for most purposes—e.g. constructional steel—0·06 per cent. should not be exceeded. Certain steels contain quantities in excess of 0·10 per cent., but owing to the liability of steels containing much above 0·08 per cent. of this element to failure under shock, the last figure may be considered as a safe limit for most purposes. In high carbon steels the effect of phosphorus is much more noticeable, an increase of 0·01 per cent. being quite noticeable (*Howe*) in 1·00 per cent. carbon steel. A limit of 0·04 per cent. is considered advisable in the latter steels.

Stead quotes the following figures for the effect of 0·10 per cent. of phosphorus on the mechanical properties of steel :—

Yield point is raised	2·5 tons per sq. in.
Max. stress is raised	2·4 ,,
Elongation is reduced	0·7 per cent.
Reduction is reduced	1·5 ,,

The specific work required to produce rupture decreases as the content of phosphorus increases.

6. The Tenacity of Steel as affected by the above Elements.

McWilliam quotes the following formula :—

$$T = 38000 + [800 + 4(C - 20)]\,C + 1205 + [100 + 2\,(C - 20)]\,Mn + 1000\,P$$

as representing the maximum stress value of normalised basic steel in pounds per square inch. There is a difference between steels of acid and basic origin such as renders the formula of little value for purposes of determining the properties of steel of the former type.

7. The Influence of Nickel on the Properties of Steel.

The following are results of tests of nickel steel made by the St. Jacques Steel Works :—

1. 2 to 5 per cent. of nickel. Resistance increases with percentage, especially when carbon content is low. When carbon reaches 0·50 per cent., nickel has little influence. Forges and rolls well. When hardened, ratio of elastic limit to ultimate resistance is very great.

2. 10 to 20 per cent. nickel. Resistance increases with percentage of nicked. An addition of 0·10 per cent. of carbon increases ultimate resistance from 19 tons to 41 tons. With 2·0 per cent. nickel resistance is 69 tons. With increased carbon up to certain limit, over 127 tons can be obtained. Resistance with 10 per cent. nickel decreases when carbon is 0·50 per cent. These steels do not harden much, and do not harden at all when the carbon is higher than 0·10 per cent.; 20 per cent. nickel steel never hardens. All are very brittle. They forge and roll well, but when containing more than 0·10 per cent. carbon they cannot be machined.

3. 20 to 25 per cent. of nickel. Elastic limit, as well as ultimate resistance, is low. They have great elongation, and are nearly free from brittleness. When forged at a low temperature without annealing, elastic limit increases notably, and has reached 35 tons with an ultimate resistance of 51 tons, and an elongation of 25 per cent. With less than 1 per cent. carbon the steel can be easily forged and rolled. With 1 per cent. of carbon, can be forged between 500° and 1,000° with light blows. Machining is difficult, but not impossible.

An ultimate resistance of 40 tons can be obtained from 3 per cent. nickel steel with ·175 per cent. of carbon, when to obtain this strength in ordinary steel would require at least ·50 per cent. of carbon, sufficient to make the material so brittle as to be unreliable.

In general, the elastic limit of nickel steel is above 50 per cent. of ultimate resistance.

Nickel steel cannot be machined as easily as low carbon steel.

SPECIFICATION FOR 3 PER CENT. NICKEL STEEL.

Description.	Tensile Strength in Tons per Sq. In.		Minimum Elongation.	Elastic Limit.

NOTES ON STEEL SPECIFICATIONS.

(*Frank Foster, M.Sc.*)

Steel Forgings.—These should be of Siemens-Martin open-hearth make, and in this country it is usual to specify acid steel. In Germany and America basic steel is usual.

The test bars should conform to British standards or the value of the elongation is misleading. The parallel portion of a test piece should extend not less than one-quarter of the diameter beyond each gauge mark. The test piece may conform to one of the following after machining :—

Diam. 0·564 in., area 0·25 sq. in., gauge length 2 ins.
Diam. 0·798 in., area 0·50 sq. in., gauge length 3 ins.
Diam. 0·977 in., area 0·75 sq. in., gauge length 3·5 ins.

The following are suitable test requirements, all forgings being well annealed after leaving the hammer or being rough machined :—

Forging.	Tensile, tons sq. in.	Elongation per cent.
Crankshafts and general	28–32	27–23
Piston rods	33–37	22–20
Connecting rods and pins	30–35	25–20

The carbon content varies from 0·2 to 0·35 per cent., according to tensile strength ; 0·3 per cent. carbon giving, according to H. Brearley, 34 tons tensile and 30 per cent. elongation with 52 per cent. reduction in area.

Nickel Steel.—It is usual to specify that nickel steel shall contain 3·5 per cent. of nickel, but it may fall as low as 3 per cent. It is not usual to make mention of heat treatment, although this enables the qualities to be improved. Forgings of this character, with 3 to 4 per cent. nickel, are chiefly used for heavy connecting rod bolts and important valve spindles ; also, at times, for piston rods. Typical tests results are 35 to 48 tons tensile, and 18 to 22 per cent. elongation.

According to H. Brearley and others the most reliable material for rapidly applied shock loads, of which an aeroplane engine valve with spindle is a good example, is a 25 per cent. nickel steel.

20 per cent. of nickel renders steel non-corrodible.

Nickel-Chrome Steel.—Occasionally engine builders require a specially strong, tough, and hard steel, say for pins under severe loading. It is perhaps best in these special cases to put oneself in the hands of a good steel firm, but it may be of interest to note that nickel-chrome steel is much used in such cases. It is air-hardening and can thus be cooled slowly to avoid contraction stresses after heat treatment. According to Brearley (Manchester Association Engineers, October 1914) the tensile strength varies from 42 to 130 tons, and the elongation from 30 to 10 per cent. with from 66 to 35 per cent. reduction in area, according to the heat treatment.

American Forgings.—For large forgings tensile strength not less than 75,000 lbs. (33·5 tons) ; elastic limit not less than 40,000 lbs. (17·8 tons) ; elongation not less than 20 per cent. in 2 ins. with a reduction in area of 45 per cent. Forgings to contain about 0·4 per cent. carbon and not over 0·04 of sulphur or phosphorus. To be thoroughly annealed.

Cast Steel.—Steel castings are made by firms specialising in the business and rarely by the engine-builders. As a rule a very vague specification is drawn up and no tests are called for.

Of whatever quality it is important that steel castings should be well annealed. According to Prof. Arnold about 180 hours total time is required for this.

Test bars should be cast on the work and machined before testing.

For hydraulic and steam or gas engine work the tensile strength should lie between 28 and 33 tons per square inch with an elongation of 20 per cent. or over, on a standard test piece. A test piece 1 in. wide by ½ in. thick should stand bending through an angle of 90° with an inner radius of one inch.

For heavy gear wheels the above tests may be specified, but better wearing qualities are obtained with a higher carbon content, giving a tensile strength of 35 to 40 tons per square inch and an elongation of about 12 to 15 per cent.

Chemical tests are seldom specified and are rarely necessary, provided the mechanical tests are satisfactory. The usual run of castings contain about 0·3 per cent. carbon.

Bar Stock.—Rolled and drawn bars, both bright and black, are largely used in engine construction, and the following notes are based on the British Standard specification. Two qualities, 1 and 2, are to be as follows:—

Quality.	1.	2.
Tensile, tons, not less	28	35
Elongation, per cent.	14–17	12–14·5
Carbon, per cent.	0·25	0·40
Manganese	0·85	1·00
Silicon	0·20	0·20
Phosphorus	0·06	0·06
Sulphur	0·06	0·06

The test pieces must be cut from the stock bars and not machined. Bending tests are advisable, especially with cold drawn and reeled bars, as these do not prove perfectly reliable in practice. (*Frank Foster, M.Sc.*)

Cobaltron Steel Alloy (Patent).

This alloy (patent) introduced by Messrs. Darwin and Milner, of Sheffield, is made by adding cobalt to chromium-carbon steel. The maximum temperature necessary for the hardening is 1000° C. (tungsten steel requires from 1250° to 1350° for the best results) and hardening is said to be satisfactory when the steel is allowed to cool naturally in still air. Analysis of cobaltron shows that the following elements approximate to the amounts stated below:—

Carbon	About 1·5 per cent.	Molybdenum	About 1·25 per cent.
Cobalt	,, 2·25 ,,	Tungsten	,, 0·25 ,,
Chromium	,, 11·0 ,,		

'Heenan' Oil Coolers for Heat Treatment of Steel.

The continuous introduction of hot steel into oil quenching tanks naturally heats up the oil, which retains heat for a long time, and rapidly becomes too hot to permit of the process being carried on.

Owing to the poor heat conductivity of oil, such arrangements as water-jacketing the tank or inserting pipe coils through which water is circulated are ineffective, the cool surfaces affecting only that portion of the oil in immediate contact therewith, while allowing the main body to remain over-heated.

The 'Heenan' system of oil cooling is to extract the hot oil by means of a suitable centrifugal pump, and pass it through a 'Heenan' oil cooler before returning it to the quenching tank. This oil cooler is built up on lines similar to those of the water cooler described on page 1107. In effect, oil is spread over a large cooling surface with which cool air from the surrounding atmosphere is then drawn into contact. Circulating water is not used.

This machine has been applied amongst other purposes to quenching processes in connection with the hardening and tempering of gun tubes, rifle barrels, steel tools, gear wheels, springs, aeroplane engine parts, etc.

CASE-HARDENING.

The case-hardening of steel is dependent upon the fact that above certain temperatures the affinity of iron for carbon is so great that when iron or steel is heated at these temperatures in contact with suitably chosen carbonaceous materials ready absorption of carbon supervenes. The quantity of carbon that can be absorbed by iron or steel under the above conditions varies according to the following factors—

1. The composition of the iron or steel.
2. The temperature at which the process is conducted.
3. The length of time during which the process is continued.
4. The nature of the carburising material.

The Composition of the Iron or Steel.

Case-hardening, in the accepted sense, is rarely practised on steel containing more than 0·20 per cent. of carbon or 0·40 per cent. of manganese. The process is stated by Guillet to be hindered by the presence of nickel, silicon and aluminium, and hastened in the presence of manganese, tungsten, chromium and molybdenum.

The Temperature at which the Process is Conducted.

The process is best conducted at temperatures above the critical range of the iron or steel treated. The usual temperatures for carburisation vary from 900° C. to 1000° C. The higher the temperature of carburisation the greater the rate of absorption of carbon and the deeper the effect of absorption.

The Length of Time during which the Process is Continued.

This factor can only be determined by experiment. It is generally considered that the best results are obtained when the carbon content of the surface layers of the case-hardened material are of eutectoid composition (about 0·90 per cent. C.).

The Nature of the Carburising Material.

The carburising material may be either solid, liquid or gaseous. Solid materials are employed more generally than are liquid or gaseous materials.

Solid Case-hardening Materials.

For the purpose of obtaining deep 'cases' the articles to be hardened are packed in a suitably designed box with solid case-hardening substances or mixtures of substances, of which the following are examples :—

Charcoal (animal or wood).
Charred leather.
Crushed bone or horn.
Barium carbonate 40 per cent. and charcoal 60 per cent. (Caron's mixture).
Charcoal (wood) 95 per cent. and soda ash 5 per cent.
Charcoal (wood) 90 per cent. and common salt 10 per cent. (Guillet).

As case-hardening composition is bought by weight, and is required to fill up the case-hardening boxes, the specific gravity is an important consideration. The speed of conduction of heat through various depths of carburising material requires determining by experiment. A good case-hardening material should not diminish in volume appreciably during the carburising operation, and should be free from sulphur and phosphorus.

The box should be of plate iron not less than $\frac{1}{8}$ to $\frac{1}{4}$ inch thick. The lid of the box has two holes pierced in it for drawing testing-pieces out if required. For small articles a piece of wrought-iron tube, plugged or capped at one end, may be used ; the other end is closed by a second plug fastened with an iron pin passing through it and the pipe, the whole being luted with fine clay. The articles being previously finished, except polishing, are put into the box in alternate layers with the carburising mixture, commencing at the bottom of the box with carburising mixture to the thickness of about $\frac{3}{4}$ inch ; upon this a layer of the articles is placed, then another of carburising mixture about one-third the thickness of the first, and so on until the box is nearly full, finishing with carburising mixture about the thickness of the first layer, leaving room every way for the expansion of the articles by the heat, otherwise they will bend each other in the box. The packing completed, the lid is put on, the box luted and placed in a suitable furnace. The contents of the box require to be very gradually and uniformly heated to redness, and retained at this heat for the period required for the depth of caburisation desired. The depth of carburisation depends on the length of time the temperature is kept up. For testing pieces plain pieces of the same kind of iron as the articles may be used. They require to be brightened, and are placed, at the time of the packing of the box, in the central part, in such a manner that they may be readily pulled out through the holes in the lid, either by a piece of iron wire attached or by being made long enough to project through the holes, so that they may be gripped with pliers ; the holes are luted the same as are the other parts. When the articles are sufficiently carburised the box is drawn from the fire, the lid taken off, and the contents are immersed in pure cold water ; taken out when cold they are ready for polishing. To prevent rusting the articles may be dried by riddling in a sieve with dry saw-dust, after which they are wiped with a greasy cloth. If the articles be immersed in oil instead of water they will be much tougher but less hard, though sufficiently so for some purposes. It is not necessary to immerse them direct from the box, as it answers equally as well to allow them to remain in the box till cool, and then reheat them in an open fire and immerse them separately.

When the case-hardening is required to terminate at any particular part of the article, the part needed to be soft may be bound with iron wire and cased with loam. This prevents the iron from absorbing carbon at that part. The loam requires to be gradually dried on the article previous to putting in the box, otherwise it will crack. 'Harbee,' in a letter to *Engineering* (August 15, 1913), states that, in order to 'stop off' that portion of the article required to be kept soft, a thin coating of copper (one thousandth of an inch in thickness is sufficient) electrolytically deposited will effectually resist any attack of the case-hardening material. After case-hardening the film of copper can be readily removed by the aid of a pocket knife. Copper plating, however, is expensive. Another method is to cover the part needing protection with a copper tube (this is the most satisfactory method when the shape of the work will allow the use of the tube) or to paint it with a protecting paint (paint can be made from china clay and blacklead or from sodium silicate and sand). A frequent procedure is to carburise an object and allow it to cool in the box, finally machining off the carburised portion before quenching wherever it is desired to keep the surface soft. It is of course necessary to leave sufficient metal on the object before carburising in order to ensure complete removal of all carburised metal before quenching. With long objects, one end of which requires hardening while the other is to remain soft, it is possible to carburise the entire length, then reheat and quench one end only, allowing the other end to cool in air.

For the purpose of superficial case-hardening it is necessary only to heat the iron or steel to be treated to redness, to sprinkle one or other of the following finely powdered compounds or mixtures on the surfaces to be hardened, and to plunge the iron so treated into pure cold water. This method is simple and speedy, but the case obtained is insufficiently thick to resist much wear.

Potassium cyanide.
Potassium ferrocyanide.
Potassium ferrocyanide and potassium bichromate.
Sodium ferrocyanide 90 per cent. and anhydrous sodium carbonate 10 per cent.
Sodium ferrocyanide 80 per cent., anhydrous sodium carbonate 10 per cent., and potassium ferrocyanide 10 per cent.

Liquid Case-hardening Materials.

The immersion of steel articles in a bath of molten potassium cyanide (the fumes of which are of a highly poisonous nature) heated to 850° C. results in the formation of very hard but shallow cases.

Gaseous Case-hardening Materials.

The following gases have been employed for case-hardening iron and steel—illuminating gas, carbon monoxide, acetylene and petroleum vapour. All, according to Brearley, are supposed to be more effective if they are led through a solution containing ammonia, or otherwise are partly saturated with ammonia gas before entering the furnace. By increasing the pressure of the gaseous mixture it is possible to increase the rate of carburisation.

Thermal Treatment of Case-hardened Materials.

Quenching.—If the quenching takes place directly after the carburising operation, the resulting product is liable to possess a coarse structure in both the core and the case. In order to improve the structure it is better to allow the work to cool in the box after cementation, and then reheat it in a separate operation. The reheat may be made bare in the furnace, but with large objects which take long periods to obtain the desired temperature it is advisable to protect them from decarburisation by covering them with charcoal or old case-hardening mixture. This second reheat is most satisfactory at temperatures of about 780° to 820° C. It is claimed that very good results may be obtained by reheating twice, first with a view to refining the core and secondly to refine the case. A sample treatment of this description is :—

1. Carburise at 900° C. and allow to cool in box.
2. Reheat at 900° C. bare, and allow to cool in air.
3. Reheat bare for 20 minutes at 810° C. and quench in water.

Another common treatment which is said to yield fine core structures is to reheat twice and quench after each reheat, e.g. :—

1. Carburise at 920° C.
2. Reheat to 900° C. and quench in oil.
3. Reheat to 810° C. and quench in water.

In order to refine the cores of case-hardened articles it is advisable to heat the same to at least 875° C. (unless the carbon content of the core is above 0·20 per cent.) and quench. This treatment refines the core of the article but coarsens the case, hence it is necessary to reheat, to a temperature somewhat above the critical range corresponding to the carbon content of the case (775° C. to 825° C.), subsequently quenching the article in water, or in oil.

Oxy-Acetylene Welding *and* Cutting Plants

TRADE **'OXALENE'** MARK

ACETYLENE GENERATORS: Stationary and Portable

WELDING BLOWPIPES: Single and with Exchangeable Nozzles

Quenching in water results in a much more rapid cooling than oil quenching; the former is necessary for ball races, cams, and all parts which have to be subjected to hard wear and require extreme hardness (80 to 90 scleroscope). Oil quenching of correctly carburised mild steel results in a hardness of 50 to 70 scleroscope. Small objects cool more rapidly, and therefore become harder than large objects undergoing the same treatment.

Tempering of the quenched articles still further improves the properties of the same.

OXY-ACETYLENE WELDING AND CUTTING.

(Contributed by D. Richardson, Wh. Exh., A.M.I.M.E., Capt. R.A.F.)

EQUIPMENT.

The apparatus required for an oxy-acetylene installation usually comprises a generator for generating the acetylene gas, which may be a fixed or portable plant, the most portable type of plant uses compressed or dissolved acetylene in portable safety cylinders instead of a generator; chemical and mechanical purifying apparatus; oxygen apparatus for the production of oxygen, or the use of oxygen in cylinders; oxygen regulator for lowering the pressure of the gas after it leaves the cylinder, to the pressure required for the blowpipe, and, in the case of dissolved acetylene, an acetylene regulator for the same purpose; hydraulic safety valve or other safety device; welding and cutting blowpipes of various capacities; accessories, such as flexible tubing, goggles, welding benches, blowpipe support, preheating devices, tools, jigs, filling materials, etc. etc.

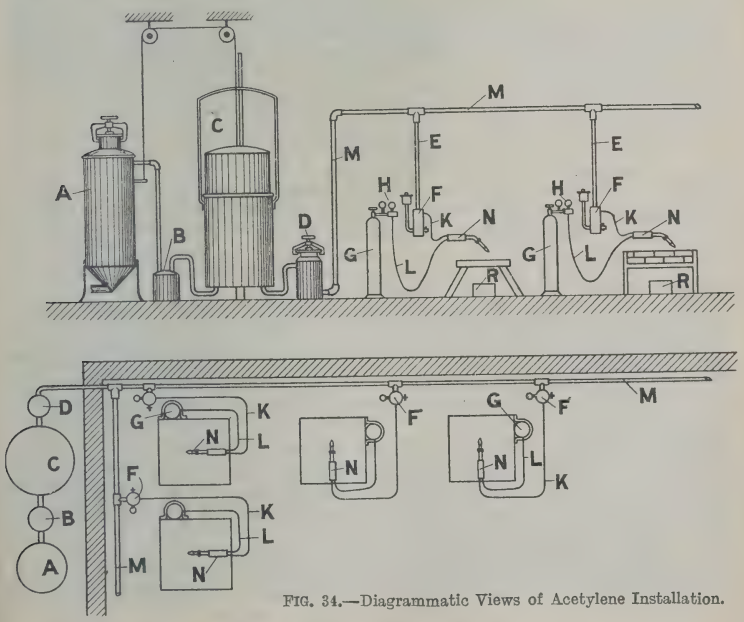

FIG. 34.—Diagrammatic Views of Acetylene Installation.

Fig. 34 shows in diagrammatic form an elevation and plan of the general lay-out of an acetylene welding and cutting installation. The letters refer to the same details in both views.

The acetylene generator, shown at A, is usually automatic, that is, the generation of gas is controlled entirely by the gasholder regulating the water supply or the carbide supply; B is a condenser, washer, and water-seal; C is a gasholder, consisting of a tank to contain the water-seal and a bell to store the gas; D is a purifying chamber and filter. The main piping, M, is

connected to the purifying chamber and forms a complete circuit of the welding shop ; branch pipes, E, are taken from the main for supplying acetylene to each welding station ; F is the hydraulic safety valve or other safety device ; a flexible tube, K, connects the hydraulic safety valve to the welding or cutting blowpipe, N ; G is the oxygen cylinder, on to which is screwed the oxygen regulator H ; a flexible tube, L, connects the oxygen supply to the blowpipe N ; two common types of welding benches are shown.

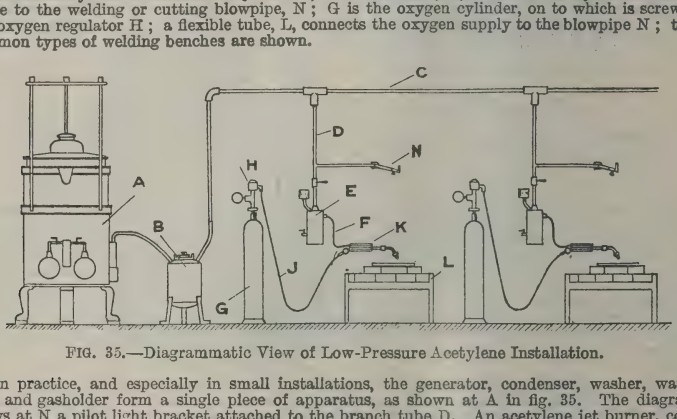

FIG. 35.—Diagrammatic View of Low-Pressure Acetylene Installation.

In practice, and especially in small installations, the generator, condenser, washer, water seal, and gasholder form a single piece of apparatus, as shown at A in fig. 35. The diagram shows at N a pilot light bracket attached to the branch tube D. An acetylene jet burner, consuming about 5 litres of acetylene per hour, screwed into the bracket, forms an efficient and economical method of lighting the blowpipe. The burner should be at least 18 inches from the hydraulic safety valve and not more than 6 ft. above floor level.

OXYGEN SUPPLY.

The oxygen may be obtained in cylinders or may be produced on the premises. There are three processes for the production, namely :—(1) By the chemical process ; (2) by the electrolysis of water ; (3) by the liquid-air process. The first is practically obsolete, and the second is generally used for producing oxygen on the premises. The gas can then be charged into cylinders or piped into the welding shop from large tanks into which it has been compressed. The cylinders supplied by manufacturers usually contain 100 cub. ft. of gas at a pressure of 1,800 lbs. per sq. in. Care must be taken against leakages, and particular care must be exercised not to oil or grease any part of the oxygen apparatus or supply line. Dust and moisture should be expelled by opening the cylinder valve before the cylinder is put into use. Repairs to cylinder valves should not be attempted by the user, and full cylinders should be handled carefully. No attempt should be made to transfer oxygen from one cylinder to another by rigging up some form of communicating tube. A cylinder valve should never be opened suddenly when the oxygen regulator is attached. In the event of the oxygen supply being restricted owing to the freezing of the cylinder valve, only hot water should be used to put it right. Leakages can be discovered by the hissing noise produced by the escaping oxygen, by the use of soap-suds spread over likely places, or by closing the blowpipe, cylinder and regulator valves and noting how long the pressure holds up on the gauges.

For estimating costs of welding, the following table will be found useful. The table gives the number of cubic feet of oxygen remaining in a 100 cub. ft. cylinder corresponding to various readings of the high-pressure gauge on the oxygen regulator. The amount of oxygen indicated by the gauge reading is more or less approximate as it depends upon the temperature of the oxygen. For practical work the deviations can be ignored, and would not affect the usefulness of the table.

THE 'OXHYCARBON' Oxy-Acetylene CUTTER.

The Oxhycarbon Cutter and Blowpipes have been imitated by many but equalled by none.

Oxygen is supplied to the trade at prices which vary according to the size of the cylinder, quantity required, and other conditions. Cylinders are loaned, or may be purchased outright. Demurrage charges are made on hired cylinders when retained above a certain period. Oxygen cylinders are conveyed by the railway companies under strict regulations and conditions.

Acetylene Supply.

The acetylene may be obtained in cylinders, when it is generally known as dissolved acetylene, or may be generated on the premises. The precautions in handling acetylene cylinders are much the same as for oxygen cylinders. The gas should not be drawn off at too high a rate; in other words, the greater the demand the larger the cylinder. For general work cylinders containing 200 or 300 cub. ft. of gas at a pressure of 225 lbs. per sq. in. are advisable.

Before the gas is compressed into cylinders it is first purified and dried by several processes, and then compressed in solid drawn seamless steel cylinders, filled with a patent porous filling substance, throughout the pores of which a film of acetone is held in suspension.

The acetylene and oxygen being under high pressure a perfectly even mixture of both gases can be maintained in the blowpipe and the pressure varied according to requirements. The elimination of the injector device, necessary in low-pressure blowpipes, and the hydraulic safety valve are advantages claimed for dissolved acetylene or the High Pressure System, as it is called. Dissolved acetylene can be used with any type of oxy-acetylene blowpipe.

No demurrage charges for the use of cylinders are made on hired cylinders returned within thirty days of despatch, so that it is not necessary to purchase cylinders, although these can be supplied.

The amount of acetylene in a cylinder cannot be determined, as in the case of oxygen, by the pressure gauge. The only accurate method of calculating the gas used from, or left in, a cylinder is by weighing before and after use. For calculating the volume of acetylene used the following are the equivalents:

1·1 ozs. of acetylene = 1 cub. ft. (approx.)
1 lb. „ „ = 14·5 „ „

The design and layout of a generating plant must be such that the acetylene reaches the blowpipe in a good condition, in sufficient quantity and at sufficient pressure, otherwise the welds will be porous, brittle, and burnt. The acetylene generator should be of good and solid construction, and the gasholder capable of storing all gas generated under working conditions or after stoppage of work. There should be no signs of polymerisation of the gas even when working at the maximum delivery. The cross-section of tubes, pipes, and passages through valves should be such that the gas flows normally at the maximum delivery without loss of pressure. The pressure of gas should be as high as possible, and at least equal to 6 ins. of water pressure in the case of small plants and 8 to 10 ins. in larger plants. The pressure should remain practically constant and not vary more than ½ in. water pressure. The charging and cleaning of the plant should not result in any appreciable waste of gas, and without introducing sufficient air to interfere with the working of the blowpipe. The generator should comply with the recommendations of the British Acetylene and Welding Association. The size of carbide suitable for the type of generator should be used. The choice of carbide-to-water, water-to-carbide, etc., generating plants depends on several factors, such as location, class of work, etc.

The Carbic system of generation is based upon the use of a carbic cake, which consists of specially prepared and treated carbide compressed into cylindrical cakes. It is claimed that the process renders every particle of carbide impervious to moisture, so that generation can only take place while water is in actual contact with the cake. Freedom from danger in handling, and from after-generation, convenience in handling, elimination of waste and purity of gas are factors which have led to the success of this system.

Overloading of the plant is a common cause of defective welds. In carbide-to-water generators an allowance of not more than one cubic foot of acetylene per hour for each pound of carbide in the rated charge is recommended. In the case of water-to-carbide generators the maximum rate of gas consumption should be half this value. In well-designed generators the yield of acetylene gas from the generator will be 85 to 90 per cent. of the carbide yield. Practically, for every 10 lbs. of carbide used in the generator a yield of 40 cub. ft. of gas at the blowpipe can be assumed. The proper care, cleaning, charging, and maintenance of generators is of first importance if reliable welds are required. Leakages of acetylene should be traced by means of soap-suds and never with naked lights.

The acetylene generating plant should be installed in a well-ventilated shed or building, or in a lean-to having no direct communication with a workshop or adjacent building, and no unauthorised person should be allowed to enter the building. Where artificial light is required in a generator house or near a generator, electric incandescent bulbs, encased in outer gas-tight globes, should be used. A conspicuous notice prohibiting lights or smoking should be exhibited on the outside of the generator house. Generators should be cleaned and charged in daylight. Electric switches, fuses, etc., should be placed outside a generator house, or they should be so

constructed that risks due to sparking or fusing are avoided. To comply with existing regulations, a licence under the Petroleum Acts (fee 5*s.* per annum) must be obtained from the local authority for the storage of carbide, where a stock of more than 28 lbs. is kept. A raised platform in the generator house should be provided for the storage of carbide. Drums containing carbide should not be placed in the welding shop or near a flame. Care must be exercised in opening drums to avoid striking sparks; a proper drum opener should be provided for this purpose.

Purification of the gas must be efficient, and the care and maintenance of the purifying chamber is very important. The cross-sectional area of the purifier should be ample, and the depth of purifying material should not exceed that specified by the makers, otherwise loss of pressure and overheating of the gas will take place. The quality of the gas can be simply and quickly tested by the use of a white absorbent paper, saturated with a 10 per cent. solution of silver nitrate and exposed to the gas. Should the paper turn black after a few seconds' exposure, the gas is unsuitable for welding purposes.

The chief impurities found in acetylene gas are (*a*) those which affect the quality of the weld, such as sulphur, phosphorus, silicon, finely subdivided lime; and (*b*) those which affect the cost of the weld, such as hydrogen and hydrogen compounds, nitrogen and nitrogen compounds, and water vapour. An efficient chemical purifier must be provided capable of removing sulphur and phosphorus compounds, the acetylene must pass through an efficient water-scrubber to remove or partially remove the impurities soluble in water and, finally, the gas should be filtered to remove solid impurities not eliminated by washing or chemical purification. A first-class purifying material will generally remove chemical impurities, moisture, and lime dust which are a common cause of defective welds.

Oxygen and Acetylene Regulators.

Regulators in common use to reduce the pressure of gases are of the diaphragm type, and may be roughly divided into two classes—first, where the pressure of the gas closes the inlet, and, second, where the inlet is closed by a spring. They are designed to automatically deliver gas to the blowpipe at any uniform pressure to which the regulator is set. Oxygen regulators are usually equpiped with two gauges, a high-pressure gauge, which shows the pressure of gas in the cylinder, and a low-pressure gauge. For successful welding the regulator should be provided with a low-pressure gauge, giving the pressure at which the gas is delivered to the blowpipe. Regulators must be kept in good order, otherwise defective welds are inevitable. Regulators intended for use when welding should not be used when cutting unless the work is within the range of the regulator. It is dangerous to use oil, grease, or any organic material for lubrication. If it becomes necessary to lubricate the pressure-regulating screw, or to repack a needle valve, make use of a little glycerine. The pressure-adjusting screw should always be released after ceasing work and before changing from one cylinder to another.

Acetylene regulators are painted red and have a left-hand screw thread corresponding to that on the standard valves of acetylene cylinders. Regulators for oxygen are painted black and have a right-hand screw thread. Any possible confusion is obviated by this distinction.

Cylinder valves should be opened very slowly so that pressure does not come on to the gauges or diaphragm suddenly. The proper working of regulators largely depends upon the care given them. They should not be left in places where dirt or dust may get into the interior, and be deposited on the seat or inlet nozzle, and they should never be repaired by inexperienced workmen.

Hydraulic Safety Valves.

These are indispensable in low-pressure installations, i.e. where the acetylene is generated on the premises. Their function is to provide a water-seal and, more important, to prevent explosive mixtures entering the acetylene piping or generating plant. The valve should be chosen so that the maximum supply of gas is obtained without burning the metal. Safety devices based on mechanical principles, such as valves, etc., may more or less prevent the return of the flame, but are not infallible in preventing the formation of explosive mixtures.

Hydraulic safety valves should be charged and examined daily, and should be installed so as to facilitate filling to the proper level. In general, the valve should be charged with water whilst the acetylene tap admitting gas to the valve is open. No safety valve should have more than one outlet to which a blowpipe can be connected.

Piping and Flexible Tubes.

The piping should be large enough to avoid loss of pressure. The size of piping should be dependent upon its length and the maximum supply of gas required. Piping and connections should be installed by workmen experienced in the installation of acetylene apparatus. All cocks, valves, unions, and joints should be full bore, and the installation should be thoroughly tested when the system is completed. It should not show a loss of pressure exceeding two inches of mercury within twelve hours when subjected to a pressure equal to a column of fifteen inches of mercury. Acetylene piping should be painted a distinctive colour.

The flexible tubes conveying the gases to the blowpipe should not be too long, too flexible, or too rigid. Armoured hose is not necessary or recommended for ordinary welding and cutting

operations. Avoid greasing the ends of the tube to facilitate fixing to the blowpipe or other connectors; use water. Tube clips for securing the tube firmly to the connectors should be used in preference to wire, etc.

Flexible tubing should be examined regularly, and defective tubing should never be used. Special care should be taken to avoid the interchange of the oxygen and acetylene tubes when connecting up to the blowpipe. Both acetylene and oxygen tubing should be blown through occasionally, so that dirt and dust will not be carried into the blowpipe.

Welding Blowpipes.

Welding blowpipes are classified in relation to the pressure of the acetylene. Low-pressure blowpipes are those fitted with an injector to aspirate the acetylene, which is supplied from a generator under a pressure of 6 to 12 inches of water. Medium-pressure blowpipes, sometimes called positive pressure, use acetylene generated in a pressure generator at a pressure up to 15 lbs. per sq. in. An injector or partial injector forms part of the blowpipe. High-pressure blowpipes use the acetylene supplied from acetylene cylinders, and are designed to mix acetylene and oxygen in equal volumes. No injector is required, and a change of nozzle with a corresponding adjustment of pressures is all that is required when changing over from welding one section to another.

In the low-pressure system efficient mixing of the gases in the blowpipe is very necessary. The oxygen and acetylene should mix in approximately equal proportions. Oxygen and acetylene should not pass through the flame in a free state, otherwise oxidising or carbonising flames, both injurious to the metal, may be obtained. A proper mixture produces a correct or so-called 'neutral' or 'normal' flame. To obtain this, well-designed blowpipes carefully adjusted to the oxygen pressure recommended by the maker are essential. A typical low-pressure blowpipe

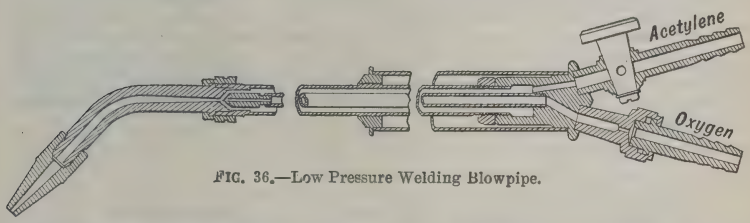

Fig. 36.—Low Pressure Welding Blowpipe.

working on the injector principle is shown in fig. 36, and the character of the flames produced under different conditions of mixing are shown in figs. 37, 38, and 39.

The size or power of blowpipe which should be used depends upon the thickness to be welded. Too small a power produces the defects of adhesion, inclusion of oxide, overheating, and burning of the welds. Too large a power produces a molten bath which is much too large, holes, and adhesion in the lower part of the weld.

A good practical rule in welding steel is that the hourly consumption of acetylene should be 4½ to 5½ cub. ft. (120 to 160 litres) for every $\frac{1}{16}$ in. in thickness.

Fig. 37.

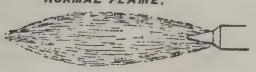

Fig. 38.

Fig. 39.

A very useful table can be made up from these figures, in which the approximate bore of the nozzle orifice is included.

POWER OF BLOWPIPE FOR IRON AND STEEL.

Thickness of Material in inches.	Consumption of Acetylene per Hour.		Bore of Nozzle in $\frac{1}{64}$ inch.
	In Litres.	In Cub. Feet.	
22 gauge	60–80	2¼–2¾	2
$\frac{1}{16}$	120–160	4¼–5⅔	3
$\frac{1}{8}$	240–320	8½–11	3 full
$\frac{3}{16}$	360–480	12¾–16½	4
$\frac{1}{4}$	480–640	17–22	5
$\frac{3}{8}$	720–960	25½–33	6
$\frac{1}{2}$	960–1280	34–44	7
$\frac{5}{8}$	1200–1600	42½–55	8

The figure denoting the power of blowpipe is usually supplied by the maker, and is sometimes marked on the blowpipe. In welding materials other than wrought iron and steel the power of blowpipe to be used is dependent upon the material, its dimensions, and whether preheating has been adopted. As a general rule the power of blowpipe is greater for other metals, as in melting, for example, cast iron, copper, or aluminium, more heat is required to melt a given weight of the metal and, in addition, the high temperature part of the flame is held further from the molten metal.

It is necessary to emphasise that the white cone of the flame should never be brought into contact with the molten metal, and that its distance from the molten metal depends upon the kind of metal and its thickness.

All blowpipes should be carefully handled and treated as precision tools. Carefully avoid the use of grease or oil, and never dismantle a blowpipe with a view to overhauling, as this may lead to irregular working after assembling. In the event of obstruction of the nozzle a soft brass wire should be used for cleaning. Dust in the interior of the blowpipe can be removed by blowing oxygen through from the nozzle end. In the case of back-firing due to overheating the tip should be cooled in water, taking care to close the acetylene valve and to leave the oxygen valve slightly open.

Back-firing, which is a common cause of defective and expensive welds, may be due to one of the following causes :—

(*a*) Faulty design and manipulation of the blowpipe.
(*b*) Enlarging the nozzle orifice when removing obstructions.
(*c*) Working in confined spaces or with an accumulation of slag on the nozzle.
(*d*) Necessity for overhauling and internal cleaning.
(*e*) Restricted and fluctuation in the acetylene supply due to bad lay-out, exhausted purifier, etc.
(*f*) Defective hydraulic safety valves leading to air and moisture being carried with the gas.
(*g*) Defective oxygen regulators.
(*h*) Presence of solid matter in the gas either from the acetylene generator or inferior flexible tubing.

GOGGLES.

For welding with acetylene it is necessary to protect the eyes with goggles fitted with suitable coloured glasses. There are a great many different kinds of special safety glasses on the market and many combinations of ordinary coloured glass are in common use. The eyes must be protected from injurious rays, the heat and glare from the work and from particles of hot metal that fly up from the weld. To obtain the clearest definition or visibility with the least amount of glare, the selection of the colour tint in safety glasses should properly be decided by an expert; the depth of the tint may be determined best by the operator himself, owing to the individual difference which will permit one man to see clearly through a glass that would be too dark for another man. Amber, dark-amber, or dark-amber-green glasses are the most efficient protection. Glasses showing blue or violet tints should be avoided, except in certain combinations where they are used to obscure other colours.

Filling Materials.

The necessity for employing the best materials for every welding operation cannot be too strongly emphasised. It is only by using the most suitable filling-in wires, rods, and fluxes, specially manufactured and controlled for each particular metal or alloy, that the most satisfactory work can be done.

Thin material may frequently be welded by bringing the edges into contact and melting them together, but generally a filling material or 'welding rod' is melted into the groove or crack.

ACETYLENE EQUIPMENT

OF ALL KINDS

Manufactured and Supplied by

Allen-Liversidge Ltd.

with which are amalgamated

Imperial Light Ltd. and Dissolved Acetylene Co. Ltd.

Dissolved Acetylene Cylinders and Gas

for

BRAND

FLUXES

For Oxy-Acetylene Welding

Manufactured from reliable formulæ and under control of a recognised Oxy-Acetylene Welding Expert.

Fluxes *for* Cast Iron, Medium and Hard Steels, Copper, Brasses, Bronzes, Steel Castings, Nickel Steel, Ferro-Nickel and Aluminium and its Alloys, &c. Silicated Cast Iron Rods 'made to specification,' Welding Wires and Accessories.

CORRECT NON-FERROUS WIRES.
Stocks held.

'SUDER' BRONZE for Brazing Malleable Iron.
'SUDER' BRAND CASE-HARDENING COMPOUND, for the Box Process.
THE IMPROVED 'CASE MAKER.'

Price List and information on any class of Welding on application to:—

THE DISTRICT CHEMICAL CO., LTD.
1 FENCHURCH AVENUE, LONDON, E.C. 3.

Filling materials must not only be of the correct chemical requirements so as to replace loss in the molten zone, to counteract the tendency of the metal to oxidise, to assist in making the molten metal flow readily, or to break down oxides when formed, but they should also act satisfactorily under the blowpipe.

The choice of the right size of welding rod is important, and melting of the rod should take place in the molten bath and not in the flame. The following table gives the sizes of wire for 'forward' welding iron and steel. In the case of other metals the figures hold good, except for very thin material, when a size of not less than $\frac{1}{16}$ in. should be used.

SIZES OF WIRE FOR WELDING IRON AND STEEL ('FORWARD' WELDING).

Thickness of Material.	Size of Welding Rod.		
	S.W.G.	Decimal equivalent.	Nearest $\frac{1}{64}$.

$\frac{9}{16}$,,			
$\frac{5}{8}$,,			
$\frac{3}{4}$,,	0	0·324	21

The following table also gives the sizes of wire for 'backward' welding; it should be pointed out that this method of welding is more reliable and economical than 'forward' welding, and is rapidly displacing the latter for the welding of iron and steel.

Fluxes.

It is not always possible to include deoxidisers and special elements in the welding rod itself. By using a combination of chemicals in the form of a powder, liquid, or paste, known as a flux, the difficulties of producing sound and reliable welds is overcome. A flux is used for the purpose of cleaning the parts to be welded, for eliminating and preventing the formation of oxide, for replacing elements burnt out by the flame, and, when melted, protecting the surface of the molten metal from the action of the flame and the formation of blowholes. A flux is necessary in welding steel, cast iron, copper, aluminium, etc.; for successful welding the proper flux should be used, and as the welding rod and flux are important factors in welding they should only be obtained from reliable manufacturers.

Preparation of the Work.

One of the first principles of sound welding is securing complete fusion and perfect union of the filling material and the edges of the parts to be welded. To ensure this, good preparation is necessary, which includes, as a rule, the cleaning of the edges and the welding wire, the bevelling or chamfering of the edges, the adjustment and maintenance of the parts in position, and allowance for expansion and contraction effects. In general, the preparation of the parts varies according to the thickness and nature of the metal and upon the organisation and equipment of the workshop.

Cleaning the parts to be welded and the welding rod is essential. Bevelling is necessary for materials $\frac{1}{4}$ in. and above in thickness. Bevelling ensures good penetration, increase in ductility and strength, economy, and reduces the overheating effects. The angle of the bevel depends upon the thickness of material and whether 'forward' or 'backward' welding is practised. All metals from $\frac{1}{4}$ inch up to $\frac{3}{8}$ inch, and in some cases $\frac{1}{2}$ inch, should be bevelled from one side only. Where possible, pieces exceeding $\frac{1}{2}$ inch should be bevelled from both sides. In forward welding the V formed by the two bevelled plates should be about 90°. In backward welding for material up to $\frac{1}{2}$ inch an angle of about 45°, and above $\frac{1}{2}$ inch an angle of 60° can be used. The bevel should extend to the bottom of the plate, and thorough penetration and complete fusion should be obtained. In repair work preparation of the work is a very important feature and will save considerable time and keep the cost of welding low. In the case of aluminium repairs, for example, good judgment means success, and bad judgment a ruined casting.

Expansion and Contraction.

It is impossible to produce satisfactory work unless expansion and contraction effects are properly allowed for. Warpage and internal strains, followed by failure, are the common result of welders failing to master this subject. The methods commonly employed are, in the case of thin sheets, tacking; in the case of heavier material and castings, setting the plates so as to form an angle, heating the entire work, partial heating, heating restraining members, breaking a member so that expansion and contraction can take place freely, bending or springing the material, etc.

If the expansion can take place in all directions, it will give the welder no trouble. If, however, the welding takes place at a point that is confined by various parts or by the particular construction of a piece, it is then necessary to give it due consideration.

The resultant effect of contraction must be considered equally with that of expansion, as failures, cracks, etc., can often be traced to neglect to allow for this property.

Preheating.

This may be partial or total, depending upon the work in hand, and is mainly employed with a view to (*a*) allowing for expansion and contraction, (*b*) decreasing the cost of welding, and (*c*) producing a more homogeneous joint. Preheating is usually carried out with the welding blowpipe, oil or gas burners, charcoal, or other suitable fuel. The method used should be governed by the particular work in hand.

No general rules can be given for preheating temperatures, as the degree of heat necessary will, of course, depend upon the size and shape of the object to be welded. As a general rule, however, cast iron should be preheated to a dull red heat for small and simple castings, and to a blood-red heat for large or complex castings; aluminium and its alloys should be preheated very carefully, as too high a temperature will lead to the collapse of the article being welded.

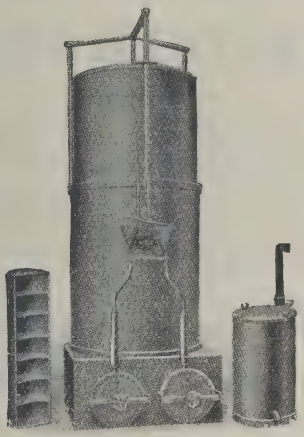
Preheating machines burning paraffin and giving a flame of high calorific value, smokeless and transparent, have been introduced and give satisfactory results where portability and a powerful flame are required.

After Treatment of Welds.

Improvement in the structure of welds with a consequent increase in strength and ductility are the result of proper after treatment of welds. Thermal or mechanical treatment, or both, carried out in a correct manner is always beneficial, except in the case of defective welds.

Strength of Welds.

With proper equipment and suitable filling materials, the strength of the weld will depend mainly upon the care and skill of the operator. A good operator should be able to obtain welds 95 per cent. the strength of the original material; for the average welder 85 per cent. should be taken as the lower limit of strength.



Steel Welding.

The welding of wrought iron and mild steel is apparently simple; in reality it is somewhat difficult to produce strong and reliable welds. Oxidation is the most serious defect, and this must be reduced to a minimum, in view of the fact that up to the present no reliable flux has been discovered. Welding wires containing a small percentage of vanadium have recently been introduced, with highly satisfactory results. To produce the minimum of oxidation the blowpipe must be well designed and handled efficiently, and the parts to be welded must be thoroughly cleaned. Expansion and contraction must receive proper consideration. The welding rod should be a material low in phosphorus and sulphur, and free from oxide. The use of ordinary iron or mild steel wire is unsatisfactory, and welding wire, such as 'Suder' or 'Ferrox,' made specially for the oxy-acetylene process, should be insisted upon. It will be found that economy is on the side of the scientific but more costly product.

COMPLETE OUTFITS FOR

OXY-ACETYLENE WELDING & CUTTING

Acetylene Generating Plant,
Atoz Flares & Portable Lamps.

ATOZ BLOWPIPES; ATOZ Hydraulic Back Pressure Valves; Oxygen & Acetylene Pressure Regulators; Welding Wire; Silicated Cast Iron Rods; ATOZ FLUXES.

FERROX COMPANY LIMITED

FERROX

Manufacturers of Welding
Wire, Rods and Fluxes for

OXY-ACETYLENE WELDING

□ □ □

FERROX for Iron, Steel, Wrought Iron and Malleable Cast Iron—requires no flux.

FERROX is the finest and most scientifically prepared Welding Wire produced and is used all over the World.

FERROX is particularly suitable for Building up operations by the Bare Wire Arc Process.

FROXITE A special composite rod for Hard Welds—particularly suitable for Railway and Tramway repairs.

SIFROX A Cast Iron Rod with high Silicon content—giving a weld which is easily machined.

SIFLUX Specially prepared Flux for use with SIFROX.

Aluminium, Brass, Copper, Phosphor-Bronze Rods and Rods for Nickel Steel, Chrome Steel and Manganese Steel Welding.
Fluxes for use with the same.

Use FERROX materials and you will use THE BEST.

FERROX COMPANY LIMITED
12 Grosvenor Gardens, London, S.W. 1

The following specification data in connection with the welding wire for iron and mild steel are of importance. The surface of the wire is to be smooth, of uniform homogeneous structure, free from irregularities in surface hardness, segregation, oxides, pipe, seams, etc. Diameter shall not vary more than ± 3 per cent. of the diameter specified. The chemical composition to be within the following limits :—

Carbon	not more than	0·10 per cent.
Silicon	,,	0·08 ,,
Manganese	,,	0·15 ,,
Sulphur	,,	0·04 ,,
Phosphorus	,,	0·04 ,,

The surface shall be smooth and free from scale, rust, oil, or grease. In the hands of an experienced welder the wire shall demonstrate good weldability, and shall flow smoothly and evenly without any unusual characteristics.

The following table is of use as a guide in ordering welding wire :—

Size, inches	$\frac{1}{16}$	$\frac{3}{32}$	$\frac{1}{8}$	$\frac{6}{32}$	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$
Lbs. per 100 ft. .	1·04	2·3	4·1	6·5	9·3	16·7	26	37·5
Ft. per 100 lbs. .	9,615	4,273	2,403	1,537	1,067	600	383	266

The flame must be carefully regulated and held so that the tip of the white cone is about $\frac{1}{8}$ in. from the surface of the molten metal. The blowpipe must be given a motion which will cause the flame to describe a series of overlapping circles in the case of light and medium sheets, and oscillated in a series of semicircles in the case of heavy sections. A variation of these movements has been introduced which gives more economical and better welds. The welding rod, in this case, follows the flame instead of preceding it, and the flame is directed towards the starting point instead of towards the finishing point. The blowpipe is given a slight gyratory motion, whilst the welding rod is given a more or less elliptical or longitudinal motion. This method of welding is known as ' backward ' welding. Subsequent thermal treatment will improve the structure of steel welds and materially increase the strength and toughness of the weld. Hammering may be resorted to with good effect, provided the hammering is not too vigorous or done at too low a temperature.

The following table gives the speed at which the welding of mild steel plates can be done under average conditions :

Thickness of Plate in Inches.	Speed of Welding.	
	Feet per Hour.	Feet per Hour for Average Day's Work.
$\frac{3}{64}$	30 to 33	23 to 26
$\frac{5}{64}$	20 ,, 21	16 ,, 20
$\frac{1}{8}$	15 ,, 16	13
$\frac{5}{32}$	13 ,, 15	10
$\frac{13}{64}$	10 ,, 12	9
$\frac{1}{4}$	9 ,, 10	$7\frac{1}{2}$
$\frac{9}{32}$	8 ,, 9	$6\frac{1}{2}$
$\frac{21}{64}$	7 ,, $7\frac{1}{2}$	6
$\frac{23}{64}$	$5\frac{1}{2}$,, 6	5
$\frac{13}{32}$	$4\frac{1}{4}$,, $4\frac{1}{2}$	$3\frac{1}{4}$
$\frac{15}{32}$	$3\frac{1}{4}$,, $3\frac{1}{2}$	$2\frac{1}{2}$ to 3
$\frac{1}{2}$	$2\frac{1}{4}$,, $2\frac{1}{2}$	$1\frac{1}{2}$,, 2

Owing to metallurgical changes that take place when melting medium and hard steels with the blowpipe, the welds obtained are invariably unsatisfactory. It is possible to get fair results on medium steels, but a flux, rapid welding, and thermal after treatment, which requires skill to properly carry out, are necessary.

The data at hand shows that for welding medium carbon steel, welding wire having a carbon content ranging from 0·06 to 0·60 per cent. are of no particular value.

For welding high carbon steel and worn surfaces where great resistance to abrasive wear is desired and where machining is not necessary, a welding wire containing 0·60 to 0·75 per cent. of carbon and 0·60 to 0·90 per cent. of manganese is desirable.

For welding mild steel and to produce a weld of greater strength but of lower ductility than that obtained with ordinary welding wire, the wire should contain 0·15 to 0·25 per cent. of carbon, 3·25 to 3·75 per cent. of nickel and 0·5 to 0·8 per cent. of manganese.

Alloy steels, such as chrome and manganese steel, are weldable, provided the percentage of carbon does not bring them into the range of medium and hard steels, which is frequently the case. The welding wire should be of the same character as the steel, and a flux must be used. In the case of nickel steel it is necessary to use a flux which will form a varnish over the molten metal and prevent the absorption of the gases from the flame of the blowpipe.

Cast-Iron Welding.

The two principal defects in cast-iron welding are the production of hard spots and blowholes in the weld and subsequent cracks or fractures in the weld or adjacent metal. The oxide formed must be removed or destroyed by the use of a flux. Expansion and contraction should be considered as of great importance. Preheating should be used to some extent in all cast-ironwelding. The welding rod must be of good material and specially made for this purpose. One great trouble with cast-iron rods in general is that the quality is by no means uniform. This is especially true with the cheaper and uncontrolled products. Rods made from ordinary cast iron produce blowholes and hard spots. The parts must be thoroughly cleaned, and in the case of cracks their extension must be prevented by drilling holes a short distance from the ends in the direction the crack would follow. The weld should be arranged horizontally, and where this cannot be arranged carbon blocks should be used to prevent the metal flowing away. To protect machined surfaces during preheating operations they should be coated with flaked graphite and oil. This can be made into a paste and painted on, or the surfaces can be oiled and the graphite dusted on. The graphite must be coarse, as fine flake is not satisfactory. The flame must be held so that the tip of the white cone is between $\frac{1}{4}$ and $\frac{3}{4}$ in. from the molten metal, the distance depending on the thickness of the metal. The after treatment consists in annealing and allowing the metal to cool very slowly.

Certain cast irons of great strength and in which the carbon is in the combined state are practically unweldable. Cast iron which has been submitted to the heat of a fire for a considerable time is frequently unweldable. The metal in both cases melts under the blowpipe in a distinctly different manner from ordinary cast iron, and the welder should have no difficulty in recognising that the blowpipe should not be applied to make a joint.

Malleable Cast Iron.

It is difficult to produce satisfactory joints on malleable cast iron by welding. The welds are hard, brittle, and porous. The best results are obtained by brazing with the oxy-acetylene blowpipe, using the same methods of preparation as for cast iron, and using tobin or manganese bronze as a filling material.

The introduction of acetylene for brazing purposes provides a fuel which has the highest known flame temperature and high calorific value. By using dissolved acetylene with a special brazing blowpipe no air-bellows or oxygen is necessary, as the blowpipe is atmospheric and a clean and relatively small flame is obtained.

Aluminium Welding.

Sheet aluminium welding can be handled in very much the same way as steel as regards preparation and allowance for expansion and contraction. The principal difficulty lies in the formation of the oxide, which must be dealt with by an energetic and reliable flux. The filling material is pure aluminium wire; before starting to weld, the wire and parts to be welded must be thoroughly cleaned by scraping. A delicate hand and considerable practice is necessary, especially on thin material. The flame must be carefully regulated and the tip of the white cone should be from $\frac{1}{4}$ to $\frac{3}{4}$ in. from the molten metal. After welding, the welds should be thoroughly washed with warm water and, where possible, internal strains should be removed by annealing. The structure and strength of the metal in the welded zone are improved by hammering when cold.

Aluminium castings are generally alloys of copper, zinc, and aluminium. The material expands greatly and is very weak at high temperatures, consequently contraction strains are likely to produce cracks and distortion unless the work is properly handled. In welding castings—crank cases, for example—it is often necessary to preheat them either completely or partially. The preheating must be done carefully, otherwise the casting may collapse. For supporting the casting evenly and lining up, carbon putty is useful. For missing parts, and where the welder is not well skilled in this class of work, it is advisable to back up with sheet copper or galvanised iron. In rigging up jobs for repairs, care must be taken that expansion and contraction effects are not interfered with. The parts should be carefully cleaned and free from oil and grease. A good grade of filling material of average composition is necessary; pure aluminium wire should not be used. The acetylene should be pure and the blowpipe should give a soft, non-oxidising flame. The casting should be reheated slightly to remove any local strains and then allowed to cool very slowly.

Each "No. 20" Carbic Cake produces 10 cu. ft. of pure acetylene

THE success of the CARBIC CUTTING and WELDING SYSTEM is due to Carbic Cake—specially prepared carbide compressed into cakes—each of which is *guaranteed* to produce a definite quantity of gas. Generation can *only* take place when Carbic Cake is in direct contact with water. There is no waste whatever as each cake produces 'full pressure' gas until completely used up.

The Carbic Cutting and Welding Generator is the most portable and simple in action. A few hours acquaintance enables any unskilled workman to completely master its principles.

THE CARBIC CUTTING and WELDING SYSTEM

is indispensable in Railway and Engineering Works, Shipyards, and Repair Depots of every description.

Copper Welding.

Copper may be welded, but only with difficulty. It oxidises very readily and the oxide dissolves in the copper. The flame must be carefully regulated. Without a correct welding rod, which contains a small quantity of phosphorus, it is impossible to satisfactorily weld copper. A flux is useful. Preheating to avoid adhesion is necessary. The tip of the white cone should be about $\frac{1}{8}$ in. from the surface of the molten metal. The welds should be hammered at a dull-red heat to improve their ductility and strength, and afterwards annealed.

Brass and Bronze Welding.

These are only welded indifferently without the correct welding rods. The filling material for brasses and bronzes should be almost of the same composition, and in the case of brass should contain a little aluminium, and in the case of bronze a little phosphorus and traces of aluminium. Bronze filling materials are cast. Fluxes should be used in both cases, and the power of the flame should be the same or slightly higher than that for copper, that is, distinctly higher than for steel plates of the same thickness. The position of the flame is the same as for copper. The after treatment of the welds consists in annealing at definite temperatures.

Lead Welding.

The oxy-acetylene blowpipe is rapidly supplanting the older methods of welding lead, or lead burning as it is generally called. It has proved superior in convenience, quality of joints, and economy. A small type of blowpipe is required, consuming from $\frac{1}{2}$ to 6 cub. ft. per hour. When it is necessary to fill up a hole or to build up any part of a lead object, the work is facilitated by using a mould or a backing of steel plate.

Nickel Welding.

Nickel when melted has the property of readily absorbing gases, especially oxygen. The welds obtained are very porous, and it is extremely difficult to obtain satisfactory welds. A method which has given fair results consists in placing the two parts to be welded on a heated anvil and then heating the parts to a white heat with the blowpipe, afterwards carefully hammering the parts together.

Machines for Welding.

Acetylene welding machines for the manufacture of tubes have been in use for many years. The development of automatic welding machines for the manufacture of tanks, etc., is more recent. For repetition work machines have been designed which accomplish the work in less time with comparatively unskilled men. The machines consist of two parts, (*a*) holding devices for the work, and (*b*) apparatus for carrying the blowpipes, with or without motion, over the seam.

Recent developments in welding machines have been mainly in the direction of the use of multi-jet blowpipes. In order to obtain speed it was recognised that more than a single jet of flame should be employed, and from two jets in tandem it has become customary to employ a large number of jets extending for a considerable distance along the line of the weld. The defects of this method have been overcome by distributing the heating at opposite sides of the centre line of the seam. The welded section produced in this way is wider, stronger, and more certain to penetrate than is the case with the narrow weld made by a central line of flame.

Training Welders.

An oxy-acetylene welder has been defined as a person who has the requisite manipulative skill and technical knowledge to successfully operate welding and cutting apparatus, and, at the same time, has skill in the operation of hand tools used in the preparation and finishing of the work in connection with welding, and also has a reasonable amount of ingenuity. He must also have a knowledge of accuracy commensurate with the type of work to be welded. Naturally, a trade in which so much depends on the personal equation has drawn attention to the need of training men to produce sound work. No doubt the best method is that which expounds principles followed by practice under expert supervision. Welding skill grows rapidly under a well-worked-out system of exercises which aim at developing skill in making typical welds on various metals. Testing the welds is also an important requisite of a training course. Classes for training welders are held in the principal centres, and manufacturing concerns who train their workmen must follow methods depending upon the size of shop and class of work.

A common error is to attempt work, especially repair work, in a shop where the tools and apparatus for successful all-round welding are not provided, or to endeavour to repair jobs which are beyond the capacity of the welder. It is much more economic, in such cases, to hand over work of this character to firms specialising in general repairs who have the necessary equipment for carrying out and testing the work, and welders who are not mere blowpipe operators.

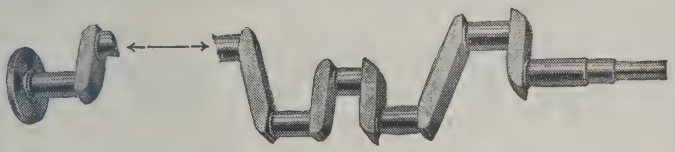
Testing Welds.

The importance of testing welds has, in recent years, become very great. It is well known that the quality of a weld cannot be assumed from the general appearance, finish, etc. At the present time the usual methods of testing include tensile and impact tests on specimens welded under identical conditions as the work, microscopic examination of specimens, bending and hammering tests, and X-ray examination. In the latter the actual welds can be examined, and flaws, blowholes, and other defects discovered.

During the past year the American Bureau of Welding have drawn up Standards for Testing Welds which are intended primarily to serve as a standard uniform basis for testing and comparing sample welds as distinguished from welds on structures. The testing of the latter must necessarily be by non-destructive methods which would therefore be, in general, quite different from those employed in examining sample welds made for the purpose of testing a welder's proficiency, comparing welding wires, or comparing welding methods. For the shop standard a bending test is recommended; for the commercial standard, a bending and tensile test.

CUTTING.

Wrought iron, steel, and steel castings can be cut with the ordinary cutting blowpipe, and with a special cutting blowpipe, or the ordinary cutting blowpipe operated in a special manner, cast iron can be cut.



The cutting blowpipe usually consists of a compound jet made up of one or more heating flames with a pure oxygen jet in the centre. A spot of the metal is first heated to a bright red heat with the heating flame, and then the oxygen jet is turned on. It has been proved that only partial combustion takes place, the phenomenon of cutting being really a disintegration by the current of gases from the blowpipes. The oxy-hydrogen flame is often used for cutting in place of acetylene. Material up to 36 ins, has been cut. The same acetylene equipment is used for cutting as for welding. For heavy cuts special regulators are used. There are two kinds of cutting blowpipes, known as the 'central' and 'following jet' types. Mechanical contrivances have been devised for special forms and shapes and for heavy cutting. One type of machine, known as the Godfrey Universal, uses as its cutting instrument the oxy-hydrogen or the oxy-acetylene blowpipe. It has the full range of movements found on a machine tool intended for universal use. The degree of accuracy is such that accurate gear teeth can be cut, and 1, 2, or any desired number of thousandths can be left for finishing. Fifteen inches of ½-in. plate can be cut in less than one minute at a cost of less than one penny for oxygen. When it is desired to cut a piece out of the centre of a plate it may be necessary to drill a hole to get a quick start.

The following table is an abstract from the manufacturers' table of cutting data.

TABLE OF APPROXIMATE METAL-CUTTING RESULTS.

Thickness of Plate.	Oxygen pressure at Regulator Outlet.	Consumption of Oxygen per hour.	Foot run of Metal cut per hour.	Oxygen consumed per foot run of cut.
Ins.	Lbs. per sq. in.	Cub. ft.	Ft.	Cub. ft.
¼	24	48	65	·75
½	28	60	60	1
1	32	88	40	2·2
1½	39	105	30	3·5
2	45	125	25	5
3	52	180	20	9
4	58	300	20	15
5	65	420	20	21

8	80	504	18	28
9	95	510	17	30
11	115	620	13	48
14	125	900	12	75
17	130	1,350	12	112

Blowpipes have now been placed on the market for cutting steel under water. Under-water cutting is based on the fact that the water must be forced away from the heating flame and cutting jet. With an efficient arrangement an ordinary hand-cutter can be adapted for cutting

Can a Crankshaft be Welded?

Here is the proof from a man who knows.

IS WELDING RELIABLE?

'Q.E.D.,' in 'The Motor' of September 1st, enquires whether a welded crankshaft can be relied upon. The answer is emphatically 'yes,' provided the work is carried out by a specialist who knows his work. I had a crankshaft belonging to one of our cars welded by Barimar over five years ago. The car has since run 20,000 miles, and the repaired shaft is still as good as ever. Most welding firms, judging by their own experience, do not recommend such repairs, but that does not do away with the fact that a welded crankshaft repaired by a specialist, properly equipped with up-to-date tools and machinery, will certainly stand up to its work.

PEUGEOT (ENGLAND) LTD.,
H. DERMIGNY,
Works Manager.

Barimar can say with certainty that a Crankshaft repaired under the Barimar Guarantee is, in most cases, stronger than a new one, delivery is quicker, and it shows a large saving in cost.

The Barimar Metallurgical Process for Repairing Scored Cylinders makes a permanent, 'Money-back' repair in THREE DAYS. AIR-COOLED, WATER-COOLED, STEAM, OIL, any type of cylinders made right. No welding, no regrinding of bores, no new pistons needed. Write for Scored Cylinder Folder 'T.R.'

The Barimar Book. — 'THE WELDING TEST.' Barimar Scientific Welding does things that no other process can do. Write across your letter heading 'Manual T.R.,' attach 6d. in stamps and post to Barimar. Omit stamps if you have a repair to be made now.

How to send Repairs to Barimar. Remove all fittings, attach two adhesive labels bearing your name and address as sender, and consign carriage paid to 'T.R. Dept., Barimar Limited, 10 Poland Street, London, W. 1,' or to the nearest service depot. Post a letter advising despatch and giving full instructions for repair.

Address all Repairs to 'T.R. Dept.'

under water. In salvage work steel plates have been cut at a depth of 40 ft. Various re-lighting devices for lighting the flame when it becomes extinguished have been successfully introduced.

The cutting blowpipe for cast iron is of the same character as that used for cutting steel, except that an ordinary iron tube fitted with several wires in the interior is used for the cutting operation An ordinary iron tube, of approximately $\frac{5}{16}$ in. internal diameter and an exterior diameter of $\frac{3}{4}$ in., containing three wires of 12 gauge, gives the most regular and satisfactory results for the demolition of castings, etc. The pressure of oxygen varies, according to the thickness to be cut, between 70 and 150 pounds per square inch. The process of cutting cast iron consists of piercing a series of holes along the desired line of cut; the cutting operation is much more rapid than appears at first sight.

ELECTRIC WELDING AND CUTTING.

(Contributed by D. Richardson, Wh. Exh., A.M.I.M.E., Capt. R.A.F.)

Electric welding processes can be placed in two distinct groups, one producing heat by the resistance of the metal being welded to the passage of the current, the other using the heat of the electric arc. They are known as Resistance Welding and Arc Welding, respectively. These two main groups have formed the basis for many processes of welding. The differences rest entirely on methods and special applications. The subdivisions are as follows:—

Arc Welding.

(1) Carbon electrode.
(2) Metallic electrode.
  (*a*) Bare electrode.
  (*b*) Covered electrode.
(3) Electro-percussive welding.
(4) Electric blowpipe.

Resistance Welding.

(1) Butt welding.
(2) Spot welding.
(3) Seam or line welding.
(4) Button and disc welding.
(5) Bridge welding.
(6) Multiple electrode welding.
(7) Point or projection welding.

The many systems of welding which have developed from these main groups are generally associated with the inventor's name or company exploiting the process, such as:—

Benardos System.
Slavianoff System.
Kjellberg System.
Zerener System.
Thomson System.
Premier Electric System.
Alloy Welding Processes.
Quasi-Arc Process.
Cyc-arc Process.

ARC WELDING.

The three chief requisites are:—

(1) A suitable form of electrical energy and control.
(2) Electrode material of proper physical, chemical, and electrical characteristics.
(3) A trained and experienced welder.

Carbon Arc Welding.

The characteristic principle of this process, commonly known as the Benardos process, is that an electric arc is held between the metals to be joined, which forms one electrode of the circuit, and a carbon rod or pencil manipulated by the welder which forms the other electrode. By placing the carbon electrode in contact with the metal, thus closing the circuit, and instantly

withdrawing it again, an electric arc is formed between the two electrodes and, owing to the high temperature of the arc the metal is melted. Steel up to $\frac{3}{32}$ is satisfactorily melted together without using a filling material, but for greater thicknesses a 'melt bar' is melted into place by the heat of the arc. Automatic machines for repetition work on thin materials and equipped with carbon electrodes are in use. Experience has shown that the metal to be welded should be the positive electrode, and the carbon the negative electrode. If this order is reversed, a shorter arc is obtained and particles of carbon can enter the molten metal and cause brittleness.

The current used is direct, the voltage being from 60 to 90, and the amperes vary from 250 to 600, depending upon the thickness of the metal.

Where the carbon electrode is used it has been found that the graphite electrode, as distinguished from the hard carbon electrode, yields longer life. Probably the chief field of usefulness for the carbon electrode is for cutting or for rapid repair welding where strength of weld is not as important as the speed of doing the work.

Metallic Arc Welding.

The use of metallic electrodes for arc welding has proved more satisfactory than the use of carbon or graphite electrodes, which necessitate feeding the new metal into the arc by means of a rod or wire. A very wide variety of metal electrodes are used.

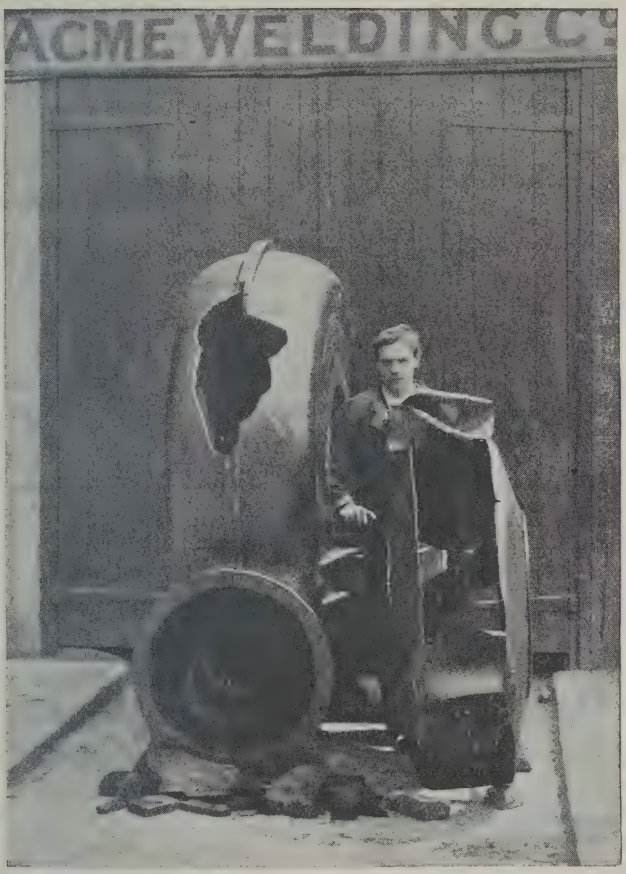
Bare Electrode.

The Slavianoff System, using a bare metal electrode, has not been developed in this country to any extent. There is considerable discussion as to the efficiency of bare electrodes, and although it may be possible to successfully weld mild steel with such electrodes, where toughness is desirable or necessary, or for the welding of steel alloys, a special coating will give better and, in many cases, the only successful results. The decision of Lloyd's in approving the use of covered electrodes has not caused the adherents of the bare-metal electrode to abandon their position. The use of copper, nickel, and bronze electrodes for special purposes has been carried out successfully using the electrode bare. The use of manganese steel, containing about 12 per cent. manganese, as an electrode has proved successful either as a bare wire or using one of the several types of coverings.

Covered Electrodes.

The use of covered electrodes aims at improving the metal in the weld and, where necessary, allowing the use of special alloy steels, etc. Covered electrodes may be placed in two general classes, the first class being the electrode which has a heavy covering of scientifically prepared material containing a deoxidizer. The second class of covered electrode is of the type which has a very thin coating on the wire which aims at obtaining the same results as the heavy covered electrodes without the disadvantage of manipulating the heavy coating of slag deposited during the welding operation.

Kjellberg System.



The effect of refractory coverings on the metal electrode was first discovered by Kjellberg. In the Kjellberg process, controlled by the *Anglo-Swedish Electric Welding Co., Ltd.*, the steel rod is covered with a coating or sleeve of normally non-conducting materials, that is to say, conductors of the second class, the function of the cover being, amongst other things, to direct the metal where it is required, to protect the fused metal from oxidation, and to make up the loss in the arc, of certain constituents of the iron or steel forming the object.

In carrying out the process the covered rod is held in a clip or holder connected to a continuous current supply, and forms the positive pole, the object forming the negative, though in some cases the poles are reversed.

The covering is removed from the end of the rod to enable the current to pass and an arc is struck between the rod and the object. As soon as the arc is struck a portion of the metal of the object, having an area approximately equal to the section of the rod, fuses together with metal from the end of the rod, and at the same time the covering, which is of a friable nature, partly fuses and breaks away at the same rate as the metal of the rod is deposited. In this way metal can be gradually deposited on an object until a sufficient quantity has been obtained for the purpose required. From time to time the deposited metal is hammered so as to consolidate it in exactly the same way as a weld made in the fire.

A further advantage of the covering on the rod is that the tensile strength of the weld can be varied within certain limits to suit the purpose required. For example, by this process a tensile strength of from 20 to 35 tons per sq. in. can be obtained. It is possible also to obtain various degrees of hardness merely by altering the composition of the covering.

The use of welding rods covered in accordance with Kjellberg's Patent has rendered it possible to do a large amount of work that could not be successfully undertaken before. As the metal is deposited in small quantities and the heat is localised within a very small area the danger of setting up internal stresses is reduced to a minimum. There is no limit to the size of the work that can be undertaken.

Extensive Repairs to this cast-iron fan-casing were carried out in **48 HOURS** by the

North-Western Anglo-Swedish Electric Welding Co., Ltd.

38-44 Beau Street, LIVERPOOL.

The following table shows the results of mechanical and other tests on welds made by this process:

RESULTS OF TESTS ON WELDS MADE BY THE KJELLBERG PROCESS.

Tests.	Lloyd's Requirements.	Results Obtained.
Tensile (average of 10 pieces).	Not less than 90 per cent. of the strength of plate.	Over 100 per cent. of the strength of the plates, the average tensile strength of which was 29 tons per sq. in.
Alternating stress.	5,000,000 reversals of a stress of 6 tons per sq. in.	5,000,000 reversals of a stress of 11·7 tons per sq. in.
Impact.	Two blows from a falling weight of 2 cwts. from a height of 9 ft. on a ½ in. welded plate, and 4 cwts. from a height of 12 ft. on a ½ in. welded plate.	Withstood without the slightest sign of cracking.
Modulus of elasticity of deposited metal.		13,100 tons per sq. in. Practically the same as good quality steel plate.
Chemical analysis of deposited metal.		Quite satisfactory, the carbon and manganese being largely retained.
Microphotographs.		Completely satisfactory, the junction between original and deposited metal being well merged with no sharp line of demarcation and the effect of the heat being in nowise injurious.

The tests were carried out by Professor B. P Haigh, D.Sc., M.B.E., A.M.Inst.C.E., Royal Naval College, Greenwich, at the works of Messrs. David Kirkaldy & Son.

The results of resistance tests made on tramway rail joints are as follows :—

No. 1. Fish-plated and welded, no bolts. Drop 3 millivolts or $R=2{\cdot}00\times10^{-5}$ ohms.

No. 2. Fish-plated and welded, but with bolts. Drop 2·4 millivolts or $R=1{\cdot}60\times10^{-5}$ ohms.

No. 3. Fish-plated and copper bonded in ordinary way, *not welded*. Drop 8·8 millivolts or $R=5{\cdot}87\times10^{-5}$ ohms.

No. 4. Butt-welded all round, no fish-plates. Drop 3·5 millivolts or $R=2{\cdot}33\times10^{-5}$ ohms.

Solid Rail. Drop 3·4 millivolts or $R=2{\cdot}465\times10^{-5}$ ohms.

Length tested, 3 ft with 150 amps. passing through rail.

Quasi-Arc System.

In this process, controlled by the *Quasi-Arc Co., Ltd.*, the electric arc is superseded by a quasi (or partial) arc, which is brought about by a slag covering around the wire of the ordinary metal electrode. The electrode known as the Quasi-Arc Electrode, according to British Patent Specifications 11079–12 and 13538–13, consists of a steel wire core with an aluminium wire running beside it and covered with a wrapping of *blue* asbestos suitably treated.

In making a weld or reinforcing a worn surface the electrode is held in an insulated holder connected by flexible leads to the positive pole of an electric generator and an arc is struck between the electrode and the work carrying the negative connection ; this arc is immediately destroyed and a quasi-arc formed and maintained, owing to the blue asbestos covering passing into the molten state and acting as a secondary conductor maintaining electrical connection between the work and the metallic core of the electrode.

The welding operation is continued by holding the point of the electrode just under the surface of the molten slag, and the quasi-arc is thus maintained and metal is deposited on the work continuously and with regularity.

Blue asbestos, being a ferrous silicate and an acid flux, can, in the molten condition, combine with and remove oxide or scale from work, so that it is not necessary to clean the latter in order to obtain a good junction between the electrode metal and the work. The molten steel and adjacent work, from the time of fusion until in the solid condition, is covered with this acid flux, so that oxygen from the atmosphere is prevented from entering the weld and oxidising the steel and forming blow holes. This is considerably helped by the presence of the aluminium wire, which readily takes up oxygen. The slag formed on the surface of the weld is of great advantage, as it covers the weld uniformly and allows the steel to cool much more slowly, thus adding to its mechanical strength, and when cool is easily removed.

The heat of the arc is localised to the weld, and the junction between the work and the welding metal is complete and free from oxide inclusions and shows a gradual diffusion of carbon from the work into the metal.

The following tables give the comparative strength of riveted and quasi-arc welded joints :—

TABLE SHOWING COMPARATIVE TENSILE TESTS OF QUASI-ARC-ELECTRICALLY WELDED JOINTS, AGAINST RIVETED JOINTS.

QUASI-ARC WELDED LAP JOINTS.

The quasi-arc process has been authorised by the British and Foreign Admiralties, Lloyd's Register of Shipping, the British Corporation for the Survey and Registry of Shipping, and Det Norske Veritas, for use in the more important parts in ship construction.

Note on Corrosion, in relation to Quasi-Arc Welding.

In view of the importance which the subject of corrosion bears to that of welding, the following notes on this matter may be added :—

Fundamentally, corrosion is electrolytic in character, and depends on the difference in potential of contiguous areas.

Commercial iron and steel contain areas which in the presence of an electrolyte (which may be merely atmospheric moisture) are capable of forming voltaic circuits, the necessary conditions being afforded by the presence of small particles of impurities or by local conditions of strain in the metal itself. These impurities or strains give rise to areas of higher electrolytic potential, and form electro-positive points which are first attacked by the corroding agent. Thus, in a caulked joint, corrosion will commence at the caulking, and similarly a riveted joint will be attacked round the rivet head, owing to the local strains in the metal at these points.

In a welded joint, if the metal at the weld be less pure than the surrounding metal, the weld will be first attacked. Similarly, if the added metal be not homogeneous, local differences in potential in the weld itself will cause corrosion at the weld.

A microscopic examination of the metal deposited by the Quasi-Arc process shows it to be of great purity, and the usual laboratory tests show it to be always electro-negative to the surrounding metal. Hence it follows that a Quasi-Arc weld will have a high factor of resistance to corrosive influences.

Alloy Welding Processes System.

The 'A.W.P.' electrodes are flux-covered electrodes, in which the coating and the metal core have been specially selected to give the best results as regards tensile strength and ductility, combined with ease of application and reliable and uniform results. The electrodes are coated by special machinery designed to suit the flux and deposit a perfectly even, concentric, and correctly proportioned amount of flux around the rod.

The slag produced is of such low specific gravity and high viscosity that it does not in any way impede the flow of the metal, or mix with the molten metal and get trapped when cooling. In making a second run the slag need not be removed except by slight brushing to remove dust and loose pieces. The electrodes produce a stable, even, and quiet arc, and the metal is evenly deposited and easily controlled. Special alloy electrodes can be supplied to successfully weld any particular specification of steel.

Arc welding plant to meet all conditions, portable and self-contained, and for use on alternating and direct current supplies, have been designed from efficiency and economy points of view. The 'A.W.P.' electrodes can be used on alternating or direct current. If the operator is on direct current from a separate generator the voltage should be adjusted by the shunt regulator to as near 60 volts as possible. If welding with alternating current a non-inductive grid resistance should not be used in the circuit to adjust the current. An adjustable choking coil, which provides the same variation in current in addition to steadying the arc and saving power, should be obtained.

Premier System.

The flux-coated wire electrodes of the *Premier Electric Welding Co., Ltd.*, is an alloy wire of carefully controlled composition, which is coated with a thin coating of non-metallic substances. The metal of the electrode is chosen with a view to producing a sound weld with a low nitrogen content and with consistently good mechanical properties. The coating on the electrode does not produce a layer of slag which has to be removed by chipping, but is there for the purpose of producing a steady arc and keeping the nitrogen and oxygen content of the weld at the lowest possible point. Four types of electrodes, classified according to requirements, are available—viz., standard electrode for general service, cast iron, high carbon, and manganese steel; in addition special electrodes will be made where necessary.

The Premier System of arc welding aims at distributing the current at the required welding voltage without any mechanical control whatsoever. This is obtained by the use of a dynamo of a special type connected with the arc through a special reactance coil in the main circuit. This coil absorbs no appreciable energy, but effectively damps out any sudden rise in current and at the same time helps momentarily to build up the current when any sudden break takes place. The reactance coil largely prevents breaking of the arc, thus reducing the skill required in electrode manipulation and eliminating flaws in the weld. It is claimed that with the Premier plant the consumption is less than one-third that of ordinary welding dynamos.

Electro-percussive Welding.

This is a process which is chiefly intended for manufacturing applications in which large quantities of duplicate parts are to be produced. The underlying principles utilised in percussive welding were discovered in 1905 by Mr. J. Chubb, of the Westinghouse Company. Following his original experiments, machines were developed for welding metals in wire form of rather small cross-section. Widely different physical properties offered no obstacle, and ductile welds can be made with copper and aluminium, platinum and lead. Electrical devices are used whereby a rapid small separation of the parts to be welded causes an intense arc to melt the surfaces. At the proper moment a forging-hammer forges the pieces together. The advantages claimed for the process are (*a*) power saved; (*b*) time of welding negligible; (*c*) welds of unequal sections are possible; (*d*) welds of unlike metals can be made; (*e*) uniform welds; (*f*) cost of finishing welds reduced. Recent results have shown that percussive welding has many valuable applications, especially in non-ferrous and steel-alloy welding.

Electric Blowpipe Welding.

In this process the electric blowpipe is essentially a horizontal-flame arc lamp using two carbons mounted like the letter V. The process was introduced by Dr. Zerener in 1890, and is usually known as the Zerener system. The flame of the arc was directed away or deflected downwards by means of an electro-magnet in series with the arc. The apparatus is bulky and complicated and for even moderate-sized work it must be suspended from above. This method of welding eliminates the passage of the current through the work. It is in use in several plants in Germany. The Voltex Process is a variation of the Zerener method in which the carbon electrodes are impregnated with metallic oxide which s vaporised by the flame of the arc.

Arc Welding Equipment.

Electric-arc welding may be done with any direct-current arc, having a reasonable degree of stability and sufficient amount of heat to accomplish fusion. The design of the welding machine affects the cost of welding. The necessity for a special machine rests upon economic factors, and the differences between the various types used are differences of power, cost of operation, difference of speed of operation due to the relative stability of the arc.

The question of direct or alternating current raises many interesting points which have never been clearly determined. Comparative data by independent authorities is missing, and the question of whether direct-current welding is faster or slower, whether flux-covered electrodes enable direct-current to take the lead in welding speed, whether the practical losses in motor generator and resistance compares favourably or otherwise with the alternating-current system, etc., etc., are questions which are answered by contradictory claims by both parties to this controversy. However, there are advocates for both systems, and equipment can be obtained for arc welding with direct or alternating current.

The successful application of arc welding is largely dependent upon the selection of the proper equipment. There are two systems in general use—(*a*) Single operator system, where a separate machine is provided for each operator, each machine receiving its current supply from the supply circuit; (*b*) Multiple operator system, where more than one operator receives current direct from the same machine, but each operator is provided with a control panel which enables him to vary the current without interfering with the other operators.

The equipment consists of a motor generator, control panel, and accessories. When using alternating current use is made of a transformer to reduce the distribution voltage to that suitable for the weld.

Amongst the accessories are protective equipment and electrode holders.

Protective Equipment.

The intense glare emitted in the process of arc welding consists of a combination of invisible infra-red rays, visible light rays, and invisible ultra-violet rays, and special safety devices are required to protect the operator from their harmful effects. For light electric welding it is necessary only to protect the eyes with goggles fitted with suitable coloured glasses. Hand shields are made for medium-weight electric welding work which can be done with one hand. They serve the double purpose of protecting the eyes of the operator and also shielding the face from the heat rays and ultra-violet radiations. For heavy electric welding it is common practice to use a helmet or hood which provides protection for the eyes, head, face, and neck, and leaves the hands free. For the protection of the hands and wrists leather gloves are used. These devices are subject to modifications to meet the requirements of special work. With regard to the tint of the protective glasses, a reference to the note on goggles in the section on oxy-acetylene welding will be useful.

Automatic Arc Welding.

Depositing metal using an automatic feed for the electrode results in a materially increased rate of deposition. Machines have been developed which are capable of welding steel 0·109 inches thick at the rate of 22 ins. per minute. This method of depositing metal is particularly advantageous on sections of uniform shape upon which a considerable amount of metal is to be deposited. Automatic welding does not eliminate the human element in welding, but does in certain cases greatly increase the speed of the process, and in other cases obtains results which are beyond the limitations of manual operation.

Resistance Welding.

There is a marked distinction between the joining of metals by the two electric processes, viz., arc welding and resistance welding. In the former the heat is localised through the action of the electric arc and no pressure is applied; in the latter the heat is localised by the resistance to the flow of the current and pressure is used.

The process of resistance welding is based upon the phenomenon that a poor conductor of electric current will heat if current is forced through it, or that a good conductor will also heat if enough current is passed through it, and that the heating effect will be greater if alternating current is used than if direct current is used. Since an imperfect joint, such as the abutting ends of two pieces of metal, or the lapping of two pieces of metal which are to be welded, is a poor conductor and offers great resistance to the passage of the current, it will naturally heat and finally cause the metal to fuse and flow sufficiently to weld. In practice the operation is very rapid because comparatively large amounts of current are used.

For this type of welding a single-phase alternating current of any commercial frequency is used. The transformer in the machine will take the current from an ordinary shop circuit and reduce it to a suitable welding current.

Resistance welding is only suitable for duplicate or repetition work. In general one machine is designed for handling pieces of the same metal and for making joints of similar design. Repair jobs have been done in special cases, but it is only in rare cases that such an adaptation is attempted.

A resistance welding machine is simply a single-phase transformer having a secondary of one or two turns, the voltage required between the terminals being only five to ten volts, and the current being limited only by the size of the pieces to be handled. The transformer is built into a heavy frame which supports the clamping jaws to handle the work and mechanical devices to regulate the heat and pressure. The machine has reached a high degree of perfection, and large savings of time and labour have resulted in production work. The principle involved has been applied in the construction of a variety of machines indicated in the following definitions

Butt Welding

Consists in joining pieces end to end, securing complete fusion of the entire cross-section of the pieces. The pieces to be welded are placed in the clamping jaws, one of which is stationary and the other movable; enough pressure is exerted to bring the ends into contact and the current is then turned on. As soon as the welding temperature is reached the operator increases the pressure, thus forcing the pieces together, and turns off the current. Nearly all metals used commercially have been welded by this process.

Seam or Line Welding

Consists in joining pieces along a continuous line or seam, usually by moving the joint in the path of the current, so that fusion is secured continuously. The process combines the features of butt and spot welding. Machinery has been developed very successfully, but is limited to work on light stock and short seams. Standard seam welders are usually equipped with two electrodes, one connected to the work and the other a roller running over the seam, or both electrodes may be converging rollers, with the converging edges resting on opposite parts of the work near the edge to be welded. The work is passed beneath the rollers, which carry the current into the metal, and makes a continuous line of welding. The work must be carefully cleaned and be securely held by the machine to get good results.

Spot Welding

Consists in pressing the pieces together while passing the current through them, and localising the flow of the current so that the weld is confined to 'spots' between the electrodes, which are used to secure the pressure.

The material to be welded is placed between copper die points supported on the ends of two arms, and the points are brought firmly together on the metal by the use of either foot or motive power. The current is then turned on. The metal, being a poor conductor, becomes heated, and when heated to a sufficient degree, pressure is applied. In the case of automatic control, the current is turned on and off and the necessary welding pressure applied automatically by controlling mechanism usually driven by a variable-speed motor. The majority of commercial metals can be spot welded, but it is essential that the metal to be welded should offer a considerable resistance to the electric current, otherwise sufficient heat cannot be generated. The spot welding of light materials guarantees a successful product and increased production.

During the past few years considerable investigation has been carried out with regard to heavy spot welding for ships and constructional work. Large machines capable of supplying a welding current up to 100,000 amperes, and equipped to exert a pressure up to 30,000 lbs. per square inch on each spot, have been constructed. The main difficulties which have been encountered are, briefly, electrode-tip protection and the preparation of the materials to be welded. Two secondary considerations have been the separation of the electrodes and the shape of the head of the spot welder.

Button or Disc Welding.

Where very thick work is to be spot welded it is often desirable to find means to localise the current and cut down the amount of pressure required. Small metal discs or buttons can be used for this purpose placed between the head of the welder and the metal to be welded. Disc-depression welding differs from button welding in that in the disc-depression method an annular depression is provided in one of the sheets, around the disc. The method makes possible the use of a comparatively light machine for welding heavy steel plate, and also the use of less power and time for making the welds.

Bridge Welding

Is used to join thin sheets edge to edge without overlapping and without reducing the dimensions of the pieces. The sheets are brought together in their correct position, and then thin strips or discs are spot welded across the joint.

Multiple Electrode Welding.

Time and power can frequently be saved by making several welds at once, in which case the spot welder is equipped with two or more electrodes. It is advisable to have projections on one of the pieces to be welded to assist in localising the current. Successful multiple welding requires a separate transformer for each weld.

Point or Projection Welding.

In this method the metal to be welded is provided with points or projections. The points are brought in line with each other, and the welding effect is to provide a smaller contact point which increases the resistance and allows the weld to be made with the consumption of less time

and power. Ridge welding is the same as point welding, except that, instead of a single point a ridge is raised in the metals in such a way that the ridges on the two pieces come together in the form of a cross.

Combinations of all the above processes have been made for special jobs. Sometimes it is only necessary to make a change in the construction of the electrodes to make a machine do work of a varied character

Arc-welding Applications.

The application of arc welding to repair and manufacturing are very extensive, but its application should be made with a full knowledge of the possibilities and limitations of the process. In the welding of iron and steel, with their great variety of physical properties, a familiarity with the wide range of conditions is necessary to meet and solve the problems presented. In welding cast iron, copper, brass, aluminium, etc., the application of arc welding should be looked upon as in the experimental stages when welds with physical, chemical, and mechanical propert es similar to the base metal are required.

Cost of Arc Welding.

The cost of doing electric arc welding with the metal electrode process depends upon several variable factors, such as : (1) the price of labour ; (2) the characteristics of the arc, (*a*) arc easy to maintain, (*b*) arc difficult to maintain, (*c*) amount of heat available ; (3) the cost of power ; (4) the cost of electrodes ; (5) supervision required, (*a*) production work, (*b*) work of a varied character ; (6) interest charge on equipment.

See also 'Electric Welding,' Vol. ccviii (April 1921), *Proc. Inst. C.E.*

ELECTRIC ARC CUTTING.

Although cutting with a blowpipe has many advantages over electric arc cutting, yet there are many places where the electric arc can be used advantageously. The groove is not so narrow as that cut with a blowpipe, nor is the surface cut as clean.

The electric arc will cut any metal, ferrous or non-ferrous, and has been found particularly useful for the cutting of cast iron. The thickness that can be economically cut by the arc varies from 4 to 6 inches, for straight cutting. The current necessary for cutting operations on general and heavy cutting varies from 800 to 1,200 amperes. The voltage of the cutting arc varies between 25 and 45, a good average being 37.

It will be seen that heavy values of current are required, and special apparatus has been designed so that the arc could be controlled with these heavy currents. An important part of these developments is the design of a handle to protect the operator, hold the electrode, and to carry 1,000 amperes. A small item like the use of pure graphite instead of carbon for electrodes means the difference between success and failure.

Increase of current means larger electrodes and hence more metal to be cut out. The latest development for this work is a low resistance graphite and the approximate sizes for various current densities are as follows :—200 amperes, $\frac{1}{4}$ to $\frac{3}{8}$ in. electrodes ; 300 to 400 amperes $\frac{3}{8}$ to $\frac{1}{2}$ inch electrodes ; 400 to 600 amperes, $\frac{1}{2}$ to $\frac{5}{8}$ in. ; 600 to 800 amperes, $\frac{5}{8}$ to $\frac{3}{4}$ in. ; 800 to 1,200 amperes, $\frac{3}{4}$ to 1 in. electrodes.

Cutting on heavy sections is generally best accomplished from the underneath side or from a vertical face tipped slightly greater than 90 degrees so that the molten metal can flow away, although the action is not entirely simply melting metal. In cutting with the arc a reasonably smooth surface can be made by paying attention to one side only, or the cut may be made rough and trimmed up smooth by a second application of the arc.

Recent developments consist of a special electrode for cutting with the arc, and for such work as piercing holes. This special electrode, covered with a coating giving off free oxygen under the temperature of the arc, gasifies the entire metal melted, so that the boring action is uninterrupted after once started. This electrode is used by starting the arc and immediately pushing the electrode into the puddle. After the hole is through the piece it can be widened to any size or shape by drawing the arc around its edges. This type of electrode only takes from 250 to 350 amperes.

Thermit Welding.

This process consists in uniting the parts to be welded by pouring between them molten metal at a sufficiently high temperature to fuse them, so that on cooling union is perfected. The parts to be welded, where fractured, are cut away in order to leave a space for the molten metal. The Thermit mixture is composed of powdered aluminium and iron oxide. The two are intimately mixed, and heated at a point by a special ignition powder. At the temperature produced by igniting this powder, the aluminium reacts very energetically with the oxygen in the iron oxide. The reaction spreads rapidly throughout the mass in the crucible and produces a quantity of fluid metal, covered with a slag of alumina. The temperature set up by the reaction has been ascertained to be about 5,400° F. The crucible is a lined sheet-iron cone. It is suspended over the parts to be welded, and when the reaction is complete it is tapped, the metal running into the mould which has been built round the fracture. The weld is usually larger than the original section, and the mould may be made from a wax pattern fitted around the fracture. The wax is melted out with a preheating torch, leaving a space for the

Thermit metal, and the parts then preheated to a bright red heat before tapping the crucible. Iron oxide produces a very mild material, and it is usual to mix in with the Thermit compound small pieces of steel and ferro-manganese in certain proportions, so that the metal produced is similar to ordinary mild steel.

The welding of tramrails is carried out by means of the Thermit process. The rail-ends are carefully butted at the joint, and the weld made by running (into a suitably shaped mould) the superheated liquid steel along the base and web of the rails, followed by a slag which covers the head of the rail and raises it to a welding temperature. The rails are then drawn together by special clamps, with the result that the base and web of the rails are welded by fusion with the liquid Thermit metal, and the head is butt-welded.

CORROSION OF METALS.*

Corrosion of Iron.

Professor T. Turner in his book on 'Iron' says the results of the experiments of the Admiralty Committees which issued report in 1877 and 1880 led to the conclusion that common iron was less affected by corrosion than best Yorkshire iron, which is in accordance with the statement of Gmelin that phosphorus diminishes corrosion in iron.

In these experimente :—

Common iron resisted corrosion better than Yorkshire iron 9·6 per cent.

Yorkshire iron resisted corrosion better than mild steel, 16 per cent.

In another series of experiments conducted by D. Phillips, in Cardigan Bay, and lasting for seven years, it was found that the average corrosion of mild steel during the whole period was 126 per cent. more than wrought iron.

The independent experiments conducted by T. Andrews also showed that wrought iron corroded less rapidly than mild steel when the cleaned metallic surfaces were exposed to the action of the water.

Iron rusts very quickly when immersed in water from bogs and marshes which contain a large quantity of carbonic acid, derived from decayed vegetable matter.

Iron does not rust in dry air.

Iron subject to vibration rusts slowly. Railway rails in running roads where trains are passing frequently rust much less than those in sidings which are little used. Rails which are kept in reserve and not in use rust more quickly still.

Thin iron rusts more rapidly than thick, because the expansion and contraction owing to changes of temperature throws off the scales more quickly.

In moist air, steel rusts more rapidly than wrought iron, and wrought rusts more rapidly than cast. (See table, page 252.)

Cast iron in salt water becomes in time soft and porous. The smoother the surface of iron the more slowly it rusts.

Once rust forms the process goes on more rapidly; rust being a porous substance it absorbs moisture and acids from the atmosphere.

Protection of Iron from Rust.

The types of coating applied to iron and steel for their protection may be classified as follows :—

1. Adherent coatings. 2. Compound coatings.

1. Adherent Coatings.

These may be metallic or non-metallic in character. Of methods for the production of metallic coatings of this type the following are the most noteworthy examples :—

(*a*) Galvanising.—This is a process which has for its object the coating of the material with zinc. Two processes, known respectively as hot galvanising and electro-galvanising, are employed for attaining the desired object.

Hot galvanising consists in the immersion of the object to be protected from corrosion in molten zinc or spelter, the surface of which is largely protected from oxidation by a supernatant layer of ammonium chloride. Modifications of the simple process briefly described in the last sentence are known under the following names, Winiwarter's process, Kufler's process, Bedson's process, Reese's process, Porter's process, etc.

The amount of zinc on modern galvanised sheets varies from 1 to 2·5 oz. per square foot coated. The coating generally contains from 0·25 to 1·00 per cent. of lead and from 2 to 6 per cent. of iron.

The most obvious disadvantages of galvanising are two in number: first, the iron or steel coated has to be raised in temperature for the desired effect to be attained; second, a layer of weak zinc-iron alloy forms at some point intermediate between the true zinc layer and the iron or steel upon which it is designed to rest. This thin lamina of weak alloy, mainly the compound $FeZn_7$, may be insufficient in a majority of cases to cause trouble, but a serious reduction in tensile strength is frequently brought about as a result of the presence of this weak material in fine gauge wires and sheets.

* See also page 252.

Electro galvanising (cold galvanising) consists in the deposition of zinc electrolytically upon the object to be protected from corrosion, a soluble zinc salt being employed as electrolyte. The most important process under this head is that of S. Cowper-Coles, wherein an electrolyte of zinc sulphate is used, the electrolyte being continuously regenerated by circulation through tanks containing zinc dust. The methods of cold galvanising associated with the names of Heathfield, Powick, Pottkoff, Rawson, Wagner, Walker, etc., are worthy of note. Particulars of their processes are obtainable in the technical press.

The electrolytic process leads to the formation of an intermediate lamina of only minute thickness. In this particular the coating produced by the electrolytic process is an improvement upon that obtaining as a result of hot galvanising. It is, however, porous, and in this respect is inferior to the zinc coating produced in the dipping process. No marked superiority can be claimed for either of the processes.

Electro galvanising has made great progress during the past few years, and may now be regarded as an efficient method of rustproofing. By its means a wide range of articles may be coated with a film of zinc which, while ample to protect from oxidation, does not affect ductility or tensile strength. The fact that perfect cleanliness must be achieved before the adherence of zinc can take place prevents dirty patches on the article becoming coated. The main cause of failure with hot galvanised work is the covering up, through the surface tension of molten spelter, of dirty or scaly places, which blister or otherwise fail in a comparatively short time. A commercially protective coating is obtained with a deposit of 4 oz. per square yard of surface. The deposit is practically pure, lead being the chief adulterant, then only in a fraction per cent. Accurately machined parts can be assembled after coating, this overcoming a difficulty ever present in the past. Hot galvanised bolts must have the thread bared before the nut will fit. Cold galvanising coats the thread so that the configuration is not destroyed, and unless the nut is a very tight fit the zinc remains on the thread and thus protects it against corrosion.

Admiralty specifications require a deposit of 0·86 oz. of electro-deposited zinc per sq. foot of surface of the articles treated.

(*b*) Tin plating is a process similar to hot galvanising, tin being the coating metal. The protection afforded to iron and steel by tin is less effective than is that of zinc.

(*c*) Terne plating consists of the coating of the material to be protected with an alloy of lead containing from 50 to 75 per cent. of tin (generally 70 per cent. tin).

(*d*) Lohmanising—in this process the metals to be protected are (i) pickled in an acid bath, (ii) dipped into a salt bath which deposits a metallic salt over the entire surface of the body, (iii) immersed in a bath of molten alloy of zinc, lead and tin heated to a temperature of from 500 to 600° C. The composition of the tin-lead-zinc alloy is varied to suit the material being treated.

(*e*) Electro-plating—the coating of iron and steel electrolytically with copper, nickel, etc., is well known.

(*f*) Copper 'clothing'—the casting of copper round or the welding of copper to steel and the rolling of the resultant material to the required shape and dimensions has been practised, e.g. Monnot process, Willis process, etc. (vide *Iron Trade Review*, vol. li. 479).

(*g*) Nickel 'clothing'—processes similar to the Monnot and Willis processes have been successfully applied to the coating of iron and steel with nickel and cupro-nickel.

(*h*) Metallic spraying—the application of liquid metal in finely subdivided form by a spraying machine has been accomplished by M. U. Schoop, whose process, 'the Schoop process,' allows of the coating of iron or steel with an adherent layer of tin, lead or zinc, the material being coated remaining meanwhile at the ordinary temperature. The material under treatment must be scrupulously clean if adhesion of the finely-divided spray is to be perfected (vide *Metal Industry*, vol. xvi. 41).

Of methods for the production of non-metallic coatings of this type the following are the most noteworthy examples :—

(*a*) *Painting* (see page 2355)—The term 'paint' is applied to such substances as are employed as protective coatings in liquid form, but which under the action of oxygen dry and finally become hard and resistant. Paints are composed of :—

(*i*) solid substance in a state of fine division (pigment);
(*ii*) liquid in which the solid is held in suspension (vehicle); and, frequently,
(*iii*) salts of manganese, etc., for the purpose of hastening oxidation of the vehicle (drier).

Friend (*Carnegie Schol. Mem.* vol. ix. 1918, 117) summarises the conclusions respecting painted ironwork exposed to atmospheric corrosion as follows :—

1. The practical value of acceleration tests is shown to be very small in the present state of our knowledge. Reliable results can only be obtained from tests carried out under conditions closely resembling those required in practice.

2. Addition of pigment to oil increases the efficiency of the latter as a protective paint until a maximum is reached. After this, further addition of pigment causes deterioration. The best results are obtainable from paints possessing as high a percentage of good oil as is compatible with good body and any other working property that has to be considered.

3. Linseed oil on setting expands by some 3·3 per cent.; this is the primary cause of crinkling. Further oxidation causes a decrease in volume; this in time leads to cracking.

4. Linoxyn is permeable to moisture. The permeability is reduced by heating in absence of air, the oil increasing in density, viscosity, and molecular weight.

5. Polymerised linseed oil affords a better protection than raw oil when used as a paint vehicle.

6. The functions of a pigment are to toughen the film and render it less permeable to water vapour and oxygen. It also reduces the expansion of the oil on setting and thus minimises the tendency to crinkle.

7. A thick coat of paint protects the underlying metal more efficiently than a thin coat, provided the coat is not so thick that running or crinkling takes place.

8. The very best results are obtained by multiple coats. Two thin coats are better than one thick one of equal weight.

9. Thinners enable thin coats of paint to be applied. Turpentine leaves a very slight residue behind upon evaporation, but its effect on the efficiency of the paint is small.

10. Other things being equal, the most permanent paints are those containing black or red pigments, since these absorb the shorter rays of light and prevent them from hastening the destructive oxidation of the linoxyn by the air.

11. Finer pigments afford more efficient protection than coarse pigments, since they are more thoroughly in contact with the oil.

12. Iron structures should be painted whilst their scale is still on after loosely adherent flakes and rust have been scraped off. The paint will last rather longer than if applied to the pickled or sand-blasted surface, and the labour of removing the scale is saved.

13. Experiments with rusty plates are not conclusive, but suggest that the rust need not be so carefully removed, prior to painting, as is usually thought to be necessary.

(*b*) Varnishing—the term 'varnish' is applied to such liquids as are produced by the solution of gums, resins, etc., in volatile substances such as spirit, turpentine, fusel oil, etc. Varnishes are open to the objection that they are not entirely impervious to gases and liquids. The application of several coats of varnish and the stoving of such articles as have been varnished tend to increase the efficiency of these types of protective. The former method of treatment is, of course, costly; the latter can only be employed where relatively small articles are being dealt with.

Frequently mineral oxides, etc., are added to give 'body' to varnishes, and such protectives are far preferable to the mere gum or resin solutions mentioned above. Provided the solvent utilised in manufacture is not too volatile and the substances employed to give 'body' to the varnish do not act injuriously upon either the iron or the solute, these varnishes are of considerable value. Of materials employed to give 'body' to varnishes, calcined hematite ores and the mixture of finely-divided zinc and zinc oxide ('blue powder') obtained in the distillation of zinc, are the most effective. (*Lewes.*)

(*c*) Coating with bituminous substances—the substances tar, pitch and asphalt, together with other tar products of like nature, form excellent protective coatings for iron and steel. Care requires to be taken to ensure the absence of acid or alkaline substances from these bituminous materials. Where the articles to be coated can be heated without deleterious effect most excellent 'enamels' can be produced by applying warm tar to the same as hot. A variety of coatings may be obtained by altering the relative temperatures of the articles to be treated and the bituminous material employed in treatment (*cf.* Angus Smith's process, page 2358).

(*d*) Coating with Portland cement—the use of cements as a protective coating is frequent where the same can be afforded suitable support. In many cases the difficulty of attachment of the protective coating more than counterbalances the rigidity and adherent properties of the cement. Consideration must, of course, be taken of the possible effect of metallic expansion and contraction upon the cement coating applied, and cement should only be utilised where it can be applied in relatively thick coatings and where one can be assured that rupture of the hardened cement will be unlikely.

(*e*) *Enamelling.*—The enamelling of iron and steel is frequently conducted with a view to afford protection to the same. The enamels employed are boro-silicates of sodium, potassium, calcium, and aluminium. Finely-divided glass, flint or quartz forms the general source of the silica; felspar or clay that of the alumina. To render enamels translucent fluorspar is added, while borax furnishes the anhydride of boron required to complete the true enamel. Soda ash and pearl ash are utilised as fluxes. As oxidising agents the nitrates of sodium and potassium and manganese dioxide are used in light- and dark-coloured enamels respectively. To give adhesiveness to such enamels as come into direct contact with the metals to be coated, oxide of cobalt is employed. The following oxides are used as colouring agents:—

White, oxide of tin; blue, oxide of cobalt; violet, oxide of manganese; brown, oxide of manganese; grey, oxide of nickel; green, oxides of copper or of chromium; yellow, oxides of uranium or of titanium; red, oxides of iron, selenium, or of gold.

The enamel is put on either as a powder or as a suspension. It may be applied in one coat either by dipping, by spraying, or by powdering. Sometimes, however, a non-vitreous base material is applied and burned in to make it adherent, after which the true enamel is introduced to the surface to be coated. In any case the finely-divided particles which form the basis of the enamel are fused together in a solid coating of boro-silicate by subjecting the same to a temperature of about 1,000°C. The process generally requires from 3 to 4 minutes.

A process similar in some respects to that of enamelling is Ward's inoxidising process, which consists of the application of a solution of a silicate to the iron or steel to be protected. The articles so prepared are heated to such a temperature as will cause partial fusion of the silicate to occur and union of the same with the iron finally to ensue (*cf.* also Dode's inoxidising process).

It is obvious from the above that enamelling can be applied to relatively few articles of importance to the engineer.

2. Compound Coatings.

The term ' compound ' is applied here to such protective coatings as are produced by chemical action, the ultimate result of which is the formation of a chemical compound, such, for example, as magnetic oxide of iron (Fe_3O_4), iron-zinc ($FeZn_3$), etc. The compounds formed may be, as already noted, either chemical (in the general sense of the term) or intermetallic (in the specialised sense of the term).

Chemical Compounds.

Barff's process consists in passing superheated steam over the objects, which are heated in an air-tight retort to about 260° C.; for the formation of a more perfect protective coating higher temperatures are necessary (650° C.). Articles so treated are said to be ' barffed.' Relatively small objects only can be treated as above. The coating formed consists of the mixed oxides of iron (Fe_2O_3 and Fe_3O_4).

The Bower-Barff process is an improvement on the above, and consists in the heating of the objects to be protected to about 900° C., at the attainment of which temperature superheated steam is introduced to the same, which has the effect of producing a coating of the mixed oxide already referred to. This operation having continued for about twenty minutes, carbon monoxide is injected into the retort for a period of from fifteen to twenty-five minutes, during which time the entire reduction of the coating to the condition of magnetic oxide of iron is completed.

The Gesner process treats iron and steel at a moderately high temperature (550° C. to 650° C.) in a retort whereinto may be introduced an atmosphere of steam. The preliminary heating occupies twenty minutes; the steam is then allowed to react with the oxide formed in the first operation for about half an hour, when naphtha is introduced and allowed to remain in contact with the material under treatment for about ten minutes. Finally, steam is again introduced. The whole sequence of operations occupies about one hour and twenty minutes.

The Parker ' dry ' process.—Under a patent assigned to the Parker Rust-proof Company, of Detroit, the formation of an adherent coating of oxide may be obtained by first heating the objects to be treated to about 600° F. and then subjecting them to fumes of the acid metaphosphates of strontium, molybdenum and tungsten.

The Hans Renold process.—Remove all grease or oil from the articles to be treated by suspending in a bath of hot lyco (11 oz. per gal.) for about three minutes, wash in cold running water for a few seconds, then suspend from cathode brass bars by steel hooks in an electrolytic bath (KCN, 98 per cent. pure, 4 oz. per gal. of water), iron plates forming the anodes. Leave here for five minutes, and when a current of 25 amps. at 8–10 volts is passed through the bath all foreign matter on the surface will be removed. Wash off the cyanide by means of hot water to facilitate drying.

Heat the articles to 700° C., then quench in cotton-seed oil by immersing in the main body of the quenching tank for seven or eight seconds before allowing to fall to the bottom.

Dry by heated sawdust and hot-air blast (dried and filtered by passing through calcium chloride and cotton wool).

Insufficient oxidation results in the finished bodies having a grey appearance, due to the atmosphere of the furnace containing too much gas. Blistering is due to overheating.

Villon's process consists in subjecting the iron or steel to be protected to the vapour of sulphur, as a result of which treatment the monosulphide of iron is found.

The Bertand process requires that the articles to be treated be thoroughly cleaned by sand-blasting or similar means before they are immersed in a bath, such as will lead to the deposition of copper upon the same as a result of reaction between the iron and a suitable electrolyte. The deposition may be achieved by the application of electricity or by more purely chemical means. After thorough washing the articles are heated in an oxidising atmosphere to a temperature of about 600° C., which treatment leads to the formation of a fairly adherent coating of magnetic oxide of iron.

The De Meietin's process depends upon the formation of a coating of magnetic oxide (Fe_3O_4) upon iron or steel which is placed as the positive pole in a bath of distilled water, maintained at a temperature of from 70° C. to 80° C., a current of electricity being passed through it. The oxide coating is adherent, provided the current density is not over great, and may be rubbed and polished. This method is of value in the treatment of such articles as cannot be submitted to any processes which might tend to temper or anneal the objects under treatment.

The Parker ' wet ' process (patent) consists in the immersion of the iron or steel to be protected in a bath of a 1½ per cent. solution of the acid metaphosphates of tungsten, molybdenum, or any of the metals of the third, fourth or fifth group of elements.

The Coslett Process (Coslettising).—Cast iron or steel articles treated by this process are not only rendered rust-proof but improved in appearance.

The articles to be treated should be perfectly clean and free from tin, nickel, or grease.

The best results are obtained on a frosted surface, such as is left by sand-blasting or pickling. Sand-blasting is to be preferred, as any traces of acid render the treatment ineffectual.

The coslettising bath is prepared by heating in a cast-iron or welded steel tank a sufficient quantity of distilled water to easily cover the articles to be treated. When boiling add for every gallon of water in the bath (1) two ounces of phosphoric acid (syrupy sp. gr. 1·5); (2) one ounce of iron filings. This should be carried out in the open or under an uptake, as the reaction results in the formation of disagreeable fumes. When this reaction has ceased the bath is ready for use.

The articles should be placed in the bath as soon as possible after sand-blasting, and should be gently boiled for two hours.

A second tank should be prepared containing distilled water, which should be heated in time to wash the articles as taken from the coslettising bath.

At the expiration of the specified time the articles should be taken from the coslettising bath and placed directly into the hot water and thoroughly scrubbed with a stiff bristle brush.

They may then be dried off, and if heavy will dry quickly themselves, but if light should be placed in an externally heated oven.

As soon as dry and while warm they should be dipped in a mixture of lubricating oil and turps substitute, in the proportion of 2 to 1, and left to drain. When cold, surplus oil may be removed with clean waste or wiper.

To allow for evaporation of bath a mixture similar to that in the bath should be made up and added as required.

To keep the bath at the correct strength it is necessary to titrate a sample of the bath with $\frac{1}{10}$ normal sodium hydrate. To make this test, 10 c.c. of the bath should be placed in a conical flask, a few drops of phenolphthalein solution being introduced as an indicator. The $\frac{1}{10}$ normal sodium hydrate should be added from a burette, until a permanent pink tinge is given to the liquid in the flask. The amount of sodium hydrate dropped into the flask should be noted, and if the bath is correct this amount will be 10 c.c. If more sodium hydrate is used, the bath is too strong and will require diluting with distilled water; if less is used, the bath is weak and will require the addition of phosphoric acid and iron filings in the given proportion.

The appearance of the deposit obtained on the article is a rough guide to the state of the bath. The proper deposit is of a uniform dull black colour, but if the bath is too strong this black coat is covered with a pearly white deposit which will not scrub off. If the bath is too weak the articles appear unevenly covered with a thin grey coat.

Granulated zinc may be used in place of iron filings, in which case the articles appear to be coated with metallic zinc.

The need for the absolute cleanliness of the articles before treatment cannot be too strongly emphasised, and they should not be handled after cleaning, or before they are finally oiled.

Intermetallic Compounds.

Sherardising.—The articles to be coated are first cleaned and dipped in an acid bath as for galvanising; they are then put in a suitable retort which is, if possible, airtight, and are surrounded with 'blue powder'; the retort is then raised to a temperature of 500° or 600° F.

If the retort cannot be made airtight, about 3 per cent. of finely-powdered carbon should be mixed with the zinc to prevent the formation of zinc oxide.

The heat is kept up for a few hours, after which it is allowed to gradually decrease.

A coating is formed which consists mainly of an intermetallic compound of zinc and iron ($FeZn_3$).

Calorising.—A somewhat similar process to the above, in which aluminium powder is utilised as the agent and wherein the resultant protective coating consists chiefly of an intermetallic compound of iron and aluminium.

Rustless Iron.

The composition of rustless iron (carbon, 0·7; silicon, 0·8; manganese, 0·12; chrome, 11·7 and nickel, 0·57) is, except for a variation in the carbon content, the same as that of the steel possessing similar qualities.

Colouring Metals Electrolytically.

Chiefly in grey, so as to give the effect of old metal, is largely carried out.

When the colouring is only to be partial, a shellac or asphalt varnish is applied to the parts it is desired to leave untouched. The *Ironmonger* points out that with cyanide baths the retention of the varnish on the metal is almost impossible, and that in all such cases it is desirable to use a bath of acid reaction.

For a grey surface on iron a bath of the following composition is recommended:—

12 litres water.		100 grammes white arsenic.	
4 „	crude hydrochloric.	100 „	green vitriol.

1 litre of ferrous chloride solution.

As usual with acid baths, a considerable strength of current is required. Plates of carbon are used as anodes.

The bath can be used for colouring silver, nickel, German silver, etc., and by altering the composition of the bath and the current from grey to a deep black is produced; but the black adheres very indifferently—a high current is necessary for the latter. (*Horobin.*)

Electro-Deposition of Iron.

A bath that will give very satisfactory results is composed of 75 grms. of ferrous ammonium sulphate to 1 litre of water, with a current density of 1 amp. per 30 sq. cms. To ensure a uniform deposit the anode should be moved about the work by means of a small motor. A good anode is made up of 16 S.W.G. Swedish iron wire wound into the form of a cylinder and thoroughly annealed. The temperature of the solution should be kept above 68° F., and it is desirable to decant and settle it every three days or so to remove oxides of foreign matter which cause roughness in the deposited metal.

It has been found possible to coat with a layer 2 mm. thick any cylindrical wrought iron or steel surface. Properly done this layer cannot be chipped off with a chisel, and when carbonised and hardened the dividing line, shown by microphotographs, entirely disappears. The surface can be filed or ground and given a high finish.

(*B. H. Thomas*, '*Institution of Automobile Engineers.*')

COPPER.

Copper containing at least 99·95 per cent. of the pure element is produced on a commercial scale in large quantities. The average tenacity of cast copper is about 10 tons per square inch, that of worked copper is about 15 tons per square inch, while Roberts-Austen quotes the following figures for the mechanical properties of slowly annealed, hammered, rolled bars of copper of a high degree of purity :—

Elastic limit	1·16 tons per sq. in.
Maximum stress	13·47 ,,
Elongation	37·0 per cent.
Reduction of area	61·0 ,,

Impurities in Commercial Copper.

Arsenic.

Arsenic increases the hardness and the tenacity of copper. When present in moderate quantities it increases the percentage elongation of the metal. It improves the rigidity and strength of copper at high temperatures, hence, for fire-box plates, the use of copper containing from 0·3 per cent. to 0·5 per cent. of arsenic is frequently specified. In copper that is to be employed in the manufacture of brass subsequently to be cold-worked, not more than 0·05 per cent. of arsenic should be allowed.

Antimony.

Antimony is similar in action to arsenic, but it should be limited to traces in such copper as is to be used for the manufacture of brass that is to be cold-worked.

Bismuth.

Bismuth being the most deleterious element that can be present in copper, owing to its tendency to induce red-shortness, not more than traces of this element should be allowed.

Iron.

Iron is rarely present in copper in more than traces.

Lead.

Lead is, after bismuth, the most objectionable impurity likely to be present in copper, although it is of value in metal that is to be rolled into sheets, on account of its softening effect on copper. Not more than the smallest quantities of this element should be allowed in copper for cold-worked brass.

Nickel.

Nickel hardens copper, but is in no way deleterious when present in such amounts as are usual in commercial copper.

Oxygen.

Oxygen in small quantity does not have any very radical effect on the mechanical properties of copper. It is important in bringing copper up to the ' pitch,' and in combining with deleterious impurities to form insoluble and infusible compounds, thus separating and distributing these impurities and rendering them harmless.

Sulphur.

Sulphur tends to embrittle copper, but is rarely present in refined copper.

Tellurium.

Tellurium is similar to sulphur in its action on copper.

Silver, Tin and Zinc.

Silver, tin and zinc are sometimes present in copper, but are rarely present in such quantity as to have much effect on the metal.

It has been found practically impossible to cast copper which is mechanically sound and of high electrical conductivity, on account of the porous metal that is obtained. By an addition of boron this can be accomplished. One per cent. of boron suboxide flux—equivalent to 0·08 to 0·1 per cent. of boron suboxide—is added to the copper, and a casting that is commercially sound is obtained.

ZINC.

Zinc is marketed in two forms—as sheet zinc (see Sheet Zinc Trade Gauge, page 2391) and as spelter, i.e. flat rectangular ingots from 1 to 2 inches in thickness. The tenacity of zinc as cast is about 1 ton per square inch, and its elongation is practically nil. Zinc, after compression under a stress of 20 tons per square inch at 100° C., has a tenacity of about 11 tons per square inch.

It is ductile between 212° F. and 302° F. and can then be shaped as required. But when either above or below these limits it becomes brittle and unpliant, and therefore not adapted for treatment. It melts at about 786° F. if volatilisation is guarded against.

Impurities in Commercial Zinc.

Arsenic.

Arsenic is a common impurity in spelter. It does not occur in such quantity as to have a deleterious effect upon the mechanical properties of spelter or of such alloys as contain it. It is, however, an objectionable ingredient in such zinc as is to be employed in the production of hydrogen.

Cadmium.

Cadmium is nearly always present in zinc; in electrolytic varieties of the metal it rarely exceeds 0·07 per cent., in other varieties as much as 0·40 per cent. is found. The effect of this element is to harden spelter and to make it more brittle. Cadmium is, on this account, objectionable when the zinc has to be rolled into sheet or to be used for galvanising telegraph wires. In zinc for the manufacture of brass subsequently to be cold-worked as much as 0·20 per cent. of cadmium may safely be allowed.

Copper.

Copper tends to harden zinc, but is rarely present in quantity sufficient to effect radical change in the metal.

Iron.

Iron hardens and embrittles zinc. Its presence tends to the formation of dross in the galvanising process.

Such zinc as is to be used in the manufacture of cold-worked brass should not contain above 0·10 per cent. of iron. Electrolytic spelters rarely contain above 0·025 per cent.; as much as 2·5 per cent. of iron is, however, to be found in certain zincs.

Lead.

Lead is present in certain brands of zinc up to 2·5 per cent. The purer brands of spelter contain up to 0·20 per cent. of lead. The presence of lead is not deleterious where the spelter containing it is to be used for general brass manufacture, but where brass is to be cold-worked or specially treated care must be taken that the spelter used has not too high a content of lead.

Lead in moderate quantity tends to make zinc softer in rolling. When present in quantities in excess of 0·7 per cent. it tends to the production of serious cracks in slush castings of zinc.

Other elements occasionally present in spelter in traces are sulphur and carbon.

TIN.

The London Metal Exchange form of contract (1911) for the purchase of tin recognises two classes of tin—Class A, tin assaying not less than 99·75 per cent. of pure metal; Class B, tin assaying not less than 99 per cent. of pure metal.

The tensile strength of cast tin varies (according to Thurston) from 2,000 to 6,000 lbs. per square inch. The elongation is, for all practical purposes, nil.

The principal impurities in commercial tin are lead, iron, copper and arsenic. Sulphur, silver, bismuth and antimony are of frequent occurrence.

NICKEL.

Nickel containing small quantities only of impurities is a commercial article. On account of its readiness to occlude carbon monoxide and other gases, and its affinity for carbon, it is difficult to obtain nickel in a pure state in the cast condition. Parker, experimenting on pure, dead soft, wrought nickel, has arrived at the following figures for the mechanical properties of nickel :—

Elastic limit	6–10 tons per sq. in.
Maximum stress	18–20 ,,
Elongation	8–15 per cent.

Impurities in Commercial Nickel.

Carbon.

Carbon is present in nickel up to 0·20 per cent., though it rarely exceeds 0·15 per cent. It has an embrittling effect on nickel when in the form of graphite, but when combined with nickel as nickel carbide it has a strengthening effect.

Cobalt.

Cobalt has a strengthening and hardening effect on nickel, but in the quantities—up to 1·00 per cent.—usually found in commercial nickel, this element has but little effect.

Copper.

Cōpper is similar to cobalt in its action, but rarely exceeds 0·20 per cent. in amount.

Arsenic.

Arsenic should not exceed about 0·025 per cent. in such nickel as is to be subjected to cold-work, or in alloys for a similar purpose.

Iron.

Iron has an effect on nickel similar to that of cobalt and chromium, but, being rarely present in quantities in excess of 0·75 per cent., its presence is scarcely noticeable.

Silicon.

As much as 0·30 per cent. of siliceous matter can be present in commercial nickel. Its effect on the properties of the nickel is uncertain.

Sulphur.

Sulphur is occasionally noted in samples of nickel.

Nickel, if it is to be satisfactory for the manufacture of copper-nickel alloys for cold-working, should be free from all unreduced oxides.

ALUMINIUM.

Aluminium which contains up to 99·9 per cent. of the pure element can be produced on a commercial scale, but the commercial metal is rarely above 99·5 per cent. pure. The mechanical properties of cast aluminium are as follows :—

Elastic limit	3–4 tons per sq. in.
Maximum stress	5–7 ,,
Elongation	3–4 per cent.

The tenacity of hard-rolled aluminium can be as high as 18 tons per square inch.

Annealing Sheet Aluminium.

1. Prepare a mixture of ordinary whiting and oil, mixed to the consistency of thick paste. Coat the metal on both sides with this preparation, and place it on a clean fire or in a furnace, allowing it to remain until the oil in the paste becomes ignited. When this occurs withdraw the work from the furnace and allow it to cool gradually. The coat of whiting should then be removed from the surface of the metal by washing and brushing.

2. Heat the metal to a dull red colour, perceptible in the dark, and cool slowly. With this method care must be exercised to get an equal annealing temperature distributed over the entire surface of the work.

3. Heat the sheet aluminium until pine-wood sawdust just glows when sprinkled on it, which indicates a temperature of about 750° F. At this temperature a dry match-stick will just char when rubbed on the metal. (*A. Eyles*, '*Machinery*,' *Aug.* 11, 1921.)

The Protection of Aluminium from Corrosion.

Aluminium and its alloys can be efficiently protected against atmospheric corrosion under the most severe conditions only by the use of an enamel or varnish paint. Oil paints are very inferior in protective power to those referred to above.

Impurities in Commercial Aluminium.

Copper.

Copper is present in aluminium in quantities up to 0·10 per cent., which quantities are insufficient to affect the properties of the metal noticeably.

ALUMINIUM CASTINGS

OF EVERY DESCRIPTION.

We make a Speciality of Aeronautical and Automobile Work.

We are making many thousands of **Aluminium Die Castings** weekly under the celebrated **Cothias** process—in many cases **entirely eliminating** machining operations, and we hold the sole manufacturing rights in the British : Empire for this process. :

Chemical and Physical tests are made on our own premises, and our **Castings**, both **Sand** and **Die**, are produced under the most up-to-date and :: scientific methods. ::

Sole makers of the **Birmal Aluminium Pistons**, thousands of which are running to-day in a highly satisfactory manner under the most severe :: :: conditions. :: ::

Highest Class Castings to Government Specifications

Iron.

Iron has the effect of hardening aluminium, but is never present in sufficient amount to cause appreciable change in the physical properties of the metal. The iron content varies generally from 0·25 to 0·75 per cent.

Silicon.

Silicon is always present in aluminium, varying in percentage from 0·25 to 0·50 per cent. Occasionally the upper limit given is exceeded; excessive quantities of silicon render aluminium susceptible to atmospheric corrosion.

Sodium.

Sodium is now occasionally, though rarely, noted in aluminium.

Copper, Nickel, Zinc, and Magnesium.

Copper, zinc, nickel, and magnesium harden aluminium and are frequently employed for the purpose in question. They are rarely, with the exception of copper, present in commercial aluminium.

MAGNESIUM.

Magnesium, which is a lighter metal than aluminium, promises to play an important part in the future of light alloys, particularly for aircraft construction.

NON-FERROUS ALLOYS.

COPPER AND ZINC.

The alloys of copper and zinc containing over 50 per cent. of copper are generally termed 'brasses.' The mechanical properties of these alloys have been the subject of numerous investigations; in this connection such authorities as Thurston, Charpy, Lohr, Guillet, etc., should be consulted.

Below are given the results of Guillet's tests on the brasses. His tests were carried out upon material which was worked, then heated for ten minutes at 750°C. in a salt bath and finally cooled in air.

Alloy Composition.	Yield Point.	Max. Stress.	Elongation per cent. on 100 mm.	Hardness.

Figs. 40 and 41 show the relation existing between the mechanical properties of the pure brasses and their copper content.

The casting temperatures of these alloys are of exceptional moment. The following tests show the influence of varying casting temperature on the tensile properties of 40 5 per cent. zinc-copper alloy castings poured from one crucible within a short interval of each other. Chemically the three castings were identical.

Casting Temperature °C.	Maximum Stress per Square Inch.	Elongation per cent.

FIG. 41.

In every case with other alloys similar temperature variations have a similar effect on the mechanical properties. The following results obtained from manganese bronze were obtained by Guillemin :—

Casting Temperature °C.	Maximum Stress. Tons per Sq. In.	Elongation per cent.
1,400	15·2	13
1,300	19·7	45
1,250	21·6	35
1,200	22·9	30

In judging a suitable pouring temperature the appearance of the alloy in ladle or crucible may be used as a guide. With manganese bronzes this appearance is somewhat confused by the aluminium present, for, as is well known, this imparts a characteristic skin to the surface of the molten alloy. The practical effect of this is to make the alloy appear colder and less fluid than is really the case. Careful observation readily overcomes this difficulty.

There is little doubt that the pyrometer is, in the hands of careful workers, the best means of determining the temperatures of metal or alloy in the ladle or crucible.

(See also Zinc-Tin Alloys, page 2335.)

Cast Brass.

Cast brass is somewhat variable in composition, but usually contains about 66 per cent. of copper, this percentage being that found in English standard brass.

The metals employed in the production of cast brass are not generally selected with such care as are those used in the manufacture of malleable brass. Lead, tin and iron are common impurities.

Lead in proportions varying from 1 to 3 per cent. is frequently added for the purpose of facilitating machining. It reduces the tenacity and hardness and increases the corrodibility of the resulting alloy, and is liable to segregate in those parts of the castings that solidify latest on cooling.

Tin tends to harden brass and is added in quantities up to 3 per cent., though 2 per cent. is not generally exceeded.

Iron hardens and increases the tenacity of brass.

The presence of more than one of these elements in quantity is to be deprecated, as their combined effects on the mechanical properties of the resulting alloy are likely to be injurious.

The mechanical properties of cast brass of average composition (66 per cent. of copper) and containing only small quantities of impurities or added elements are :—

Yield point, 6 tons per sq. in.; Tenacity, 14 tons per sq. in.; Elongation, 40 per cent.

A number of alloys, adapted for particular purposes, are tabulated below :—

Alloy.	Cu. Per cent.	Zn. Per cent.	Other Metals. Per cent.
Very delicate castings	86·00	14·00	—
Good yellow brass	75·00	25·00	Sn. 2·00
Name plates	86·00	9·00	Sn. 3·00; Pb. 2·00
Small castings (red)	90·00	10·00	,, ,,
Taps, cocks, etc.	78·00	14·00	Sn. 3·00; Pb. 3·00
Fine castings (yellow)	71·00	24·00	Sn. 2·00; Pb. 3·00
Hydraulic pumps	58·00	38·00	Sn. 2·00; Fe. 2·00

Ductile Brass.

The brasses containing upwards of 63 per cent. of copper are ductile and malleable at ordinary temperatures, provided that the metals used in the production of the alloys be of the best quality, and that the alloys be well annealed during working. The most suitable annealing temperatures for ductile brass are between 650° C. and 700° C.

Lead is admissible in alloys that are to be rolled into sheet, but is injurious in alloys that are to be drawn into wire. It should not be present in such quantity as is liable to create trouble at the annealing furnace.

The most ductile of the brasses contains 70 per cent. of copper and possesses the following mechanical properties when fully annealed subsequent to rolling :—

Yield point . 10 tons per sq. in.; Elongation . 60 per cent. on 2 ins.;
maximum stress . 23 ,, ; Hardness (Brinell) 120.

Hot-forgeable Brass.

The alloys of copper and zinc containing from 59 to 61 per cent. of copper are characterised by their ability to withstand hot rolling at temperatures ranging from 500° C. to 800° C. They are employed in sheet form for the sheathing of wooden ships and in bar form for the manufacture of bolts, fastenings, etc. They are forgeable under the drop hammer and, hence, are frequently used in the manufacture of stampings. In this last connection it is particularly noteworthy that constancy of composition must be attained, on account of the large variations in machining properties accounted for by small changes in the copper content. The alloys in the range 57 to 63 per cent. of copper are forgeable, though not capable of withstanding rolling, in the temperature range already stated, and may be considered here.

All the above alloys are retained in a harder, stronger, and less ductile condition if quenched from temperatures between 750° C. and 800° C. than if allowed to cool slowly. They are liable to spontaneous cracking if worked at temperatures below 600° C., which liability, if thought to be inherent, can be lessened if the alloys are annealed at temperatures between 200° C. and 300° C., subsequent to working. The best temperatures for annealing, with a view to reducing variations in the mechanical properties due to variations in the mechanical and thermal treatment, are below rather than above 650° C. The temperature range (750° C.–800° C.) is, according to Stead, a dangerous one in which to conduct the annealing of hot-forgeable brass.

The average mechanical properties of fully annealed cast 60/40 brass are as follows :—

Yield point . . .	10 tons per sq. in.;	Elongation . . .	35 per cent.;
Maximum stress .	25 ,, ;	Hardness (Brinell) .	85.

Drawn rod of 60/40 composition is obtainable having the following average mechanical properties :—

Yield point .	28 tons per sq. in.;	Elongation . .	20–30 per cent. on 2 ins.;
Maximum stress .	32 ,, ;	Hardness (Brinell)	140.

The last factor appears to be dependent on the diameter of the rod in question, being least when the diameter of the rod is greatest. On account of the almost infinite variety of hot- and cold-working possible in the treatment of these alloys almost infinite variations in mechanical properties are obtainable.

Effect of certain Metals on Brass.

TIN.

Naval Brass.

Tin raises the tenacity, increases the hardness and resistance to corrosion and lessens the elongation of the 60/40 alloy, to which it is added commercially to make Naval brass. The latter contains 60–62 per cent. copper, 1–1½ per cent. tin, and the rest zinc. Not more than 2 per cent. of tin should ever be present; 4 per cent. induces great brittleness.

IRON.

Iron increases the tenacity and hardness of brass. The difficulty of dissolving iron in brass was first overcome by a special process, the invention of Dick (see also p. 2323), whose alloy, generally containing 55–57 per cent. copper, 42 per cent. zinc, 1–2 per cent. of iron and traces of phosphorus, is well known.

Iron is now generally added to brass in the form of ferromanganese, an alloy of iron and manganese which is readily dissolved in molten brass.

MANGANESE.

Manganese 'Bronze.'

Manganese is added to brass with a view to improve the mechanical properties of the same. The resulting alloys are divisible into two classes.

(*a*) Alloys in which either no manganese or traces only of manganese are present, i.e. alloys to which the element has been added for purposes of deoxidation.

(*b*) Alloys in which appreciable quantities of manganese are retained in solution. These may be subdivided into (i) such as are suitable for rolling into rod and containing up to 0·05 per cent. of manganese, and (ii) such as are suitable for casting and containing less than 60 per cent. of copper, and up to 2·0 per cent. of manganese.

The manganese is introduced into the alloys by the addition of ferromanganese or cupro-manganese.

These alloys are forgeable when heated to temperatures above 750° C. They resist the corrosive action of sea water, and are employed in the manufacture of ships' propellers. Iron, aluminium and tin are generally present in manganese 'bronze.'

The analyses of the alloys known under this name are varied in accordance with the character and nature of the purpose for which they are combined, and as the results depend entirely upon

expert treatment in handling, we have obtained through the courtesy of the Manganese Bronze and Brass Co., Ltd., London, the tests on manganese bronzes recorded below.

TESTS OF MANGANESE BRONZE (CARRIED OUT BY MESSRS. BURSTALL & MONKHOUSE AT THEIR LABORATORY IN WESTMINSTER.)

STEAM CASTINGS—FOR SUPERHEATED STEAM.

Test.	Maximum Stress Tons per sq. in.	Yield Point Tons per sq. in.	Elongation in 2 ins. Per cent.
Immadium Alloy			
Cold Test	36·0	17·0	15·0
Temperature Test 500° F.	23·5	9·5	22·5
Gun-metal (for comparison)			
Cold Test	16·5	9·25	15·0
Temperature Test 420° F.	14·0	3·50	11·0

NOTE.—The Immadium temperature test pieces were maintained at a temperature of 500° F. for two hours before test was carried out, and the yield point is assumed to be reached when a permanent set of 0·003 in. on a length of 2 ins. is obtained. In Immadium the elongation is increased at high temperature, while a reduction is shown in gun-metal.

Immadium alloys	33 to 37	17 ,, 19	15 ,, 21
Parsons No. 1 alloy	32	16	15 ,, 25

CROTORITE BRONZE.

This new alloy is one of The Manganese Bronze & Brass Co.'s specialities, is zinc free, of steel-like qualities, and particularly recommended for bars and forgings subject to corrosion and high temperature.

Tests—500° to 600° F.—18–20 tons elastic limit, 30–32 tons maximum stress, 20–30 per cent. elongation; with no loss of physical properties after prolonged heating; and at 800°F. the elastic limit is 17 tons [illegible]".

As a casting alloy the physical tests are more than double cast gun-metal.

DELTA BRAND ALLOYS.

The metals and alloys sold by the Delta Metal Co., Ltd. (of London and Birmingham), under their registered trade-mark 'Delta,' are employed for a very great variety of purposes, the composition varying widely according to the requirements and purposes for which each of these metals or alloys is more particularly adapted. Some of them are based upon the introduction and chemical combination of definite quantities of iron and other elements in copper-zinc alloys. The effect of iron on brass has already been noted; the difficulty of introducing it in definite quantities was first overcome by the late Mr. Alexander Dick, the founder of the Delta Metal Co., Ltd., who adopted the name 'Delta' (the Greek equivalent of the initial letter of his name) as a trade-mark. In most of the alloys which may be classed under the 'Brasses,' the copper content lies between 57 and 62 per cent., that of zinc between 42 and 38 per cent., whilst some contain iron, phosphorus, manganese, or other metals, up to a total of about 2 per cent.

The following alloys, designated by the trade name 'Delta,' and manufactured by the Delta Metal Co. Ltd., find wide application.

Delta Bronze Nos. I and IV are practically incorrodible, and consequently of very great durability, even when used in strongly corrosive mine-waters, etc.; they are not attacked by sea-water, and resist acids much better than other copper alloys. On account of their great strength and resistance to corrosion, these alloys are largely used for parts of marine engines and mining and hydraulic plant which require a strength not less than that of the best steel, but at the same time freedom from corrosion—such as pump rods, piston rods, shafts, cranks, plungers, spindles, rams, etc. For propellers and propeller blades, Delta bronze is in great demand, and it is also successfully used for parts of ordnance, etc.

These alloys are malleable bronzes of very great strength, exceeding, even in the cast state, the strength of mild steel. They can be cast with facility, and will produce perfectly sound and homogeneous castings. When heated to a dull red heat, they become soft and highly malleable, and can then be readily forged, stamped, rolled, or pressed, to any extent required. These operations increase the strength considerably, as will be seen by the following copies of tests.

Description of Metal.	Diameter. In.	Area. Sq. in.	Ultimate Strength. Tons per sq. in.	Elongation in 2 ins. Per cent.	Reduction of Area. Per cent.
		Delta Bronze, No. I.

Extrusion Process.

The process of extruding copper and its alloys, the invention of the late Mr. Alexander Dick, developed and worked by the Delta Metal Co., Ltd., of London and Birmingham, under numerous subsequent new patents and improvements, consists of the pressing or squeezing of heated metals through dies of any desired cross section, by hydraulic pressure varying according to the section to be produced and the character of the metal operated upon.

Dick's extruded bars have a perfectly smooth and uniform surface, free from cracks or other defects; size and shape are of the greatest accuracy, and owing to their superior finish, machining is reduced to a minimum. The Company are able to produce extruded rods as ordinary round or pinion wire weighing a fraction of a pound per foot per run, to heavy round, square or hexagon rods, or other sections, more or less complicated, weighing as much as half a cwt. and over per foot. The facility of manipulation ensures rapid output, so that sections not regularly kept in stock can be supplied at very short notice.

The Delta Metal Co., Ltd., are not only the original, but claim to be also the largest manufacturers of extruded rods and sections. They supply these in various metals and alloys: in 'Delta' bronzes Nos. I, II, IV, and VII, Heagard bronze, manganese and aluminium bronze, brass, yellow metal, naval brass, etc.

They make a speciality of high-speed turning and screwing brass ('Delta' Brand and 'Dixtrudo' Brand) in every variety of shapes and sections. This material, like the stampings and pressings in brass, bronze, and copper made by the Delta Metal Co., Ltd., is used largely for repetition work and mass production, and supersedes castings.

United Brassfounders Extruded Bars.

Extruded brass and bronze bars of all sections—i.e. round, square, hexagon, flat, angle, tee, channel, etc.—in brass, yellow metal, red metal, naval brass and bronze, copper, manganese bronze, and aluminium bronze, etc., are manufactured by *United Brassfounders and Engineers Ltd.* special care being taken to obtain uniformity of composition, close limits to size, and free-cutting qualities.

Bull's Metals.

Bull's Metals are strong, malleable alloys of good casting qualities, and equal to good gunmetal in resistance to corrosion. They are manufactured in two qualities, No. II and No. III.

Alloy No. II is suitable for founding purposes, and extensively used for propellers and propeller blades, parts of guns and gun carriages, requiring the strength of cast steel with great toughness and resistance to corrosion.

Alloy No. III is very malleable and can be rolled, forged, stamped, or otherwise wrought at a red heat; this metal also casts well. Its composition ensures great resistance to corrosion and wear. It is absolutely non-magnetic.

Rolled in round, hexagon, angle, and section bars, or into sheets and plates; forged or stamped Bull's metal is used for pump rods, centrifugal pump spindles, rams, stern shafts, sluice valve spindles, parts of marine and hydraulic machinery generally. Forged propeller blades, propeller studs and nuts. Bolts, nuts, screws, studs, and nails. Parts of torpedoes and torpedo boats, ordnance, ammunition, etc. Condenser plates, strainer plates, doctor blades. Hull plates and angles for launches, torpedo boats, yachts, sailing and rowing boats.

The elastic and ultimate resistance to tensile, crushing, and torsional stresses are greater in the case of wrought Bull's metal than in mild steel, and higher working strains may therefore be used with Bull's metal. Where resistance to the action of water or chemicals enters as an important factor, Bull's metal, whether wrought or cast, becomes specially superior to steel.

Tensile Tests of Bull's Metals.

Dimensions.	Area. square inch.	Reduction area at fracture.	Extension.	Ultimate Stress.	Remarks.
Diam. Inch.		Per cent.	Per cent.	Tons per sq. in.

NICKEL.

Nickel Silver.

The alloys of copper, nickel and zinc containing from 45 per cent. to 65 per cent. of copper, 5 per cent. to 30 per cent. of nickel and 15 per cent. to 25 per cent. of zinc are of commercial importance and are classified under the general title of 'nickel silver.' The metals employed in the manufacture of these alloys must, if the same are to be used in the production of cold-worked articles, be of the highest degree of purity. For the manufacture of castings, metals of a lesser purity may be used.

Lead, tin, iron and unreduced oxides are the impurities generally present in nickel silver. Lead is occasionally added to nickel silver in quantities up to 3 per cent. when the same is to be employed for casting. Tin in quantities upwards of 2 per cent. has a hardening and embrittling effect on the alloy, while iron in similar quantity has a hardening effect only. The addition of any of these elements results in injury rather than benefit to the alloys and especially increases the corrodibility of the same.

The effect on the mechanical properties of nickel silver of almost constant copper content of increasing the nickel content has been admirably shown by Thompson (Institute of Metals, March 1916), from whose paper on 'The Annealing of Nickel Silver' the following table is taken :—

TENSILE TESTS ON CAST BARS.

Cu.	Zn.	Ni.	Mn. added.	Yield Pt. Tons per sq. in.	Maximum Stress. Tons per sq. in.	Elongation. Per cent. on 2 ins.	Reduction of area. Per cent.
60·6	31·7	7·6	—	7·16	16·88	34·5	37·2
60·2	31·8	7·8	0·25	6·60	15·28	46·5	46·9
61·8	21·7	16·4	—	9·00	17·80	39·5	32·7
61·2	23·2	15·5	0·25	8·12	18·36	39·0	45·9
61·6	15·9	22·4	—	8·52	17·20	24·5	26·7
61·6	18·5	19·8	0·25	8·24	19·36	32·5	33·5
55·7	26·7	17·4	—	9·04	17·12	33·5	37·8
54·3	29·7	15·8	0·25	8·92	16·88	38·5	40·0
56·2	27·6	16·3	1·50	9·04	17·96	44·0	41·1
61·2	9·8	28·6	—	8·76	19·72	32·0	36·7
60·4	11·4	27·9	0·25	10·32	23·68	29·0	29·7
60·9	13·2	26·7	1·50	10·88	24·16	35·0	33·1

Other results of his research show that the tendency of commercial nickel silver to 'burn' is increased (*a*) by increasing the nickel content, (*b*) as the ratio of the zinc to the copper is increased, and (*c*) with the amount of impurities present.

The following alloy is stated to be possessed of the best all-round properties :—

Copper, 46 per cent. ; Nickel, 39 per cent. ; Zinc, 20 per cent.

Platinoid.

Platinoid, introduced by Mr. F. W. Martin, is a kind of German-silver, with an addition of 1 to 2 per cent. of tungsten. The latter, in the form of phosphor-tungsten, is first melted together with a certain quantity of copper. In order to remove the phosphorus and a part of the tungsten, both of which separate dross, the resulting compound is several times remelted. Finally an alloy of a beautiful white colour is obtained, which when polished closely resembles silver, and retains its lustre for a long time. Platinoid has the properties of German-silver in a pre-eminent degree. It shows great electrical resistance, which remains almost constant at different temperatures, and is about 1½ greater than that of German-silver.

ALUMINIUM.

Aluminium Brass.

Aluminium acts as a deoxidiser and is added to cast and hot-forgeable brass, for the purpose of improving their mechanical properties, in quantities varying from 0·3 to 1·5 per cent.

Typical tests of cast aluminium brass, containing 38 per cent. of zinc, 2 per cent. of aluminium, and 2 per cent. of lead, are :—

Yield point	18 tons per sq. in.
Maximum stress	34 ,,
Elongation	12 per cent.

Melting Points of Commercial Brasses.

COPPER AND TIN.

Gun-metal.

The alloys of copper and tin containing upwards of 86 per cent. of copper are possessed of high tenacity and elasticity. Those containing from 89 to 91 per cent. of copper are the most important and are known as ' gun-metals.'

The addition of tin to these bronzes results in an increase in the hardness of the resulting alloy. Gun-metal is rarely manufactured from specially selected metals and frequently contains lead, zinc, etc. The Admiralty specification for gun-metal is as follows :

Copper	88 per cent.
Tin	10 ,,
Zinc	2 ,,

the specified tests for this material being

Maximum stress	14 tons per sq. in.
Elongation	7½ per cent.

Gun-metal containing 90 per cent. of copper and 10 per cent. of tin should give the following tests :—

Yield point	7 tons per sq. in.
Maximum stress	15 ,,
Elongation	15 per cent. on 2 ins.

Bell-metal.

The alloys of copper and tin containing from 75 to 86 per cent. of copper are used in the manufacture of bells ; iron, zinc and lead are frequently added to the alloys either for cheapness or variety of tone.

Effect of Certain Elements on Bronze.

ZINC.

Gun-metal, Bearing Metal, etc.

The alloys of copper, tin and zinc are rarely, if ever, free from elements such as lead, iron, etc. These alloys may be divided into two classes :—

(i) Alloys containing from 7 to 12 per cent. of tin, up to 6 per cent. of zinc, and up to 2·5 per cent. of lead. These alloys, among which may be noted gun-metal to the Admiralty specification, are used in the manufacture of castings, such as cocks, stuffing-boxes and pump barrels, and for bearings which are subject to but little friction.

(ii) Alloys containing from 12 to 20 per cent. of tin, up to 5 per cent., though rarely more than 2·5 per cent., of zinc and up to 5 per cent. of lead. These alloys are used in the manufacture of heavy bearings, e.g. railway wagon and locomotive axle boxes. The majority of alloys of this class contain from 14 to 16 per cent. of tin and from 1·5 to 2·5 per cent. of zinc.

Zinc combines with the oxides and free oxygen of the bronzes, producing greater fluidity in the molten state, and hence freedom from ' pinholes ' in the solid state.

LEAD.

Bearing Metal, etc.

The best bronzes should contain not more than 0·15 per cent. of lead, on account of its deleterious effect on the mechanical properties of these alloys generally.

Bearing metals having a bronze matrix and containing up to 40 per cent. of lead are in common use. A usual composition for bearings of this type is :—

Copper	64 per cent.
Lead	30 ,,
Tin	5 ,,
Nickel	1 ,,

The nickel is added to prevent the liquation of the lead. It increases the rate of cooling of the alloy and thus assists in the retention of the lead in the finely divided form.

Lead does not alloy with bronze, but separates out of the molten mass, as the same cools, in the form of globules. The lead bronzes may, therefore, be considered to consist of a network of bronze whose meshes enclose the lead content of the alloys in question.

PHOSPHORUS.

Phosphor Bronze.

Phosphorus acts as a deoxidiser and is added in small quantities for the purpose of deoxidation to copper. Not more than 0·15 per cent. is allowable.

The term 'phosphor bronze' is applied to the alloys grouped below.

(i) Bronzes to which phosphorus has been added as a deoxidiser and containing either no phosphorus or merely traces of the element.

(ii) Bronzes containing less than 9 per cent. of tin and up to 0·25 per cent. of phosphorus. These alloys are forgeable and are relatively non-corrodible. They are employed for rolling and drawing into wire and rod, and in the manufacture of general castings; in the latter case lead is occasionally added in quantities up to 5 per cent. The forgeable alloys of this group generally contain less than 5 per cent. of tin.

(iii) Bronzes containing from 8 to 14 per cent. of tin and from 0·25 per cent. to 1·00 per cent. of phosphorus. These alloys are employed for casting purposes in the manufacture of machine parts likely to be exposed to great friction. Lead up to 5 per cent. is added in certain cases.

Phosphorus is added to these alloys in the form of phosphor copper or phosphor tin.

The tensile strength of phosphor bronze varies from 14 to 18 tons per square inch, and the elongation from 6 to 10 per cent.

Delta Metal Alloys.

(The Delta Metal Co. Ltd.)

Delta Bronze No. V is an improved bearing metal of great strength and durability, and comparatively low price. It is particularly suitable for reducing friction at heavy pressures and high speeds, and is used for worm wheels for large cranes and other heavy machinery, hot neck rolls, locomotive slide valves, axle box, coupling, and connecting rod bushes, railway and carriage bearings, bushes, sliding surfaces, and other parts of machinery subject to heavy frictional wear. The metal is easy to tool, and requires no special precautions in casting.

Another metal used in lieu of phosphor bronze or gun-metal is 'Delta' Bronze No. VI, which produces fine, close-grained castings of great strength.

COPPER AND ALUMINIUM.

Aluminium Bronze.

The alloys known as the 'aluminium bronzes' are solid solutions of copper and aluminium containing not less than 88 per cent. of copper. Of these alloys that containing 10 per cent. of aluminium is the strongest, though the alloys containing less than this percentage are of industrial importance. These 'bronzes' are of use, firstly, on account of their valuable mechanical properties and, secondly, on account of their resistance to corrosion. They are malleable both when hot and when cold; the alloys containing between 8 and 12 per cent. of aluminium are affected in a marked degree by heat-treatment.

Following are tabulated the mechanical properties of some of these alloys :—

Percentage of Aluminium.	Yield Point. Tons sq. in.	Max. Stress. Tons sq. in.	Elongation. Per cent. on 4 in.	Remarks.
2·5	—	20·0	40·	Cast.
5·0		25·0	55·	Cast.
10·0	18·0	35·0	25·	Cast in chill.
10·0	18·0	46·0	25·	Cast rod reduced 25 per cent. by forging hot. Annealed.
10·0	15·0	40·0	30·	Rolled bar.
10·0	40·0	50·0	3·	Rolled bar quenched at 900° C.

The following are tests of the 'R3' and 'R4' aluminium bronzes, manufactured by the British Aluminium Company :—

R3 Bronze.—Average breaking load, 34·04 tons ; average elongation, 21 per cent. ; maximum breaking load, 37·6 tons ; maximum elongation, 35 per cent. ; minimum breaking load, 32·8 tons ; minimum elongation, 12·5 per cent.

R4 Bronze.—Average breaking load, 41·8 tons ; average elongation, 9·75 per cent. ; maximum breaking load, 43·7 tons ; maximum elongation, 13 per cent. ; minimum breaking load, 39·8 tons ; minimum elongation, 6·5 per cent.

COPPER AND MANGANESE.

Manganese Bronze, Manganin.

The term 'manganese bronze' is applied to copper-zinc alloys of 60/40 composition to which small quantities of manganese have been added (see Manganese Bronze, p. 2321). There are, however, alloys of copper and manganese of industrial application which rightly should be admitted under this heading. The alloys of copper and manganese containing up to 5 per cent. of the latter element are harder and tougher than is copper. Those containing from 2 to 4 per cent. of manganese are frequently employed in situations where high temperatures are existent, on account of their retention of their mechanical properties under these conditions.

The following figures represent the results obtainable by stamping certain of these alloys at a red-heat (*circa* 800° C.) :—

Copper.	Manganese.	Maximum Stress.	Elongation. Per cent.
97	3	18·5	32
96	4	21·0	60

Manganin is the name applied to an alloy of copper, manganese, nickel and iron, characterised by low electrical conductivity and almost zero temperature coefficient. It is employed in the construction of electrical resistance coils. The composition is somewhat variable, but the following figures will serve to indicate its approximate analysis :—

Copper . .	80 to 84 per cent.	Nickel . . .	up to 12 per cent.
Manganese . .	4 to 15 ,,	Iron . . .	Difference.

'Stella' Alloys.

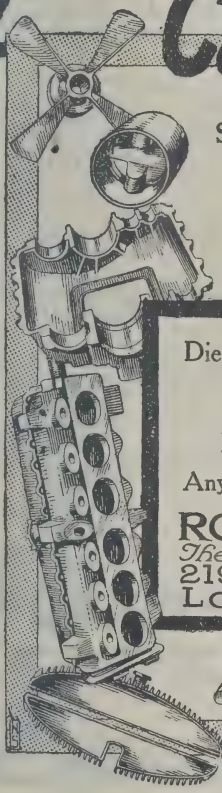
(*United Brassfounders and Engineers Ltd.*)

Under the name 'Stella,' manganese copper, ferro-zinc, manganese bronze, silicon copper, phosphor tin and copper and other special alloys are manufactured by the above Company.

'Stella' brand manganese copper is a product made by a special process which gives a thoroughly homogeneous mixture. In its preparation all impurities are removed and absolute uniformity and purity are guaranteed. The manipulation of manganese bronze castings is greatly facilitated if the manganese is introduced in the form of manganese copper, instead of ferro-manganese, owing to the fact that manganese copper melts at a lower temperature than copper, consequently overheating during alloying is impossible and uniformly good results are secured, whereas ferro-manganese will only melt at a temperature considerably above the melting point of cast iron, and in order to alloy same in the manufacture of manganese bronze a very high furnace temperature is necessary. Thus it invariably happens that the metal is considerably overheated, with the result that great harm is done to the manganese bronze, and little if any benefit is derived from the addition of the manganese.

Under the names 'Mammoth' and 'Stork' special bearing alloys are made by this firm. The 'Mammoth' alloy has great power of resistance under heavy loads, whilst 'Stork' metal is not only one of the cheapest of its kind for light work, such as bearings for line shafts, but has an exceptionally low friction coefficient. In one experiment 'Mammoth' metal withstood a maximum load of 4,355 lbs. with a temperature rise of 104° F., whilst 'Stella' metal withstood a load of 4,310 lbs. (rather less than that for the 'Mammoth'), but the temperature rise did not exceed 63° F. 'Stork' metal, although the load resistance did not exceed 3,025 lbs., had a temperature rise of but 59° F., the temperature rise experiments in all cases being made with equal loads. Each alloy has, therefore, special features.

COPPER AND NICKEL.



Cupro-nickel, Constantan, etc.

The alloys of copper and nickel containing upwards of 50 per cent. of copper are of industrial importance. The alloys may be divided into three classes.

(i) Alloys containing up to 5 per cent. of nickel and having the property of resisting high temperatures without undue deterioration. Of these alloys those containing from 2 to 3 per cent. of nickel have been employed in the manufacture of locomotive firebox tubes. Following are the mechanical properties of the 2 per cent. alloy :—

Maximum Stress.	Elongation. Per cent.	Remarks.
45·0	5·0	Hard rolled.
30·0	45·0	Hard rolled and annealed at 650° C.

Those of the 5 per cent. alloy are very similar in character.

(ii) Alloys containing from 15 to 25 per cent. of nickel and valuable on account of their ability to withstand cold working.

For the best results with these alloys only the purest metals should be employed, as small quantities of such elements as iron, silicon and sulphur are detrimental to the malleability and ductility of the resultant alloy. The maximum percentages of impurities allowable in nickel for this high-class work should be 0·050 per cent. of arsenic, 2 per cent. of cobalt, and 1·5 per cent. of other metallic impurities. The metal should be free from all unreduced oxides. Cupro-manganese, 25–50 per cent., is commonly employed as a deoxidiser in the manufacture of these nickel copper alloys, upwards of 0·25 per cent. being added to charges containing 30 per cent. of scrap. Following are the mechanical properties of the 20 per cent. alloy :—

Maximum Stress.	Elongation. Per cent.	Remarks.
40·0	5·0	Hard rolled.
20·0	35·0	Hard rolled and annealed.

The alloy containing 25 per cent. of nickel has been successfully employed in the manufacture of firebox plates.

(iii) Alloys having low electrical conductivities and whose temperature coefficients of electrical conductivity are practically nil. The 40–45 per cent. nickel alloy, known as 'constantan,' can be drawn into wire, and is employed in the construction of resistance coils and base-metal thermo-couples. Another alloy of this type, containing only 25 per cent. of nickel and 0·5 per cent. of iron, is known as 'nickeline.'

Nickel and Chromium.

Certain of the alloys of nickel and chromium now find use industrially. Of these alloys 'Nichrome,' under which trade name a number are sold, is of importance on account of its high electrical resistivity and incorrodibility. Nichrome is largely used in the manufacture of wire or electrical resistances and in the production of heat-treatment boxes, pyrometer protection tubes, crucibles, ladles, etc. Nichrome has also found use as a couple element in conjunction with Constantan (*see* above).

ALUMINIUM AND ZINC.

The alloys of aluminium and zinc are of importance as light alloys, their specific gravities varying uniformly from 2·7 to 3·3 as their zinc content increases up to 30 per cent., which may be considered the limiting percentage for those alloys of this series that may be termed 'light.' All those alloys containing upwards of 70 per cent. of aluminium are forgeable at temperatures between 300° C. and 400° C.

These alloys do not allow of their use in casting into intricate shapes, but for all plain casting purposes they are quite satisfactory. Under certain conditions these alloys corrode rapidly; the use of high-grade spelter in their manufacture eliminates this defect. The machining properties of these alloys improve as the zinc content increases.

Below are tabulated certain of the results of tests reported by Messrs. Rosenhain and Archbutt to the Alloys Research Committee of the Institution of Mechanical Engineers.

Zinc. Approx. Per cent.	Condition of Alloy.	Yield Point. Tons per sq. in.	Max. Stress. Tons per sq. in.	Elongation. Per cent. on 2 ins.
5	1	2·70	5·20	16·0
	2	2·80	6·60	29·0
	4	4·30	7·48	33·0
11	1	6·40	9·41	8·0
	2	5·00	10·24	16·0
	3	9·42	13·78	33·0 (on 1 in.)

1. Sand-casting.
2. Chill-casting.
3. Hot-rolled bars, ½ in. diam.
4. ditto 1¼ in. diam.

The addition of copper to certain of the aluminium-zinc alloys improves the mechanical properties of the same. The average results of certain tests on chill-castings of the aluminium-zinc-copper series are given below.

Zinc. Per cent.	Copper. Per cent.	Yield Point. Tons sq. in.	Max. Stress. Tons sq. in.	Elongation. Per cent.
19	1	9·5	14·9	5·5
19	2	12·5	16·5	5·7
20	2	10·4	14·0	3·3
20	3	11·5	16·8	4·5
20	4	10·4	15·3	3·8

OTHER ALLOYS OF ALUMINIUM.

Magnalium.

Magnalium is the name applied to a series of alloys having an aluminium-magnesium base, containing from 1·5 to 10·0 per cent. of magnesium and varying proportions of other elements, e.g. copper, tin, nickel, lead.

The table below gives the analyses of certain of these alloys, together with the uses to which they are generally put.

Use of Alloy.	Magnesium.	Copper.	Nickel.	Tin.	Lead.
Strong castings . .	1·60	1·76	1·16	nil	nil
General ditto . .	1·60	1·76	nil	traces	traces
Rolling and drawing .	1·58	0·21	nil	3·15	0·72

"Vickers' Duralumin."

"Vickers' Duralumin" is the trade name applied to a series of quaternary alloys of aluminium, copper, manganese and magnesium, containing over 90 per cent. of aluminium and possessed of high tenacity and hardness. The presence of magnesium confers the property of cumulative hardening on certain aluminium alloys—i.e. subsequent to suitable thermal treatment the hardness of the alloy increases slowly to a maximum, which is attained after several days.

Following are typical analyses of "Vickers' Duralumin":—

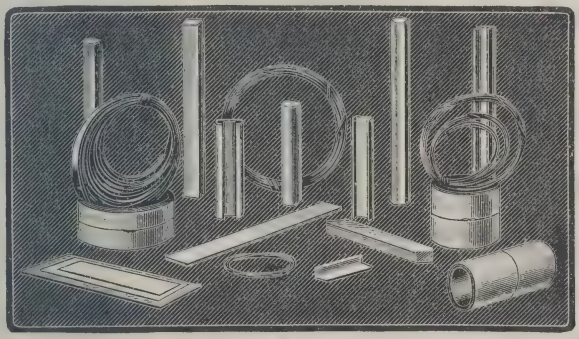
Copper.	Manganese.	Magnesium.	Silicon.	Iron.	Aluminium.
3·62	0·35	0·87	0·62	0.045	Diff.
3·00	1·00	2·00	—	1·000	Diff.
3·60	0·40	—	0·50	0·600	Diff.

The specific gravity varies between 2·77 and 2·84. The melting point is about 650° C. "Vickers' Duralumin" can be rolled, forged, and drawn when hot or cold. According to the purpose for which it may be required, the composition can be modified and the treatment so arranged that the material is susceptible to forging, rolling, and drawing, or it may be arranged that the greatest hardness, with corresponding smaller extension, can be produced. The following table gives a summary in which the properties of "Vickers' Duralumin" vary by such modifications in the composition and treatment.

Description of the Alloy.	Specific Gravity.	Yield Point. Tons per sq. in.	Max. Stress. Tons per sq. in.	Elongation. Per cent.	Contraction.	Brinell Hardness.
H	2·77	12·06	22·25	23	34	98
681d	2·84	16·5	29·20	18	26	125

These values are for soft rolled plates of 7 mm. thickness.

"Vickers' Duralumin" is supplied in sheets, bars, wires, strips, forgings, stampings, various sections and tubes.



"VICKERS' DURALUMIN"

(Regd. Trade Mark)

SPECIFIC GRAVITY 2·8.

TENSILE STRENGTH UP TO 35 TONS.

AN ALLOY OF ALUMINIUM WITH THE STRENGTH AND HARDNESS OF MILD STEEL BUT HAVING ONLY ONE THIRD OF ITS WEIGHT.

It is an ideal substitute for Aluminium, Nickel Silver, Brass, Copper, Nickel-plated and Silvered Articles, and is the only substitute for Steel where Lightness combined with the Strength of that Metal is required.

For Aeroplanes, Dirigibles, Hydroplanes, Motor Car, Yacht and Boat Fittings.

For Scientific Apparatus, Instruments of precision, Orthopædic Apparatus, and Hospital Supplies, etc.

Wolframinium.

Wolframinium is an alloy of tungsten, copper and aluminium. Its specific gravity (2·74) is about the same as pure aluminium; its tensile strength cast in sand 10 tons per square inch, in chills 12 to 13 tons per square inch, forged 15 tons per square inch, rolled or drawn 15 to 20 tons per square inch. Its elongation is 3 to 5 per cent. when hard, but 10 to 20 per cent. when properly annealed. It can be worked as easily as copper, can be forged, rolled, and drawn either hot or cold, takes a high polish and does not tarnish.

Romanium.

Romanium is an alloy of tungsten, nickel and aluminium. Its specific gravity (2·75) is a trifle higher than that of pure aluminium, its melting point about the same, its tensile strength equal to that of Wolframinium, but it is much harder and is also of greater elasticity. It can be worked either hot or cold, forged, rolled, drawn, stamped, etc. etc. It is specially recommended for large castings, large plates and angle bars for shipbuilding and machinery.

BEARING METALS.*

The requisite properties of good bearing metals are hardness, to resist wear; strength, to bear compression; and plasticity, to allow of ready adjustment of the supported body on the bearing.

Two types of bearing metal are known:—

(*a*) Bearing metals in which the hard constituents of the alloy are distributed indiscriminately throughout a soft matrix.

(*b*) Bearing metals of spongy character; the network of the sponge being moderately hard and tough, the meshwork being soft and plastic.

These types can be grouped according to composition as follows:—

(i) Brasses and bronzes containing compounds of copper with tin, phosphorus, etc.

(ii) Bronzes containing appreciable quantities of lead.

(iii) Alloys having a tin base and containing compounds of tin with antimony, copper, etc.

(iv) Alloys having a lead base and containing compounds of tin with antimony, etc.

(v) General alloys possessed of the characteristics required of a bearing metal.

Of the above, types (i) and (ii) have been considered under the heading of 'Brass' and 'Bronze' (*q.v.*), types (iii) and (iv) are known as 'white' metals, while the majority of the alloys of type (v) can be termed 'white metals.' Of types (iii), (iv) and (v) it has been observed that metals whose atomic weight divided by their specific gravity gives a high number are good anti-friction metals, while the reverse is the case for metals which have a low quotient. Hence the use of lead and antimony for bearing alloys. In using white metal for bearings the best practice is to use the bearings wholly of white metal, discarding the cast-iron shells and using up the old bearings with the addition of a small further quantity of the more volatile constituents. White metal must be melted in a clean vessel and at as low a temperature as possible. Dross and scum in the metal tends to rapid heating in service. For the metals to be properly alloyed the high as well as the low melting points of these must be reached, but care must be taken not to overheat the alloy. For a thorough alloying a temperature of about 500° C. (930° F.) and less has been found to be sufficient. The molten metal should be stirred with a stick of pine, and a layer of charcoal always kept on the surface to prevent oxidation. The rate of cooling affects the size of the crystals and also the wearing quality. As a general rule cooling too slowly and pouring too cold produces a coarse crystal formation which is liable to heat quickly in use. In the case of the tin-antimony alloys it has been found that the best size for the tin-antimony compound cubes is 0·25 mm. edge. Pouring too hot on the other hand results in a soft metal. The shell should be heated to a temperature of 100° C. to 150° C. (212° F. to 300° F.) before pouring the metal into it, as this not only prevents blow-holes, but reduces the tendency of the lining shrinking away from the shell. The bearing should not be disturbed while the lining is solidifying, since vibration tends to enlarge the crystals and produce brittleness. The matrix of the lining should be just stiff enough to support the crystals, and the latter should be as numerous as is consistent with these, lying clear of each other and thereby causing brittleness. A Brinell hardness of 23·5 for an alloy with a lead base and 30 for a tin base has been found to give excellent results.

* See also Bearing Pressures, page 897.

ALLOYS HAVING A TIN BASE.

Tin-Antimony Alloys.

These alloys, which are of type (*a*) above, are the basis of Britannia metal. The following table indicates the uses of certain of these alloys.

Tin.	Antimony.	Use of Alloy.
86	14	For seats of stop-cocks.
80	20	For plugs of stop-cocks.
79	21	Metal for bearings.
67	33	Very hard alloy, which forms the extreme limit of the ordinary tin-antimony alloys (*Hiorns*).

Babbitt, Genuine.

This alloy, whose composition is as follows,

Tin, 83·3 ; Antimony, 11·1 ; Copper, 5·6 ;

is used on important bearings under heavy loads, such as crank-shaft, crank-pin and cross-head pin journals. Closely similar alloys are employed for the axleboxes of the leading railways of the world. Several of the French railways, however, use the following alloy, which is lower in tin.

Tin, 67 ; Antimony, 22 to 11 ; Copper, 11 to 22.

Babbitt Metal, General.

In cast-iron boxes, for light work: 50 parts tin, 5 parts antimony, 1 part copper ; for heavy work : 46 parts tin, 8 parts antimony, 4 parts copper. In brass boxes: 64 parts copper, 8 parts tin, 1 part zinc. The bearing to be lined with the metal is first tinned with the Babbitt metal mixed with twice its weight of tin.

Babbitt Metal, Plastic Metal, and Phosphor Bronze.

(*The Delta Metal Co. Ltd.*)

These metals are supplied by the Delta Metal Co. Ltd., in various grades ; phosphor bronze is supplied in three qualities, A, B and C. The A quality is a hard bearing metal specially suitable for worm-wheels, bushes, crank pins, bearings, etc. ; B quality phosphor bronze is a bearing metal more suitable for general purposes, whilst the C grade is adapted for large pinions, worms, etc. The Co. also supply various grades of Babbit, plastic, and other lining metals, for various speeds and pressures.

Admiralty White Metal.

Tin, 86·0 ; Antimony, 8·5 ; Copper, 5·5.

ALLOYS HAVING A LEAD BASE.

Lead-Antimony Alloys.

These alloys should not contain more than 18 per cent. of antimony if they are not to be brittle. Such as do contain upwards of 18 per cent. of antimony must be given suitable support. The following table indicates the increase of Brinell hardness numbers of these alloys with increase of antimony.

Antimony. Per cent.	Brinell Hardness Number. 10 mm. 100 kilos.

N.O.—Not observed. C.—Cracks in compression test-piece.
S.C.—Slight cracks in compression test-piece. * Failed without compression to half length.

The results contained in this table are considered sufficient to merit the following conclusions: (1) that the effect of the presence of the tin-antimony compound in these alloys is such as to render the same brittle and weak; (2) that the general mechanical properties of the lead-tin-antimony alloys containing less than about 15 per cent. of tin are improved by the addition of antimony in quantities not exceeding about 10 per cent.

Hughes recommends the following alloy for metallic packings :—

Lead, 70; Antimony, 13; Tin, 17;

while the following alloys are used as lining by the Eastern Railroad of France :—

	Lead.	Antimony.	Tin.
1	70	20	10
2	80	8	12

1. For eccentric straps and bronze slide valves.
2. Special alloys for metallic rod packing.

Ternary alloys of lead, antimony and copper are also in use. These alloys should contain from 15 to 25 per cent. of antimony and not more than 10 per cent. of copper.

Anti-Friction Alloys.

(The Delta Metal Co. Ltd.)

Delta White Antifriction Metals, Nos. IX and IXa, are used for lining bearings, bushes, etc., and are particularly suitable for heavy bearings such as those of marine engines, for railway trucks, dynamos, etc., as they do not wear, heat, or cut the journals; they are also cheap.

The application of the metals presents no difficulties whatever; the parts required to be lined should be thoroughly cleaned, and when the metal is melted (which may be done in a ladle, over a slow fire, taking care not to overheat it) it is applied in the usual way. The melting point is about 450°C.

Richards' Plastic White Metal.

The chief qualities and advantages of this metal are durability, adhesiveness, self-tinning and antifrictional properties, minimum of contraction and linear expansion when passing from the plastic to the solid state.

This alloy can be applied to many kinds of metals, including gun-metal, steel, wrought and cast iron, also aluminium, by its own self-adhesiveness, and when properly applied no abrasive force will remove it, thus dispensing with the trouble and expense of recessing or pegging, an important matter when time for repairs is limited.

It can also be used for lining up worn parts of machinery in addition to bearings. It has a low coefficient of friction, thus saving very considerably on the cost of lubrication.

Even should lubrication be neglected for a period, the metal will not run out of the bearing, but being of a plastic character, when it becomes over-heated, will simply deposit from one place to another, and thus solidify itself when in contact with lower temperatures surrounding the body of the bearing. By this means it also prevents the possibility of cutting the crankshaft or other parts that may come in contact with it.

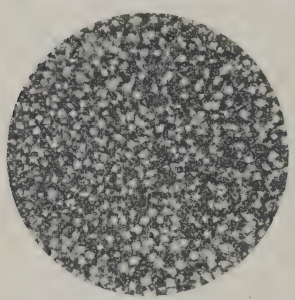

Fig. 42.—Micrograph of Richards' Plastic Metal (Magnified 50 Diameters).

The metal being self-tinning, no tinman's solder or tin is required to first coat the parts to be relined.

Its specific gravity being as much as 33 per cent. lighter than a lead basis alloy, less weight of metal is necessary for lining.

The metal itself has a particularly fine structure, which is attained by a special process of alloying. This structure is not affected by reheating, during its period of use, or when remelting, unless an exceedingly high temperature is attained. It can therefore be used over and over again.

This plastic metal has been extensively used for motor transport engines, aero engines, stationary engines, and pump work, for lining up bearing shells, and for die casting. It is particularly suitable for this last purpose. In order to produce solid die castings it is essential that the metal should be cast under pressure at a low temperature so as to preclude, by the retention of the metal as a solid rather than a fluid, the possibility of air holes and segregation of the alloy.

Richards' Plastic White Metal lends itself to these conditions. After prolonged trials it has been found that bearings made by this process are eminently suited to the onerous duties to which aircraft bearings are subjected.

The manufacturers of this alloy and bearings are Messrs. J. H. Richards & Co. Ltd., Cato Street North, Saltley, Birmingham.

Hoyt's Metals.

(*The Hoyt Metal Co. of Great Britain, Ltd., Deodar Road, Putney, S.W.* 15.)

Hoyt's Standard Babbitt or Anti-friction Metals are made in eight qualities, this range being sufficient to meet the conditions in every class of machinery. The two highest qualities are 'Number Eleven' Alloy and the I.C.E. ('Internal Combustion Engine') Brand.

'Number Eleven' Alloy was, during the war, largely used for the bearings of aircraft engines, nearly 800 tons being supplied in 1918 for this purpose alone. This metal is also stated to give excellent results in the bearings of automobile engines, marine petrol and oil engines, steam turbines, marine steam engines, Diesel engines, etc. Its specific gravity is 7·34, the weight per cubic inch being ·263 lbs. Approximately 100 lbs. of 'Number Eleven' Alloy will go as far as 113 lbs. of a high-grade metal of, say, 8·5 specific gravity.

'Number Eleven' Alloy is in use by the British Admiralty for certain important work. It is of higher quality than the Air Ministry's *Specification L.* 9 for Anti-friction Metal for Aviation Engines.

The I.C.E. ('Internal Combustion Engine') Brand has been used extensively for many years by British and Continental motor-car manufacturers. It was used during the war by the British Army Mechanical Transport, the I.C.E. Brand being adopted as standard after many tests. The metal is largely used for high-speed steam engines, locomotives, steam pumps, marine engines, air compressors, etc.

The Hoyt Metal Company supply their various metals also in the form of die-cast bearings which are true to ·001 in., having a good finish, and are ready to fit, machining being unnecessary.

The Hoyt Metal Company publish a set of notes on the subject of white metalling; these can be obtained on application.

Miscellaneous Metals for Bearings and Engine Parts.

The following special mixtures are stated to be satisfactory for the duty mentioned :—

ZINC-TIN ALLOYS.

Zinc and tin form a series of eutectiferous alloys, some of which are of value as bearing metals. The alloys, in common with all bearing metals, are very susceptible to differences in casting

temperature, as may be gathered from the following table, which gives in detail the effect of varying the temperature of casting an alloy of 70 per cent. of zinc and 30 per cent. of tin :—

Casting Temperature.	Maximum Stress.	Elongation. Per cent.	Stress to compress to half length.
525° C.	5·09	3·0	7·7
500° C.	6·17	3·0	13·6
475° C.	6·56	8·0	15·4
450° C.	7·37	17·5	14·8
425° C.	7·37	35·5	15·0
400° C.	7·24	20·0	15·8

The above figures are for chill castings.

The alloys of zinc and tin containing from 25 to 75 per cent. of zinc possess, when in the chill cast condition, tenacities varying from 6·0 to 6·5 tons per square inch, percentage elongations varying from 30 to 45, and are compressible to half-length under stresses (calculated on the original areas of the test-pieces) varying from 13 to 17 tons per square inch. The eutectic melts at about 200° C. and contains 16 atomic per cent. of zinc.

In order that these alloys may approximate more closely to type A (*q.v.*) bearing metal, the zinc-tin series containing no relatively hard constituent, copper and antimony are frequently added. The addition of one or both of these constituents results in the formation of a bearing metal in which the hard compounds of antimony and zinc, etc., are indiscriminately distributed throughout the eutectiferous matrix. The following are analyses of certain alloys of this type :—

Zinc.	Tin.	Copper.	Antimony.	Use of Alloy.
80	14·5	5·5	—	Fenton's alloy for locomotive axle-boxes.
69	26·0	5·0	—	Propeller bush.
88	2·0	8·0	2·0	Bearing metal for general use.

In this connection it may be noted that ternary alloys generally are far preferable to complicated mixtures and usually fulfil all the requirements of good bearing metals.

A French report on new anti-friction metals includes trials of alloys consisting chiefly of aluminium, cadmium, magnesium, and especially of zinc. Such alloys were designed to reduce as far as possible the use of copper, tin, lead, and antimony, and the most satisfactory results are stated to have been given by a compound of 63·3 per cent. of zinc, 21·3 per cent. of tin, 12 per cent. of lead, and 3·3 per cent. of copper.

FUSIBLE METALS.

With the following combinations of metals, which form ' eutectiferous ' alloys, it is possible to prepare an alloy having a melting point lower than that of any member of the series.

Series.	Alloy with Lowest Melting Point (Eutectic).	Melting Point.
Bismuth-lead	57·4 per cent. Bismuth	124·5° C.
Bismuth-tin	56·7 „ „	137° C.
Bismuth-cadmium	60 „ „	146° C.
Cadmium-tin	52 „ Cadmium	177° C.
Lead-tin	36·5 „ Lead	180° C.
Cadmium-lead	17·4 „ Cadmium	247·3° C.

By the addition of one or both of the residual metals to any of the above combinations, systems of ternary and quaternary alloys, having individual members with melting points lower than those of all other members of these systems and less than those of the eutectics given above, may be obtained. These ternary and quaternary alloys are the true 'fusible metals.'

The alloys of lead, tin and bismuth are of value for the following purposes :—

(i) The manufacture of casts of delicate objects that would be damaged if subjected to high temperatures. The following alloys are recommended for this purpose :—

Bismuth	59·2	50·0	50·0	50·0
Lead	27·3	31·2	30·0	25·0
Tin	13·5	18·8	20·0	25·0

These alloys expand considerably on cooling and are valuable also for the taking of impressions from dies, medals, etc.

(ii) Fusion pyrometers. Parkes and Martin recommend the following fusible metals as pyrometers for the tempering of steel tools. The article to be treated is placed on a plate of the alloy, which is heated till it melts. The tool, being then in the required condition, is quenched in water.

TABLE OF MELTING POINT OF BISMUTH-LEAD-TIN ALLOYS.

Bismuth.	Lead.	Tin.	Melting Pt.	Bismuth.	Lead.	Tin.	Melting Pt.
50·0	31·2	18·8	94° C.	16·6	33·2	50·2	158° C.
47·0	35·5	17·7	98° C.	16·0	36·0	48·0	155° C.
42·1	42·1	15·8	108° C.	15·3	38·8	45·9	154° C.
40·0	40·0	20·0	113° C.	14·8	40·2	45·0	153° C.
36·5	36·5	27·0	117° C.	14·0	43·0	43·0	154° C.
33·3	33·3	33·3	123° C.	13·7	44·8	41·5	160° C.
30·8	38·4	30·8	130° C.	13·3	46·6	40·1	165° C.
28·5	43·0	28·5	132° C.	12·8	49·0	38·2	172° C.
25·0	50·0	25·0	149° C.	12·5	50·0	37·5	178° C.
23·5	47·0	29·5	151° C.	11·7	46·8	41·5	167° C.
22·2	44·4	33·4	143° C.	11·4	45·6	43·0	165° C.
21·0	42·0	57·0	143° C.	11·2	44·4	44·4	160° C.
20·0	40·0	40·0	145° C.	10·8	43·2	46·0	159° C.
19·0	38·0	43·0	148° C.	10·5	42·0	47·5	160° C.
18·1	36·2	45·7	151° C.	10·2	41·0	49·5	161° C.
17·3	34·6	48·1	155° C.	10·0	40·0	50·0	162° C.

(iii) Soft solders. For the union of metal to glass, e.g. in the manufacture of paraffin lamps, the following alloy has been suggested :—

Lead, 40·0 ; Bismuth, 33·4 ; Tin, 26·6.

(iv) Fusible plugs.

The above alloys are nearly all of a brittle character. For the manufacture of ductile fusible alloys the use of cadmium in place of bismuth is recommended.

The following table includes the best known of the other fusible metals :—

Alloy.	Cadmium.	Lead.	Tin.	Bismuth.	Melting Pt.
Fusible alloy . .	12·5	25·0	12·5	50·0	55·5° C.

Spence's Metal.

This compound is obtained by melting the three sulphides of iron, zinc and lead with sulphur. The product is a dark grey mass of great tenacity, small power of conducting heat, a specific gravity of 3·4, a melting point of 160° C. In congealing it expands like bismuth and type metal, and resists in a remarkable degree the action of atmospheric influences, alkalies and acids, even of aquaregia, its surface scarcely being affected after having been exposed to the action of the latter for four weeks. Its property of expanding in congealing, and therefore filling completely all depressions of the mould, makes it particularly available for castings. If the compound is poured on a plate on which the impression of the hand has been made, the cast will show all the lines and the pores of the palm.

It has been used for jointing gas and water pipes.

For further particulars see Patent Specification No. 2706, 1879.

Non-Magnetic Alloys.

These alloys are used as substitutes for steel wherever it is employed in the works of watches. The composition of the alloys varies from 45 to 75 parts of palladium, 15 to 30 parts of copper, 20 to 25 parts of silver, with sometimes the addition of small proportions of iron, steel, nickel, gold and platinum. These alloys are claimed to be unoxidisable in moist air, to preserve their elasticity indefinitely, not to vary sensibly with changes of temperature, and to remain uninfluenced by proximity to dynamos.

Another non-magnetic alloy, recently brought out by Messrs. Ostermann & Lacroix, of Geneva, Switzerland, is made of from 30 to 40 parts of gold, 30 to 40 parts of palladium, 0·1 to 5 parts of

rhodium, 10 to 20 parts of copper, 0·1 to 5 parts of manganese, and the same proportions of silver and platinum. The copper and manganese are first mixed, after which the other articles are added; or all the metals may be put into a crucible at the same time, the manganese being used for the bottom layer.

A non-magnetic variety of 'Bull's Metal' is manufactured and sold as No. III. and is being adopted for funnels and other erections of warships where the material must possess the mechanical properties of steel without its magnetic influence.

The Delta Metal Co. Ltd., supply under their "Delta" Brand non-magnetic metals (bronze and brass) to meet special requirements.

SOLDERS AND SOLDERING.

The following notes are published with the kind permission of the Editor of 'The Metal Industry.' (See 'The Metal Industry,' vol. 9, No. 4.)

Points to be Observed for Successful Soldering.

Attention should be paid to the following points if success is to be attained in soldering or brazing :—

1. In the preparation of the solder, uniformity of composition should be aimed at. Readily volatile or oxidisable constituents should be retained.

2. In the choice of the solder, consideration should be taken of the fusibility of the solder. The melting point of the solder should be less than that of the metal to be soldered. It should be noted, however, that the more nearly the melting point of the solder approaches that of the metal to be soldered the better is the union obtained, although the more difficult is the operation of soldering. It should be considered whether the solder will mingle perfectly with the surfaces to be united. One having mechanical and physical properties as nearly as possible approximating to those of the metals to be united should be used. One whose mechanical and physical properties will not be subsequently modified by any treatment—thermal or otherwise—should be employed.

3. In the operation of soldering, thorough mechanical and chemical cleanliness of the surfaces to be united must be obtained, e.g. by scraping, filing, grinding, etc., and by dipping in suitable chemical reagents. A source of heat both smokeless and sufficiently hot to raise the temperature of the sections to be united above the melting point of the solder is necessary. A suitable flux must be used.

Fluxes.

Fluxes are used to protect the surfaces of the metal to be united from the oxidising action of the atmosphere during the process of heating. The presence of any non-metallic materials, such as oxides or carbonates, on the surfaces to be joined, effectually prohibits perfect union. As the process of heating a metal in the air always leads to the formation of a film of oxide on its surface means must be employed to protect the surface. Use is made of readily fusible salts and of oils that are non-volatile at the temperature of soldering for this purpose. For hard-soldering borax is practically the only flux employed. It is applied as a paste with a brush to the surfaces of small articles, and as a powder to those of larger articles. For soft-soldering a variety of materials is used, the following list giving the most important of these, together with their uses.

(i) Zinc chloride is used for the soldering of sheet metal, copper alloys and bright iron. It is poisonous and corrosive, and is on these accounts unsuited (*a*) for the soldering of tins destined to contain food, and (*b*) for the production of delicate work, e.g. electric fuses.

Zinc Chloride Solution.

Kill 2 quarts hydrochloric acid with all the zinc it will take up. Add a quart of water or add part until zinc is fairly dissolved. A quart of glycerine which has been mixed with a quart of alcohol is then added to the solution.

This fluid is used for all kinds of soldering, especially with greasy and dirty connections and iron. It is claimed that glycerine prevents rust, which plays havoc with other soldering solutions containing hydrochloric acid. (*Street Railway Journal.*)

Zinc Chloride Paste.

1 lb. vaseline or petrolatum ; 1 oz. (fluid) saturated solution of chloride of zinc.

The use of petrolatum instead of vaseline is recommended. While they are identical in composition, the name 'vaseline' is registered as a trade-mark, and commands a higher price on this account. Petrolatum is much cheaper. The chloride of zinc solution is made by dissolving as much zinc in strong muriatic acid as it will take up. An excess of zinc should be present, and all the acid neutralised. This will form a thick, oily solution. The petrolatum and chloride of zinc are mixed and thoroughly incorporated by means of a mortar and pestle or by vigorous stirring. The advantage of this soldering paste lies in the fact that it does not spatter and is not corrosive.

(ii) Ammonium chloride is used as a flux when soldering copper and iron.

(iii) Ammonium phosphate is used when treating with tin, zinc, copper and brass ware. It is non-corrosive and non-poisonous, but is somewhat refractory.

(iv) Hydrochloric acid is employed when dealing with zinc and zinc-coated ware.

(v) Lactic acid is useful in connection with copper and its alloys, but has the disadvantage of producing a tarnish on the surfaces adjacent to the soldered surfaces.

(vi) Venice turpentine and Gallipoli oil are used (separately) when soldering pewter or Britannia metal.

(vii) Russian tallow is employed when soldering heavy lead work.

(viii) Palm oil is employed in the treatment of light lead work.

(ix) Resin is an advantageous flux when subsequent corrosion is likely to be deleterious. It is used on soft alloys and tinware.

Hard Solders.

The hard solders may be divided into two groups, each of which will be considered separately in succeeding paragraphs—brazing or 'spelter' solders and silver solders.

Brazing or 'Spelter' Solders.

The basis of the brazing or 'spelter' solders ('spelters' they are commonly called) is brass. As the percentage of zinc is increased in the brasses so does their utility as solders for the more readily fusible metals and alloys increase. There is, however, a limit beyond which the addition of zinc to these alloys serves no useful purpose, owing to the fact that the resulting alloys are, on account of their brittleness and weakness, of no practical value. This limiting value is at about 45 per cent. of zinc. The particular alloy which is in most general use contains 50 per cent. of zinc and melts at about 875° C. (1607° F.). It is employed in brazing general brass work, which is possessed of melting points varying from about 890° C. (1634° F.) to about 1000° C. (1832° F.). For brazing metals, etc., having higher melting points than the above, brasses containing a less percentage of zinc are used. Thus, for the soldering of general iron-work the brass containing 35 per cent. of zinc is used, while for the brazing of copper and light ironwork that having 40 per cent. of zinc is employed. The most malleable solder contains some 30 per cent. of zinc, but its refractory nature somewhat subtracts from its value.

For certain purposes, the above alloys, owing to their yellow colour, are prohibited. Occasionally—e.g. in the brazing of nickel silver and iron—whiter alloys are required. For this purpose alloys containing nickel are employed, of which the following are examples :—

Copper per cent.	Zinc per cent.	Nickel per cent.
37·50	50·00	12·50
35·00	57·00	8·00

Other white solders, for use in the brazing of brass and more fusible than 'spelters,' contain a percentage of tin. Two such solders are given below :—

Copper per cent.	Zinc per cent.	Tin per cent.
43·34	6·66	50·00
57·50	25·00	17·50

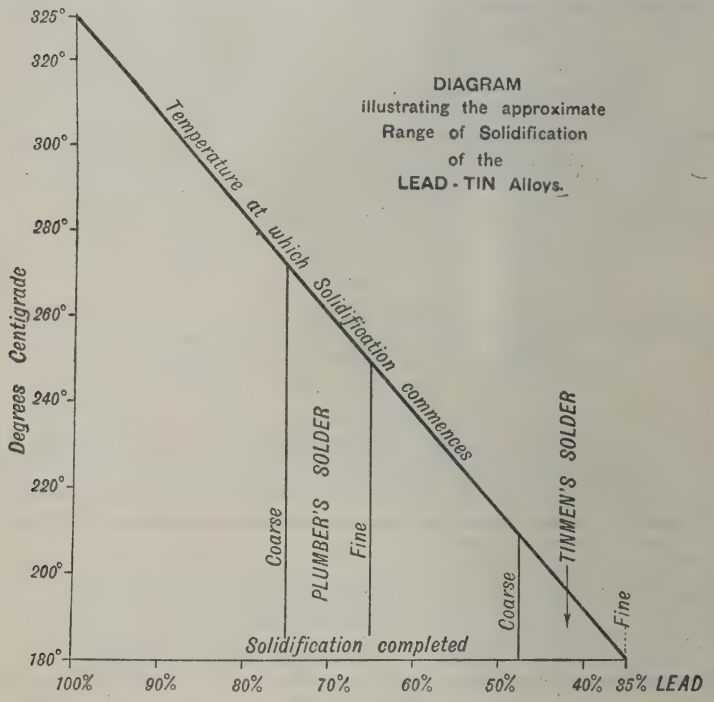
Silver Solders.

Silver solders are employed for soldering gold, silver, copper, iron, and their alloys, the flux generally used being borax, though with very hard solders—i.e. solders having high melting points—powdered glass is sometimes of value.

Such as are suitable for general soldering and brazing, and containing an excess of base metal, are tabulated below :—

Copper per cent.	Silver per cent.	Zinc per cent.	Uses.
90—95	10—5	—	Solder for thin sheets of mild steel.
55·0	45·0	—	Alloy for instrument-makers; tough and fluid
50·0	30·0	20·0	Solder for small brass work.
46·0	38·5	15·5	Solder for bronze and nickel silver.
43·0	9·0	48·0	Solder for general work on copper alloys.

Tin-Lead Solders.



Tin and lead form a series of alloys, of which only those containing upwards of 35 per cent. of lead are employed as solders. These alloys may be divided into two classes, those that solidify at practically one definite temperature and those which are pasty over a considerable range of temperature before they become completely solid. The former are used as tinmen's solders, the latter as plumbers' solders, their value to each of these craftsmen being dependent on the properties associated with their solidification already mentioned. The diagram on page 2342 indicates the ranges of composition of the two types of solder already mentioned.

It will be seen that fine tinmen's solder solidifies at a definite temperature of 180° C. (356° F.), while coarse tinmen's solder commences to solidify at about 209° C. (408° F.), passes through a pasty stage, and finally completely solidifies at 180° C. (356° F.). Soft solder is the name given to the alloy containing 50 per cent. of lead, whilst the fine plumbers' solder, used in making 'wiped' joints, which commences to solidify at about 250° C. (482° F.), contains 66·6 per cent. of lead. A solder frequently used for the union of tinplate contains about 90·0 per cent. of lead, and hence has a very marked pasty range of temperature.

The appearance of the tin-lead solders affords some idea as to their value. The surface of good solder should be smooth and even and rectangular castings of the same should have a distinct furrow along the centre of their upper surface. The presence of zinc, though only traces of this metal be present, causes the free surface of the solder to become minutely crystalline. Bismuth, copper and silver do not affect the surface condition of solders when present in

quantities varying from 0·2 per cent. in the case of the last metal to 1·0 per cent in the case of the first, while antimony up to 2·0 per cent. improves, rather than otherwise, the surface condition. The presence of any of these elements leads to a reduction of the melting point of the solder.

To prevent hot solder sticking to work mix common whiting or cold-water paint with wood alcohol, and paint the part that is to be protected. The hot solder will not stick, even if the piece is held in the melted alloy. Water will do as well as alcohol to mix the paint; but alcohol

is the most convenient, inasmuch as it can be used without waiting for the paint to dry. If water is used the paint must be thoroughly dry, as otherwise the moisture will cause the solder to fly.

Bismuth Solders.

These solders are alloys of bismuth, tin and lead, and are in general more fusible than the tin-lead solders. The useful alloys contain from 20 per cent. to 65 per cent. of lead, from 12 per cent. to 55 per cent. of tin, and from 12 per cent to 55 per cent. of bismuth. The alloys containing the higher percentages of bismuth are the most fusible of these solders, which are employed for general pewtering. The solder containing about 50 per cent. of bismuth and 20 per cent. of tin has the lowest melting point of the series, its value being 96° C. (205° F.).

Aluminium Soldering.

The only process that can be recommended for the uniting of aluminium when the union is to be possessed of strength and durability is welding (see p. 2298). In certain instances the soldering of aluminium to itself or to other metals may, however, be resorted to. The process of soldering is considerably cheaper than is that of welding, and this, of itself, is worthy of consideration. The soldering of aluminium, however, presents numerous disadvantages owing (i) to the ready oxidation of aluminium and the difficulty of removing the oxide formed when

the metal is heated, and (ii) to the rapid disintegration under the influence of moisture of soldered joints owing to the electropositive nature of aluminium with respect to those metals that may be usefully employed in the manufacture of solders.

The aluminium solders may be divided into four main groups.

1. Alloys having an aluminium-zinc base and containing varying proportions of copper. These alloys contain from 50 per cent. to 95 per cent. of zinc and from 5 per cent. to 30 per cent. of copper.

2. Alloys having a zinc-tin base and containing small proportions of such elements as aluminium (up to 12·5 per cent.), copper (up to 2·5 per cent.), phosphorus (in traces), etc. These alloys contain from 30 per cent. to 80 per cent. of tin.

3. Alloys of cadmium and zinc or possessed of a cadmium-zinc base. The cadmium content in these alloys rarely, if ever, exceeds 30 per cent.

4. Alloys that are members of none of the above well defined groups of alloys.

Of group 1 solders, those aluminium-zinc alloys, containing from 3 per cent. to 30 per cent. of aluminium have been largely employed for general soldering. For light aluminium work, where somewhat stronger solders are required, an alloy consisting of 80 per cent. of zinc, 12 per cent. of aluminium and 8 per cent. of copper has been found to be of value, while for heavier aluminium work a solder containing 90 per cent. of zinc, 6 per cent. of aluminium and 4 per cent. of copper is useful.

Of group 2 solders, the most satisfactory alloy (according to the *Iron Age*) consists of 69 per cent. tin, 2·5 per cent. of 10 per cent. phosphor tin, 26 per cent. of zinc and 2·5 per cent. of aluminium. To avoid loss of the more easily volatile of these metals, the aluminium is melted first, zinc is then added in small pieces, then tin in small pieces, and lastly the phosphor tin. No acid is used, the solder being self-fluxing, but the surfaces to be soldered or joined are covered with a thin coat of solder in the usual way, and then brought together, heated with a soldering copper (iron), blow-pipe, or torch, until the solder already upon them is melted, when pressure is applied and the joint is made. The aluminium must be heated to about 660° F. before it can be soldered.

Of group 3, solders it can be stated that most satisfactory results have been obtained with the alloys of cadmium and zinc containing from 20 per cent. to 30 per cent. of cadmium, both as regards strength and durability.

In preparing aluminium for soldering, the parts to be united must first be scraped or filed, in order that the thin skin of oxide always present on aluminium that has been exposed to the atmosphere may be completely removed.

It is scarcely necessary to state that all oil, grease, or organic matter must be completely removed from the parts to be soldered. In practically all cases solders for aluminium are best applied without a flux. Generally speaking, the process of soldering aluminium is identical with that of ordinary soft soldering. It is well, however, in the case of aluminium soldering, to heat the parts to be united until the solder will just melt upon the surfaces to be joined and then to rub the solder into the metal with a wire brush or rod, in order that intimate contact may be made between the solder and the metal to be soldered. The strength of the joint depends to a large extent on the thoroughness with which this preliminary treatment is conducted. Soldering is then continued in the usual manner.

Cold Solder (Amalgam Solder).

By shaking finely-divided copper with mercury in a little dilute sulphuric acid an amalgam can be prepared which may be used to unite joints at ordinary temperatures. The amalgam is formed into pellets, which are heated till mercury begins to exude from the surface. These pellets are wiped free from mercury and are then rubbed to a soft paste in a mortar. The surfaces to be united are first treated with sodium amalgam (sodium 2 per cent.), the soft paste of copper amalgam being then applied. The surfaces to be joined are then tightly pressed together, the union being completed in about three hours.

Soldering Aluminium Bronze.

To solder aluminium bronze with ordinary soft (pewter) solder : Cleanse well the parts to be joined from dirt and grease. Then place the parts to be soldered in a strong solution of sulphate of copper, and place in the bath a rod of soft iron, touching the parts to be joined. After a while a copper-like surface will be seen on the metal. Remove from bath, rinse quite clean and brighten the surfaces. These surfaces can then be tinned by using a fluid consisting of zinc dissolved in hydrochloric acid in the ordinary way with common soft solder. If the surface is not coppered an aluminium alloy must be used.

Soldering Cast Iron.

(1.)

If the part of iron to be soldered is cast iron that is hard and thin, it should be polished on an emery wheel and made clean and bright. Then dip it in potash water, after which dip it for an instant in clean water, and wash quickly with undiluted hydrochloric acid of the ordinary strength ; go over it with powdered resin and solder made from half tin and half lead. This must be done quickly, before the surface has time to dry.

(2)

File the surface clean, and wash as before: wipe it over with a flux made of sheet zinc dissolved in hydrochloric acid until it is supercharged, or is a saturated solution and has been diluted with its own quantity of water; then sprinkle powdered sal ammoniac on it, and heat it on a charcoal fire until the sal ammoniac smokes. Dip it in melted tin, and then remove, and rap off the surplus tin.

To solder Metal to Glass.

Coat metal with platinum, and fuse latter to glass. Paint glass, after warming with neutralised solution of chloride of platinum mixed with essential oil of camomile. Heat gently till oil is expelled, and then raise temperature to dark red heat; the chloride becomes reduced, and platinum is deposited on the glass. The platinum or layer of copper is deposited by electro-deposition. To this layer metals can be soldered.

CASTING AND FOUNDING.

Moulding-sand.

(1.)

1 cubic foot sharply burnt and pulverised pure fire-clay; 60 cubic inches sugar; 2 quarts water ½ quart paraffin oil. No lime or charcoal must be included in the mixture. Thoroughly mix. Suitable for castings of ingot iron.

(2.)

93 parts pure quartz sand; 7 parts clay free from lime; the latter acts as a cement for the former.

(3.)

For small castings:—Red sand 3 parts by measure; coal dust (finely sifted), 1 part by measure.

(4.)

For large castings:—Red sand, 3 parts by measure; coal dust (finely sifted), 1 part by measure; chopped straw, or dried horse manure, ½ part by measure.

The latter makes the sand light and porous, facilitating the release of the gases. As the sand becomes impoverished by being burnt, the coal dust is renewed from time to time. If paraffin is used to damp the mould, black sand will bind and can then be dried as when red sand is used.

Moulding-sand which has partially lost its cementing power may have it restored by mixing with fresh sand.

Green, or floor sand that has 'gone dead' (dehydrated) is frequently revived with Birmingham or Mansfield sand. Bunter sand, and also Barrow sand, have been found very good for the same purpose.

When the metal touches the clay bond the clay is undoubtedly killed, but not so the ferruginous bond, and long-life sand is generally rich in the latter.

Ferruginous bond in moulding sand is usually the cause of the production of a smooth, sound surface to the casting, particularly in the case of steel. In non-ferrous practice it is usual to ensure the smoothness of the skin by painting the surface of the mould or 'facing' it with a layer of finer sand (facing sand) or a wash.

The washes used for painting the moulds in non-ferrous work have usually either china clay or a graphitic substance as base. Graphite (plumbago) is itself used at other times. 'Scotch blacking,' which is a mixture of charcoal and graphite, is employed.

A suspension of the powder in water may be assisted by the addition of a little borax or molasses.

Cores.

For the making of 'cores' in British foundries a 'compo' moulding sand is made from ordinary sand such as Mansfield and broken fragments of graphite crucibles ground and mixed.

The admixture of the coarser material ensures good venting of cores; at times the sand alone is used.

Oil-bonded cores (where the oil is generally a commercial linseed, such as 'Baltic seed oil'), unlike those used in steel founding, have not met with much success in non-ferrous founding at home, but are adopted extensively in America, where a fairly coarse high-silica sand is the base. Sands from Lumberton and Howell, N.J., are so used. (*Horobin.*)

To repair Castings by Burning on.

A piece of machine-framing, the necks of rolls, or a standard which has been broken or found defective, may be repaired as follows: First cut away the defective parts down to the sound metal; build a coke fire round the part of the casting which is to be repaired until it is brought to a bright red-heat, then dust over the surface of the cut metal with powdered glass or borax. Then apply a hollow loam mould of the desired part to the casting, properly secured in position and provided with a hole for the exit of the metal. Pour very hot liquid cast iron into the mould, and allow it to flow away until the cut surface of the original metal of the casting can be felt with an iron bar to have become soft and pasty by contact with the hot liquid iron. Then stop the exit hole and allow the metal in the mould to set. If the operation has been properly performed the casting should, when struck, ring with the same sound as a single good casting, thus showing that the old and new metal are perfectly united.

Pattern Composition.

A composition that has many advantages over wood for making small patterns can be made as follows:—With hot water mix into a thick paste three parts by volume of starch, one part ground glue, two parts fine resinous sawdust. The sawdust should not be added until the starch and glue have been dissolved by the water. After the ingredients are thoroughly mixed, heat the whole to 190°F., and continue the heating until the whole becomes a hard mass, then allow to cool, and remove from the receptacle. The resulting composition is a strong, hard, horn-like substance, that can be machined, sand-papered and varnished just as can wood. The principal advantages of this composition over wood lie in the fact that it has no grain, and therefore turned and complicated patterns made from it do not have to be built up or glued together, and that for the same reason it is easier to turn and machine, and offers a smoother surface when finished. It is also more fireproof than wood and not so readily affected by atmospheric changes.

(*American Machinist.*)

Shrinkage of Castings.

The allowance for shrinking in casting should be for each foot in length:—

	Parts of an Inch.		Parts of an Inch.
For cast-iron pipes	·125 = $\frac{1}{8}$	Brass	·17 = $\frac{3}{16}$
„ beams and girders	·1 = $\frac{1}{10}$	Lead	·31 = $\frac{5}{16}$
„ cylinders, large	·094 = $\frac{3}{32}$	Zinc	·25 = $\frac{1}{4}$
„ „ small	·06 = $\frac{1}{16}$	Copper	·17 = $\frac{3}{16}$
In thick breadth	·156 = $\frac{5}{32}$	Tin	·25 = $\frac{1}{4}$
In thin breadth	·156 = $\frac{5}{32}$	Bismuth	·156 = $\frac{5}{32}$

Pickle for Castings.

A large proportion of the loose sand on castings may be removed in the 'tumbling' process, but the adhering sand and scale of oxide, which soon destroy the cutting edge of the tools, are best reduced by a pickle. Several compositions are used for this purpose, and the following have met with general approval.

(See also 'Lubrication Troubles,' p 912.)

Sulphuric Acid Pickle.—Ordinary commercial sulphuric acid and water in the proportion of 1 of the former to 30 of the latter. In this case the castings are required to remain in the pickle for about 10 hours, and are then washed with hot water to remove all trace of the acid and prevent rusting.

Hydrofluoric Acid Pickle.—This acid is slower in its action and not so liable to cause corrosion as the above. The castings, however, should be first tumbled in order to remove loose sand (as the sand neutralises the solution very much more quickly than the iron) and then immersed in a mixture containing 1 of hydrofluoric acid to 15 of water. The bath should be maintained at a temperature of 120°F. by a steam coil. The castings are then washed in clean hot water and sometimes in hot water with a small proportion of lime (about 1 lb. of lime to 8 gallons of water).

The baths are best made of oak, wood pinned, with no exposed metal fastenings and well lined with asphaltum. The attendant should be furnished with wooden clogs, strong leather apron and rubber gloves to protect him from the acid.

The acid should be added *very slowly* to the *water* and well stirred in the process. Never add the water to the acid, otherwise the acid vapour will be carried all over the place.

Dips for Castings.

Special for Electro-galvanising.—For preparing work for electro-galvanising the following can be used with advantage, but for no other solution except, perhaps, copper: Add to the dilute acid ½ lb. of sheet zinc to each 25 gals. of solution, adding additional amount occasionally as it works out.

Bright Dip for Iron.—Work that has been pickled in the ordinary way to remove sand and scale, and then dried, usually has a dull-black appearance. If the work is to be polished, the black will be removed and the colour restored in the polishing process; but if it is to be plated, or if it is to be left with parts of iron showing, the work should be run through the bright dip. This will bring it out white, improving the appearance and tending to make it take on a white deposit if it is to be nickelled. This dip is composed of:—

Hydrofluoric acid, 24 oz. Nitric acid, 10 oz. Metallic zinc, 2 oz. Water, 2 gals.

Work that is to be dipped should be strung on copper wire, and swirled around in the solution for a few seconds, rinsed in cold and then very hot water, and dried in sawdust. Articles should not be allowed to stay in the dip any time, as they would be spoiled and the solution ruined.

Satin-finish Dips.—Brass work requiring a satin finish may be dipped for a few seconds into a mixture consisting of:—

(1) Hydrofluoric acid, 1 part; Water, 3 parts;

then dried and run through the bright dip (4) to give it a lustre. If not satined enough the operation may be repeated.

(2) Hydrofluoric acid, 2 parts; Nitric acid, 1 part; Muriatic acid, ½ part; Water, 5 parts. After which the work may be rinsed, dried, and run through the bright dip (4) if necessary.

(3) Hydrofluoric acid, 2 parts; Nitric acid, 1 part; Water, 10 parts.

The following is a *bright dip* for copper, brass, bronze, or German silver :—

(4) Hydrofluoric acid, 4 quarts; Nitric acid, 3 quarts; Common salt, small handful.

Mechanical Treatment of Metals and Alloys.

Method of Treatment.	Details of Method to be avoided.	Consequences of Details of Method of Work.
Hot working . .	1. Excess 'reduction' or rate of 'reduction.'	Cracking of metal.
	2. Deficient 'reduction' or rate of 'reduction.'	Coarse, weak metal.
	3. Excess temperature at commencement.	Weak, brittle metal and formation of fissures therein.
	4. Deficient temperature at conclusion.	Internal strain and consequent hardening. Possible 'season cracking.'
	5. Retention of scale on metal during operations.	Rough and pitted surface and possible cracking.
Cold working . .	1. Excess 'reduction' or rate of 'reduction,' without annealing.	Surface cracking and hollow drawing. Strain-hardening.
	2. Deficient 'reduction' or rate of 'reduction.'	Insufficient hardening — where hardening is expected.
	3. Unequal 'reduction' . . .	'Season cracking' or cracking during annealing.

Heat Treatment of Metals.

Method of Treatment.	Details of Method to be avoided.	Consequences of Details of Method of Work.
Annealing . .	1. At too high a temperature .	'Burning' and 'over-heating' in steel and brass. Brittleness and sponginess generally, owing to abnormal grain size.
	2. At too low a temperature . .	Insufficient structure change.
	3. For too long a period — at correct temperature.	Diffusion and aggregation of micro-constituents of metal or alloy.
	4. Careless charging in or firing of furnace.	Sudden access of heat may lead to cracking of cold metal.
	5. In an injurious atmosphere or in contact with injurious substances.	Copper is injured by reducing gases, steel by oxidising gases. Water and oil have injurious effects in many cases.
Quenching . .	1. From too high a temperature .	Cracking, warping and brittleness.
	2. From too low a temperature .	The object of the operation is defeated.
	3. Unequal	Warping.
Tempering .	1. At too high a temperature	Removes the effects of quenching.
	2. At too low a temperature.	Does not remove the effects of quenching sufficiently.
	3. Unequal	Lack of uniformity and consequent failure.

SECTION XXXVIII

EXPLOSIVES.

(Contributed by Professor W. R. Hodgkinson, F.R.S. (Edin.), Ph.D., F.I.C., C.B.E.)

Explosives may be classified into 'Propellants,' which are required to produce a rapid but steady rise in pressure in some kind of firearm; others may be termed 'Detonators,' or the less definite term 'High Explosive.' The latter are practically instantaneous in action and produce a wave or vibration of high velocity. Under certain conditions some substances may behave as belonging to either class.

The first propellant, 'Black Powder,' has since 1770 (about) consisted of nitre 75 per cent., charcoal 15 per cent., and sulphur 10 per cent. Practically all the gases, which may be 700 times the volume of the powder, arise from the nitre, the volume varying according to the density of the powder and to the conditions at burning.

Gunpowders do not detonate, but may give a very rapid rise of pressure if burnt in a closed space. Being porous, though dense, the first formed and very hot gases are driven through the remainder of the charge, igniting it *en masse*.

Cordite.

Cordites and the like are practically the most satisfactory propellants invented; owing to their gelatine-like structure they are non-pervious to gases. All true colloids show this property in some degree; the rate of burning can therefore be well regulated by the area of surface, volume of gas, and temperature. Owing to their composition, these explosives are practically smokeless. The cold-gas volume (i.e. volume at ordinary temperature) is in the region of 1,000 times that of the powder, and the temperature seldom less than 2,000° C., and may be above 3,000° C., according to composition. 'Cordite' proper consists of gelatinised high grade gun-cotton with a certain amount of nitroglycerine and a mineral jelly incorporated while the gelatinising agent is still present, the agent eventually drying off. A number of varieties of these powders are made with lower grades of gun-cotton, their physical properties being much the same. These powders are not easily detonated and are useless for blasting purposes.

Gun-cotton.

'Gun-cotton' and 'Cellulose Nitrates' are made by the action of a cool mixture of nitric and sulphuric acids on cleaned cotton waste or the like. Strength of acids, temperature, and time of contact determine the extent and nature of nitration. Real gun-cotton contains about 13·8 per cent. of nitrogen, nearly corresponding to $C_6H_7O_2(NO_3)_3$.

Varieties of nitrated cellulose containing 10 to 11 per cent., or less, nitric-nitrogen than real gun-cotton are also used in some classes of propellants.

Gun-cotton is unaffected by water and does not burn if containing about 10 per cent. of moisture. When dry it ignites at between 160° and 180° C. It burns without smoke and is easily detonated by a sharp blow on a hard surface. When wet it can only be detonated by a primer of dry gun-cotton. When pulped and pressed into slabs, gun-cotton (13·8 per cent. N.) is used for blasting; its action is very local.

Nitroglycerine.

Nitroglycerine is formed by the action of mixed nitric and sulphuric acids on glycerine at a low temperature. It is a colourless oily liquid of sp. gr. 1·6. It freezes easily, and melts at 4° C. It is practically insoluble in, and unaffected by, water. Solid or liquid, it is easily detonated by percussion or by heating to about 150° C., hence the danger of thawing the solid nitroglycerine. As a liquid it is unpractical as an explosive, but when mechanically absorbed into a porous inert material, or incorporated in the substance of a jelly, useful preparations result.

Dynamite.

'Dynamites' which fulfil most of the requirements for blasting, and are reasonably safe, consist of nitroglycerine incorporated in kieselguhr, cork charcoal, and the like non-gritty powders. Generally some metallic nitrate, colouring or binding dope is added. Dynamites can be detonated by fulminate detonators. They are comparatively safe to handle and store for a moderate time in a place of medium temperature. Water may cause the extrusion of nitroglycerine from most forms of dynamite.

Gelignite.

'Gelignites' are mainly a thin jelly of a low grade gun-cotton in nitroglycerine; warm nitroglycerine is usually the gelatinising agent, but others may be employed. They may contain about 90 per cent. nitroglycerine. They are plastic, waterproof, and more powerful and convenient than ordinary dynamites. They should be stored in a place of cool oven temperature. Most of the gelignites are doped, for some real or imaginary object.

Permitted Explosives.

'Permitted Explosives' for use in mines are such that comply more or less perfectly to certain tests, such as non-ignition of fire damp or coal dust, not producing a dangerous amount of poisonous fumes, considerable range of safety in storage and use. In many of these explosives, ammonia nitrate is the main oxygen carrier, the combustibles being benzene derivatives such as nitrobenzene, nitronaphthalene, and the like, with or without wood meal or inert powders to cool the flash.

Perchlorate of ammonia is the chief active material in some blasting compositions for civil or military use (cheddites). They are useful in fiery mines, as a quantity of hydrochloric acid gas is produced on explosion which acts as a damper of flame. Almost any kind of organic matters may be used in this class. Paraffin wax is often used, as, amongst other properties, it is waterproof.

Perchlorate compositions are stable and keep well, but all are liable to explode on moderately strong percussion. Generally they simply burn violently on ignition by a flame.

Ordinary chlorate compositions should be completely barred, as they are never safe and are erratic in use.

Detonators.

Detonators are substances employed to start the disruptive explosion or detonation of other compounds which alone may not explode by a flame or a moderately hard blow. Owing to the extreme rapidity of their explosion, detonators initiate a molecular decomposition of the main explosive, or it responds to the wave blow of the detonator.

Mercury fulminate, $HgN_2C_2O_2$, is the oldest and most commonly used detonator. It may be used alone or diluted with nitre, antimony sulphide, potassium chlorate, or even inert substances in some proportion, in order to regulate its sensitiveness, or reduce or modify the manner of exploding.

Cap and igniting compositions contain same proportion of $KNO_3Sb_2S_3$ and $KClO_3$.

Small quantities of fulminate, say 2 grams, may flash off if fired open, but the flimsiest cover will cause it to detonate on firing by a flame contact. A very slight suddenly applied pressure causes detonation. Its function in cap compositions is to respond to the blow of the hammer and ignite the other ingredients.

Lead azide, PbN_6, acts similarly to fulminate, is stronger and quicker in action, but probably not so amenable to regulation as fulminate.

Fuses.

These are, generally, some arrangement for firing an explosive at a desired moment. They consist, as a rule, of finely ground black powder contained in a paper tube protected by tape, machine-wound over it and waterproofed by some resinous or pitchy composition. Rate of burning may be controlled by fineness of powder, and in some cases by its composition, diameter of tube, etc.

In military fuses the powder has to burn along a circuitous route of determinable length in a metal container.

Fuses for blasting are packed in barrels and cases containing 300 or 500 coils of 24 ft. length. The average rate of burning of safety fuses is 75 to 90 secs. per yard. (See also 'Trinitrotoluene.') The fuse end is inserted in the detonator cap, which is then secured in proper contact with the explosive cartridge or charge, which may be tamped in the bore hole or not according to nature of explosive. (See also 'Blasting,' page 2166.)

Lyddite, or Picric Acid.

Lyddite, or picric acid, $C_6H_2OH(NO_2)_3$, is mainly a military explosive. It is somewhat difficult to detonate, otherwise there is no reason against its use for rock blasting. When some quantity is burnt there is a liability for it to pass into the detonation stage. The chief danger in connection with it is the liability to form metallic compounds (picrates), which are extremely sensitive to heat, friction, or percussion. There are several related substances with similar properties and uses, such as dinitrophenol, nitrocresols, etc.

Trinitrotoluene.

Trinitrotoluene (T.N.T.) and trinitroxylene (and other stages of nitration of toluene, xylene, etc.) are mainly military explosives, but T.N.T. has been used for some time in instantaneous fuses for civil work. Under proper conditions all these substances could be used for blasting.

Amatols.

Amatols (of various catagories) are essentially ammonia nitrate compositions with T.N.T. and similar substances. The violence of their explosion is increased by the addition of small quantities of powdered aluminium, magnesium, and other substances.

Amatols have a great future as blasting agents, but some of them are very sensitive and are not quite waterproof.

Blasting Machines.

Dynamo Electrical Blasting Machines (supplied by *Fleming & Company*, 31 *Robertson Street, Glasgow*) are specially built to explode all blasting charges with absolute safety, either in stone quarries, coal mines, or oil shale workings. Being water and damp proof they are always ready for action.

PAINTING — LACQUERS AND BRONZES — VARNISHES — CEMENTS AND GLUES—LUBRICANTS AND OILS—CLEANING-COMPOSITIONS — COPYING-PROCESSES — MISCELLANEOUS.

(All Parts by Weight unless otherwise Specified.)

PAINTING.

PAINTING WOODWORK.

A mixture of linseed oil and white lead is the best preservative of wood. The linseed is the preservative; the white lead gives body and opacity. Spirits of turpentine is added as a solvent, to enable the paint to penetrate into the pores of the material; the solvent should be light and easily evaporated.

Boiled linseed oil dries quicker than raw, but is darker and thicker than the latter.

TO REMOVE OIL PAINT.

2 lbs. washing soda, ½ lb. quicklime, mixed to consistence of cream, spread on, and kept moist for an hour. The paint can then be washed off.

GLAZIER'S PUTTY.

Whiting and raw linseed oil, well beaten up.

TO REMOVE OLD PUTTY.

Paint it with nitric or hydrochloric acid, and after about an hour it will be soft enough to remove; or a hot iron will soften it at once.

PAINTING.

In painting woodwork for the first time, kill knots with coating of fresh slaked lime; then in 24 hours scrape off, and paint knots with mixture of red and white lead and linseed oil: or use red-lead powder mixed with strong glue size, and apply warm—the work can then be gone on with in a few minutes; when dry, smooth with pumice stone. Next put on priming coat. All holes are then stopped with glazier's putty, and the required coats added; each coat in good work is rubbed smooth with glass-paper before adding another.

Painting required to have no gloss has an additional coat, made with turpentine only, and no oil, called a *flatting coat.*

For old work, if much soiled, wash with soap and water and scour; if foul with smoke and grease, wash with lime and water; then commence with *second* coat.

New woodwork should have 4 coats; for periodical repainting 2 are sufficient.

PRIMING.

This generally consists of a mixture of white lead and red lead, irrespective of the colour to be used in finishing. The lead mixture is diluted with boiled linseed oil and a small quantity of turpentine.

PAINTING IRONWORK.

For new ironwork 3 coats Torbay or other oxide of iron paint answers well; 1 lb. mixed with oil will cover from 8 to 12 yards. For periodical painting, 2 coats. For the first, or first and second coats on iron, red lead is very generally used; 1 lb. mixed with oil will cover about 5½ yards.

SYRONITE ANTI-RUST PAINT.

Syronite (*Messrs. Pinchin, Johnson & Co. Ltd.*) is a thin transparent syrup which can be painted upon new ironwork before, during, or after erection, or upon existing structures that are already rusting. If the structure is in a bad state before the Syronite treatment is under-

taken, the surface is first well brushed with a stiff wire brush to remove all loose rust. A coat of Syronite is then applied, its action being to penetrate through any remaining rust and cause this to shed off. When shedding has taken place, another coat is applied, and then the treatment is complete.

Pigments can be combined with Syronite when required.

A peculiar feature of the material is its capacity for 'creeping' or spreading. Ordinary paint stays exactly where the brush leaves it, and as the brush cannot always get under and along joints, round rivets, etc., these parts do not get equal protection with the general surface, but Syronite on a metal surface will permeate into every crevice, thus effectually insulating the iron and protecting it against corrosion.

Minerva Bright-part Coating and Rust Preventive.

This preventive (*Messrs. Pinchin, Johnson & Co. Ltd.*) is intended for brushing on machinery bright parts prior to leaving the foundry or finishing shop, to prevent rust forming during transit and erection. It dries almost immediately with a firm, elastic, damp and acid-resisting surface that will not come off through ordinary handling. When it is desired to remove the coating, it is only necessary to wipe the surface over with a cloth damped with turpentine, petroleum, or benzine, when the coating will at once disappear, and the parts can then be polished up to a bright condition.

Minerva Machinery Finishes.

These finishes (*Messrs. Pinchin, Johnson & Co. Ltd.*) embrace one, two, and three-coat work. For loose or rough metal with surface defects, air-holes, etc., an iron-filler, known as 'Indurine, is used straight in the plastic form supplied. It is spread with a knife or leather over all bad places, so as to bring them up to the proper level, and sets 'iron hard' very rapidly. For clean castings the 'Indurine' is thinned down with 'Indurine Blender' until of a suitable consistency for brushing on. Thus applied it will bring the whole surface up level and hard, ready for sandpapering smooth to take paint. In addition its anti-corrosive character acts as a preventive against rust.

Minerva 'Intermediate Coat' is a glossy black made with a special medium and supplied in ready-to-use consistency. It is brushed direct on to the filled iron after first removing all traces of oil, grease or dirt. On account of the special medium employed in its manufacture, it grips tenaciously, dries quickly with a tough, elastic surface that is grease, oil, spirit, and acid proof, and which will be affected neither by sulphurous nor other chemically laden fumes. For an extra substantial effect, a second coat of this paint can be applied when the first is quite hard and dry.

Minerva 'Finish' is made in four standard shades from grey to black. This paint is applied upon the 'Intermediate Coat' when this is bone dry. It spreads freely, has great covering capacity, and dries rapidly with a solid, grease and oil-proof surface—perfectly flat, half gloss and full gloss finish.

'Cuirass' Anti-corrosive Paint.

Cuirass is in black only, but its merit over oxide paints is that it does not blister in tropical climates and it does not crack in arctic climates. Engineers of various railroads testify that five years after painting girders no rust is shown. The paint is insulating, and is also acid-resisting. It is claimed to cover three to four times the surface of oxide paints. The great covering power of Cuirass paint is due to the exceedingly fine particles of which it is composed. The 'pigment' of ordinary paint is obtained by grinding between rollers, the 'pigment' of Cuirass is obtained chemically, the particles being but the size of a microbe, hence the covering and penetrating power of the paint. It is stated that Cuirass does not blister and does not oxidise.

See also pp. 2356, 2357.

Preservative for Ironwork.

(1.)

Coal-tar boiled till the watery vapour and naphtha are expelled, and mixed when cold with ½ pint of naphtha and the same amount of boiled oil to each gallon of tar.

(2.)

Experiments carried out by the Military Engineering Department at Brest have shown that as an effective preservative for metal work coal tar is rendered far more efficient by the addition of a small quantity of quicklime, in the proportion of one part of lime to two parts of tar. The mixture, after being heated to the boiling point, is brushed upon the ironwork at a temperature of about 120°F. The tar should be used over a coating of red lead.

(3.)

A valuable rust-inhibitive coating for general priming or finishing work may be prepared from sublimed blue lead. Two parts of blue lead and one part of linseed oil containing about 5 per cent. of turpentine drier make a paint of the right consistency. When this paint is used for top-coat work in marine exposures—battleship gray—the addition of 1 per cent. of carbon black to the blue lead aids in the maintenance of the colour.

Rust Proof Coating for Iron or Steel.

Linseed oil, 25 parts; calcium resinate, 36 parts; manganese borate, ½ part; lead acetate 1 part; naphtha, 37½ parts; artificial graphite, 25 parts. These are mixed and applied to the

Syronite
ANTI-RUST PAINT

BEST PRESERVATIVE FOR ALL KINDS OF EXPOSED IRONWORK.

SYRONITE treatment pays for itself over and over again. It :—

(1) Prevents rust getting a hold on new work.

(2) Completely checks the spread of corrosion on existing structures, no matter how badly affected.

(3) Conserves the life and strength of IRON and reduces maintenance costs to the very minimum.

metal by brushing, or dipping, or any other method. The article is then baked at 300° F. for one hour and 40 minutes. The coating is highly lustrous and resistant to corrosion.—*American Machinist.*

Note on Iron-work Painting.

According to experiments published in the *Bulletin de la Société des Ingenieurs Civils de France*, a number of coats of paint form a much less effective rust preventive for metal than a single layer does. Iron plates well cleaned and polished were coated, some with one coat and some with two, three, or more coats of paint, and then exposed to the action of steam for a whole day, after which the paint was removed and the plates were examined. The first was as bright as it was before exposure to steam, the second showed a few rust spots, the third was still more attacked, and the fourth entirely so. This result is stated to be due to the fact that the deeper layers dry badly and tend to dissolve the uppermost coating, increasing its porosity to air and moisture.

Painting Zinc.

Dissolve 1 part chloride of copper, 1 nitrate of copper, and 1 sal ammoniac, in 64 of water, and add 1 part commercial hydrochloric acid. Paint the zinc with this, and leave to dry for 24 hours. Any oil colour will then firmly adhere to it.

To Paint in imitation of Ground Glass.

White lead, 4 parts; boiled oil, 3 parts; spirits of turpentine, 1 part; add a small quantity of dryers. The colour must be exceedingly thin, and put on the panes of glass with a large brush in as even a manner as possible. Dab the paint over lightly with a pad of cotton-wool covered with an old linen rag.

Hydraulic Cement Paint.

Hydraulic cement mixed with oil forms an incombustible and waterproof paint for roofs of buildings, outhouses, etc.

Outside Whitewash.

Slaked lime, ½ bushel. Add common salt, 1 lb.; sulphate of zinc, ½ lb.; sweet milk, 1 gallon.

Flexible Paint.

Used for painting on canvas. 2½ lbs. good yellow soap dissolved in 1½ gallon boiling water; grind the hot solution with 3½ gallons of good oil paint.

Red Paint, quick drying (8 to 20 Minutes).

(Used for Pillar-boxes.)

Japanner's gold size	40 per cent.
Red lead	60 „

When dry, varnish with outside oak varnish.

Waterproof Paints.*

For General Purposes.

(1.)

2 gallons linseed oil, boiled with 11 ozs. each of rosin and litharge, 1½ oz. each of minium and umber; add gradually 8 ozs. of sulphate of zinc and a solution of 12 ozs. of potassium hydrate, and a like quantity of alum in 4 gallons of water. For preparing the ground colour, compound 10 lbs. of chalk and 2 lbs. of zinc white with ¾ gallon of water in which 1½ oz. of alum has been previously dissolved, and mix with this a solution of 1½ lb. of glue in ½ gallon of water. This ground paint is mixed with 4 to 5 lbs. of the above composition, and the mixture diluted with petroleum.

(2.)

12 ozs. of melted rosin, thoroughly mixed with 6 gallons of fish oil and 1 lb. of melted sulphur, and some ochre or any other colouring substance rubbed up with linseed oil. Apply several coats of the hot composition with a brush. The first coat should be very thin. Suitable for either wood or stone.

For Casks and Waterspouts.

Boiled oil, 1 part; charcoal, finely powdered, 1 part. Mix to consistence of paint.

For Vessels and Submarine Works.

Sulphate of copper, 400 lbs.; grape sugar, 100 lbs.; concentrated solution of potash, 200 lbs. The precipitate of hydrated oxide of copper formed by heating this mixture is filtered, dried, and

* It has been proved that no paint film, of which linseed oil is one of the chief constituents, can be made *thoroughly* impervious to moisture.

mixed with 8 lbs. of 75 per cent. carbolic acid. Heat the mass moderately, and add about 12 gallons of crude linseed oil. When the paint is to be used it is reduced with linseed oil, and then applied. This composition is claimed to prevent the deposition of marine animals on the surface to which it is applied.

Paints for Waterproofing Outside Walls.

(1.)

Rosin, 4¼ ozs.; litharge, 3 ozs., boiled in 1 pint of clear linseed oil until the wooden spatula used for stirring becomes brown. Give the walls 2 or 3 coats of this, preferably on a hot and dry summer's day.

(2.)

A solution of paraffin wax in heavy coal-tar oil is excellent for painting houses, and especially walls exposed to the action of the weather. Several exper ments in painting damp walls with this solution have given very satisfactory results. Wall-paper which formerly became moist and detached from the walls during rainy weather remained perfectly dry after the wall had been painted with this solution, which is prepared by dissolving 1 part of paraffin wax in 2 to 3 parts of coal-tar oil at a moderate heat. A sufficient quantity of oil must be used so that the solution does not entirely congeal on cooling. To heat the paint while applying it, place the vessel containing it in hot water. It is best to apply the solution on a warm day, when the bricks are dry. Generally 1 coat is sufficient, but even if 2 coats are given the cost is considerably less than that of oil paint.

'Cuirass' Waterproofing.

This paint is applied for waterproofing worn zinc, lead, leaky felts (of any make), concrete, damp walls. It is ready mixed and is applied cold with a brush.

Paint for Wooden Floors.

Soak 2 ozs. good light-coloured glue in cold water for 12 hours, and dissolve it with constant stirring in thick milk of lime (prepared from 1 lb. of caustic lime) heated to the boiling-point. Stir in 8¾ ozs. linseed oil. Mix with any colour not affected by lime, and dilute with water if necessary. For yellow-brown or brown-red colours, boil in the ground colour ¼th of its volume of a solution of shellac and borax. A coat of varnish produces a bright surface.

Paint for Red Brick Floors.

Wash the bricks with soap-water containing ¼th part of carbonate of soda. Dissolve 1 part of glue in 16 of boiling water and 4 parts of red ochre, and stir the mass thoroughly together. Apply 2 coats of this to the bricks, and then give a coat of linseed oil varnish.

Preservative Solution for Stonework.

1 part white shellac, dissolved in 8 parts wood spirit. Apply to surface by means of a watering pot provided with a rose.

Paint for Roofs.

Pulverised slate (argillaceous schist), 35 parts; pulverised mica slate (mica schist), 30 parts; pulverised rosin, 35 parts; mix with ½ its volume of pure coal-tar, and boil to a fluid mass. This paint gives a very durable and pliant coating, which does not melt in the greatest heat of summer nor crack or break in the greatest cold. It resists moisture, and retains its lustre and smooth surface. It will last for 4 or 5 years.

Paints for Preserving Wooden Posts.

(1.)

50 parts rosin, 40 parts powdered chalk, 4 parts linseed oil; melt together in an iron boiler, add 1 part of natural cupric oxide, and stir very carefully into the mixture 1 part of sulphuric acid. Apply with a stiff brush. When dry the mass forms a coating as hard as stone.

(2.)

1¾ part rosin (melted), 48 parts fish oil, 1½ part sulphur. When the mixture is thoroughly combined and liquid, add sufficient ochre rubbed up with linseed oil to give the desired shade of colour. Apply the mass while still warm in as thin a coat as possible, and in a few days, when the first coat is dry, repeat the operation.

Paint for Felt Roofing.

Washed graphite, 2 parts; red ochre, 2 parts; cement, 16 parts; barium sulphate, 16 parts; plumbic oxide, 6 parts. These materials to be ground in an oil varnish prepared as follows: 100 parts of good linseed oil are boiled for 8 hours in a copper boiler with 5 per cent. of pyrolusite. 10 parts of flowers of sulphur and 20 parts of French pitch are then dissolved in the mixture, and the mass filtered before it becomes cold. 25 lbs. of this composition and 1½ gallons of linseed oil varnish or linseed oil, for reducing the paint, are sufficient to give 2 coats to 1,000 square feet of roof surface. The first coat, while still wet, is uniformly covered with fine dry sand by means of a sieve. The sanding should be done during the progress of the painting, so that the workman is

not obliged to step on to the wet paint. The free sand is renewed with a broom before the second coat is given, and it is best to apply this 8 days after the first. The second coat need not be sanded, its purpose being to combine with the first to form an insoluble mass hard as stone, and to give to the roof a neat, finished appearance.

'Cuirass' Roofing.

Cuirass Liquid Proofing waterproofs felts and leaky roofs of whatever make, and lead, zinc, concrete, asphalt, etc.

Quickly-drying Oil Paint.

Boil for 15 minutes in an earthenware pot 1 part of soft curd soap in 3 parts of water. Pour the mass through a colander, wash it with cold water, and press out the water in a linen cloth. To 1 part of the curd soap add $\frac{1}{4}$ part of unslaked lime and $\frac{3}{4}$ part of water. Triturate the fat slime thus formed in oil or water with the necessary pigments. Walls, ceilings, stairs—in short, anything of stone, plaster of Paris, or zinc—can be painted with this. If the paint is to be used on wood, add $\frac{1}{4}$ part of linseed oil. Ochre, chrome yellow, Berlin blue, indigo, lead, and zinc, are best adapted for colouring substances. The mixture dries so quickly that 3 coats can be applied in a day. It is entirely without odour, and is about one-third the cost of ordinary oil paint.

Fire-resisting Paint.

(1.)

20 lbs. finely pulverised glass, 20 lbs. finely pulverised porcelain, 20 lbs. any sort of stone in powder, 10 lbs. calcined lime, and 30 lbs. water glass (silicate of soda). The solid elements having been powdered as finely as possible and sifted, are moistened and then intimately mixed with the water glass. This yields a syrupy mass that may be employed for painting, either alone or mixed with colour. The coating is applied with a brush, as other paints are, as uniformly as possible over the surface to be protected. The first coat hardens immediately, and a second one may be applied 6 hours or more afterwards; two coats are sufficient. The paint must be used immediately after it is made up.

(2.)

The most practical means so far discovered by the United States Forest Products Laboratory, Madison, Wis., for economically rendering small quantities of wood fire-resistant consists in the use of fire-retardant paints. Ordinary whitewash or calcimine has proved in tests to be as fire-resistant as any paint covering tried, and it also possesses the advantages of cheapness and ease of application. While it will not prevent the burning of wood continuously exposed to a high temperature, a good coat of calcimine will decrease the likelihood of a blaze spreading from small sources of fire, such as flying sparks and matches. Calcimine is naturally more effective for interior than for exterior use. For work of the latter class the Forest Products Laboratory has developed an effective paint composed of linseed oil, zinc borate, and chrome green, which has maintained its fire-resisting properties through more than three years of exposure to the weather.

Heat-indicating Paint.

A paint for indicating an excessive rise of temperature in machinery bearings is composed essentially of a mixture of the double iodide of silver and mercury and copper mercuric iodide. The former is a pale yellow powder at normal temperatures, but turns to a vivid carmine at 90° to 100° C., while the copper salt, which is normally of a strong scarlet vermilion, changes to a chocolate brown at 60° to 70° C. A mixture of the two in the proportion of 85 per cent. of the copper salt and 15 per cent. of the silver changes promptly from vermilion to nearly black at 60° to 70° C. The paint is made with the aid of white shellac spirit varnish (100 grms. of the mixture to 70 cub. cm. of the spirit), and is applied in the form of a band or bull's-eye to the bearing. After the paint has become dry it is to receive a coat of colourless oil-proof varnish.

See also p. 898.

Painting Portland Cement.

Portland cement work which is to be painted must be thoroughly hardened and dry. It is advisable to let the work stand for a year before oil paints are applied. The durability of the paint will be assured by, first, brushing over the surface with dilute sulphuric acid—one part of acid to 100 parts water—and allowed to dry before painting. A preparatory coating for oil paint is a solution of common water glass in three or four parts of water. Two applications of this, followed by a washing with water, and then another application of water glass, will be found effective.

Coal-Tar Paint.

(1) Coal-tar, 8 parts; Portland cement, 1 part; kerosene oil, 1 part. (2) Coal-tar 16, Portland cement 4, and kerosene 3 parts. The Portland cement neutralises the action of the tar on iron and steel, while the kerosene acts as dryers. It is suitable for painting ironwork of all kinds, and is a satisfactory coating, it is said, for ships' sides, and may also be used on galvanised iron.

'Foliac' Ontar Composition.

This composition (*Graphite Products, Ltd., Battersea, S.W.*) is a coating for application over tar or bitumen coating in order that linseed oil paints may be used. Oil paints cannot

ordinarily be used on top of tar or bitumen, because these always strike through the superimposed coats of paint, and cause, *inter alia*, discoloration.

Graphite Paint.

The best and longest records of satisfactory protection against corrosion are said to be held by graphite paints containing silica in intimate admixture with the tough crystalline graphite. An example of this is the 'Foliac' silica-graphite paint manufactured by *Graphite Products Ltd., Battersea*, which is British manufacture throughout, and has been specified for a large number of steel structures, including Admiralty airship sheds, oil fuel tanks, and gas holders, Office of Works and Ministry of Munitions explosives and filling factories, docks and harbours for transit sheds, cranes, etc., and railways for bridges, station roofs, wagons, signal work, etc. The relative covering power of the paint is high, and it is therefore economical in use.

Bituminous Paints.

Bituminous paint is a good preventive to rust as it adheres closely to the material to be protected, it is strongly resistant to sulphurous vapours prevalent in the air of industrial centres, and very few of the mineral acids attack it, with the exception of nitric acid. Nitrous fumes have little or no action on the better bituminous paints. A good bituminous paint should dry within four or five hours, and the chances of injury by rain or similar eventualities during the setting are, therefore, correspondingly small. A high-class bituminous paint may be applied at a cost of something like a farthing per square foot with two coats of the paint applied. The life of a well-compounded bituminous paint extends up to twenty years' efficient protection.

Luminous Paint.

Mix 50 parts of lime with 20 parts of flowers of sulphur, heat them together in a closed crucible until all fumes cease to be evolved. When quite cold grind the product up with varnish or paint which is quite free from lead. Luminous paint produced from oyster shells is the most efficient in retaining its luminosity after dark. Take clean shells and, after washing them in warm water, place them in the fire for half an hour, and when cool, after removal, pound them up very small and fine, taking away any grey portions as being of no use, then put this powder in a crucible with alternate layers of flowers of sulphur, place on the lid and cement it round with sand made into a stiff paste with beer; as soon as this is dry, place the crucible in the fire and bake for one hour. Wait until quite cold before opening the lid. The product should be white; any grey portions must be separated as non-luminous. Sift it through fine muslin, and mix with either varnish or gum water. For use with buoys or in places exposed to the weather, varnish of the best quality only must be used.

LACQUERS AND BRONZES.

Lacquer for Iron and Steel.

Mastic, 10 parts; camphor, 5 parts; sandarach, 15 parts; elemi, 5 parts. Dissolve in alcohol and apply without heat.

A Rustless Coating for Steel.

A solution of white wax in benzine applied with a camel-hair brush. When the film of wax hardens, the bulk of it is wiped off with a chamois leather, just sufficient remaining to prevent rust, but not to be noticeable.

Angus Smith's Coating for Pipes.

Coal Tar 1 cwt., Tallow 7 lbs., Quick Lime (slaked) 10 lbs., Pine Resin 4 lbs., Coal Naphtha, sufficient to thin the composition to a degree suitable for proper coating. Heat mixture, and immerse pipes, and allow to remain until the same temperature is diffused through the mass; then withdraw pipes. This treatment leaves a very firm and hard coating of pitch. It is very essential that the mixture be heated to a proper degree, viz., 350° to 450° F. If heated too much the pitch will not adhere properly, but will scale off.

Bronzing Liquids.

(1.)

Sulphate of copper, 1 oz.; sweet spirits of nitre, 1 oz.; water, 1 pint.

(2.)

Solution of chloride of platinum, laid on surface with a feather. When dry, blacklead over with an ordinary blacklead brush, and then lacquer.

(3.)

Boil 1 oz. of ammonium carbonate and a like quantity of blue vitriol in 1¼ pint of vinegar until the latter is nearly evaporated. Then add 1¼ pint of vinegar in which has been dissolved ½ drachm of oxalic acid and a like quantity of sal ammoniac. Place the mixture (known as Walker's Chemical Bronze) over the fire until it commences to boil, then allow it to cool; filter, and put by in well-closed bottles.

If a medal, etc., is to be bronzed, it is first thoroughly cleansed, then heated, and the liquid applied by means of a badger-hair brush. In a short time boiling water is poured over the medal, and when dry it is rubbed with a cotton rag dipped in oil, and then with dry cotton.

Browning for Gun Barrels.

Tincture of muriate of iron, 1 oz.; nitric ether, 1 oz.; sulphate of copper, 4 scruples; rain-water, 1 pint. When the barrel is finished let it remain in lime-water for a short time; then scratchbrush and apply bronzing.

Lacquer for Gun Barrels after Browning.

Shellac, 1 oz.; dragon's blood, ¼ oz.; rectified spirit, 1 quart. Dissolve and filter.

To Chemically Blacken Brass.

Dissolve copper in nitric acid (out of doors) until all action ceases; when cold decant into another jar.

Sand-blast work, or clean in hot lye and soda; dry in sawdust; heat to 212° F.; immerse in the (cold) nitrate solution; remove and heat again sufficiently to dry off solution and burn off green colour; repeat if necessary; cool and free from oxide by brushing; dip in ammonia; rub dry with soft cloth or in sawdust—work is then brown. To make it dead black, heat just enough not to burn hands, and rub with soft leather and fine olive oil; heat, to dry oil.

Highly-polished work, if well cleaned and dipped in commercial ammonia before applying nitrate, will take a permanent black.

Sand-blasted work takes a black that cannot be removed by ordinary wear.

Black-bronzing Aluminium.

(1) Immerse the articles, after being thoroughly cleaned, in a hot solution containing 8 oz. of white arsenic, 8 oz. of iron sulphate, ¾ gallon of hydrochloric acid, and ¾ gallon of water. When sufficiently blackened the articles are removed, washed and lacquered. A more adhesive deposit may be obtained by adding to the solution a small quantity of ammonium molybdate and yellow prussiate of potash. (2) Paint the articles with a solution made by dissolving 60 grammes of copper chloride in 300 c.c. of water and add ammonia in excess to re-dissolve the precipitate first formed. Then heat the articles, care being taken not to melt the aluminium. A deeper black may be got by repeating the process, or by dipping the articles in a solution of sodium sulphide.

Black Finish on Steel Shears, etc.

Prepare a saturated solution of caustic soda and add about ½ lb. of saltpetre to a five-gallon solution. Boil the solution for a short time, and allow it to cool. The clear liquid should only be used, and this should be brought to the boiling point in an iron kettle. The articles should be wired as for plating and immersed in the solution. The articles will take on a grey colour at once with black underneath, and should be left in the solution until the grey finish disappears and a beautiful black remains. Rinse the articles in cold water, dry in sawdust and oil with linseed oil, and wipe clean. The resulting finish will be a fine blue-black that wears well.

VARNISHES.

Incombustible Varnish for Wood.

An application of a solution of equal parts of alum and isinglass to the place exposed to the flame prevents ignition, but not the transmission of heat. By coating wooden vessels with this varnish fluids may be boiled in them over an ordinary fire.

Varnish for Wood not acted upon by Boiling Water.

Boil in an untinned copper boiler 750 parts of linseed oil. Suspend in this, in a bag which must not touch the bottom, 150 parts of litharge and 90 parts of pulverised minium. Let the oil boil until it has assumed a dark brown colour; then remove the bag, and replace it by one containing 7 to 8 bulbs of garlic. Now melt 500 parts of pulverised amber in 60 parts of linseed oil over a strong fire; add it while boiling to the prepared linseed oil, and let it boil for 2 to 3 minutes longer, stirring it vigorously. Then take it from the fire, allow it to settle, pour off the clear liquid, and when cold put it in bottles, which should be hermetically closed.

Quick-drying Varnish.

A quick-drying varnish that is less liable to crack than that made from kauri gum is made in the United States from the nuts of the Chinese wood oil tree (*Aleurites fordii*). The tung (or wood) oil has also been found of special value for waterproofing cement.

Varnish to prevent India-rubber Gas-tubing from Leaking.

Treacle, 1½ part; gum arabic, 2 parts; white wine, 7 parts; strong alcohol, 3½ parts.

Waterproofing Material.

A new French material for waterproofing leather, cloth, paper, and other materials, consists of a mixture of eight parts of amylacetate and four of castor oil, with one part of sulphur chloride stirred into it. This forms a jelly, giving off hydrochloric acid; it liquefies after being kept tightly covered a few days, and, the acid being then neutralised with barium carbonate, gives a colourless solution on filtering. To make a varnish, nitrocellulose is dissolved in the liquid after the addition of alcohol or benzine.

CEMENTS AND GLUES.

CEMENTS.

Rust Joint.

Quick-setting.

1 lb. sal ammoniac in powder; 2 lbs. flowers of sulphur; 80 lbs. iron filings or borings. Mix to a paste with water.

Slow-setting.

2 lbs. sal ammoniac in powder; 1 lb. flowers of sulphur; 200 lbs. iron filings or borings. Mix to a paste with water. This cement is better than the quick-setting, if the joint is not required for immediate use.

For Steam Boilers, Steam Pipes, etc.

(1.)

Soft.

Red or white lead in oil, 4 parts; iron borings, 2 to 3 parts.

(2.)

Hard.

Iron borings and salt water, and a small quantity of sal ammoniac with fresh water.

(3.)

5 lbs. Paris white, 5 lbs. yellow ochre, 10 lbs. litharge, 5 lbs. red lead, 4 lbs. black oxide of manganese. The whole is to be well mixed, and a little asbestos and boiled oil added. This soon becomes nearly as hard as the iron itself.

This cement is also excellent for making fluid-pressure joints.

(4.)

Take white lead ground in oil, and add dry red lead sufficient to make a stiff putty. Pound this on a block of iron or stone until it becomes soft, continuing to add red lead until the mass will no longer soften or stick to the fingers. Interpose this putty between the flanges of the steam-pipe joints. This will make the best joint known.

For Leaky Iron Pipes.

In cases where caulking, plugging, or other mechanical means of stopping leaks in iron pipes cannot be adopted, a cement made by mixing finely pulverised black manganese oxide and raw linseed oil into a thick paste will usually be found effective. It should be thoroughly forced into the leak, and the pipe should be kept warm enough to absorb or remove the oil from the manganese. In about twenty-four hours the cement should be as hard as the iron, and should adhere thoroughly, so that leakage does not again occur.

Fire-resisting Cement for Iron Pipes.

Iron filings, 10 parts; brick clay, 20 parts; China clay or fireclay, 15 parts; common salt solution, 8 parts.

For Iron Stove-pipes and for filling Cracks in Stoves.

Pulverised brick clay, 1 part; wood ashes, 1 part. Add a little salt, and mix to consistence of syrup.

To fasten Iron to Iron.

(1.)

Sulphur, 6 parts; white lead, 6 parts; borax, 1 part. When composition is to be applied, wet with strong sulphuric acid and smear on surfaces, which must be at once pressed together. Allow one week to dry.

(2.)

Equal parts of litharge, red lead, and sufficient glycerine to form a paste. This cement is said to be waterproof, fireproof, and to resist the action of alkalies.

For Holes in Castings.

Flowers of sulphur, 1 part; sal-ammoniac, 2 parts; iron filings or borings, 80 parts. Mix to a thick paste with water.

To fasten Iron to Stone.

(1.)

Iron filings, 20 parts; plaster of Paris, 50 parts; sal ammoniac, 3 parts. Mix to a thin paste with weak vinegar.

(2.)

Sulphur, 1 part; pitch, 1 part.

To fasten Iron to Marble.

A cement for making repairs on switchboards when iron or other metal has to be fastened to marble may be made from thirty parts plaster of Paris, ten parts iron filings, and half-part sal ammoniac. These, states the *American Machinist*, are mixed with acetic acid to form a thin paste. This cement must always be used immediately after being mixed.

To fasten Metal to Wood.

In order to fasten metal to wood without the use of nails or screws, the metal parts may be roughened by the use of dilute sulphuric acid. As soon as the metal has been wiped dry, it is glued on with the best joiner's glue to which a little glycerine has been added. This process is not only adapted for small plates or slabs, but also larger ones, but care must be taken that they touch the roughened wood surface evenly throughout.

Cement for fastening Metal Letters upon Glass, Marble, Wood, etc.

Copal varnish, 15 parts; linseed-oil varnish, 5 parts; oil of turpentine, 5 parts; glue, 5 parts. The glue is dissolved by placing the mixture in a water-bath. When the solution is complete 10 parts of slaked lime are added to it.

A Strong General Cement.

4 ozs. clear gum arabic, 3 ozs. fine starch, 2 ozs. white sugar. Dissolve gum in water; then dissolve starch and sugar in gum solution; boil mixture in a water-bath until starch becomes clear. Add a few drops of oil of cloves.

To fix Paper to Metals.

Gum tragacanth, 30 grammes; gum acacia, 120 grammes; water, 500 cubic centimetres. Dissolve, filter, and add 2½ grammes of thymol in 120 cubic centimetres of glycerine. Add water to make up bulk of 1 litre.

To fix Cloth to Metal or Wood Rollers.

Glue, 1 part; isinglass, 1 part. Soak in small quantity of water for 10 or 12 hours. Then boil, and add pure tannin till it becomes thick. Apply hot.

To fasten Leather to Metal.

Digest one part of coarsely crushed gall-nuts with eight parts of distilled water about six hours, and filter through linen. Then pour one part of cold water over one part of glue, leave it to stand for twenty-four hours, and heat the whole, whereby a concentrated glue solution is obtained. Now coat the leather with the warm gall-nut extract, bring the glue solution on the roughened and warm metal, lay the leather on it, press it firmly, and allow it to dry in the air. The leather will adhere so firmly to the metal that it cannot be separated without tearing it.

To cement Leather on Iron Pulleys.

Roughen pulley with old file. Glue leather to pulley with glue, 1 part; glycerine, 1 part.

To cement Rubber upon Metal.

Soak pulverised shellac in 10 times its weight of strong ammonia. The result will be a transparent mass, which becomes liquid in 3 to 4 weeks without the use of water. This fluid makes the rubber soft, but after the evaporation of the ammonia it becomes hard, and impermeable to gases and fluids.

To join Leather Driving-belts.

Mix 10 parts of bisulphide of carbon and 1 of oil of turpentine, and dissolve in it a sufficient quantity of gutta-percha to form a paste. The pieces of leather to be joined are cleansed from oil and grease by laying a rag upon their surfaces and placing a hot iron upon it. Both pieces are then spread with the cement, and subjected to pressure until the cement has become dry.

To cement Leather to Leather.

Soak ordinary glue or isinglass for 12 hours in sufficient cold water to cover it. Boil, and add pure tannin until the solution becomes sticky and has the appearance of white of egg.

Cement for mending Rubber Goods.

Bisulphide of carbon, 26 parts; gutta-percha, 2 parts; caoutchouc, 4 parts; fish glue, 1 part.

Cement for Mending Celluloid and Hard Rubber.

For celluloid goods prepare a cement made by dissolving one part of camphor in four parts of alcohol, and adding an equal amount of shellac to the camphor solution. The cement must be applied hot. For hard rubber articles use a melted mixture of gutta-percha and genuine asphalt, which is likewise applied hot. The celluloid as well as the hard rubber goods must have the fractured surfaces kept pressed together until the cement has cooled.

To Cement Wood to Tin.

1 part yellow wax melted: stir in 2 parts gutta percha chips until quite dissolved, then dissolve therein 2 parts shellac and $\frac{1}{10}$th part boiled linseed oil. Apply melted cement to dried surface of wood and tin, and press two surfaces together for 24 hours.

Cement for quickly closing Leaky Places in Barrels.

Tallow, 25 parts; wax, 20 parts; lard, 40 parts; sifted wood ashes, 25 parts. Mix together by heating, and apply to the defective place by means of a heated knife-blade.

Cutler's Cements for fastening the Blades of Knives into Handles.

1. Rosin, 4 parts; beeswax, 1 part; brick dust, 1 part.
2. Rosin, 4 parts; pitch, 4 parts; tallow, 2 parts; brick dust, 2 parts.

Cement for Marble.

Four parts finely-powdered gypsum; 1 part finely-powdered gum arabic. Mix intimately, then with a cold solution of borax make into a mortar-like paste. Use the paste as a cement. Leave the cemented parts for several days undisturbed so that the cement shall thoroughly set.

Cement for Glass.

15 parts caoutchouc in 60 parts chloroform; add about 35 parts mastic, and allow to stand without heat for eight days.

Cement is elastic and transparent; additional caoutchouc increases elasticity.

Oil Resisting Cement.

For use in certain engineering work a cement is often required which will withstand the action of paraffin or petroleum jelly. Recent investigations show that this can be made by boiling rosin with one-third its weight in caustic soda and one and two-thirds its weight of water. After cooling the water separates and can be thrown away, the residue being then made into a plastic state with plaster of Paris. It is said that a joint made with this will stand any ordinary conditions.

Plastic Cements.*

(*J. B. Barnitt.*)

Asphalt and Pitch.

Asphalt in benzol is useful as an adhesive for uniting glass for photographic and microscopical uses, also for coating wood, concrete, brick work steel, etc., where the melted asphalt would be too thick to apply readily. Benzol is the cheapest and most satisfactory solvent. For waterproofing, melted asphalt with a small amount of paraffin added, and in particular cases boiled oil, is used:—

(*a*) Refined lake asphalt.

(*b*) Asphalt, 4 parts; paraffin, 1 part.

* *The General Chemical Bulletin*, Laurel Hill Laboratory, Feb. 1917.

(*c*) Asphalt, 10 parts; paraffin, 2 parts; boiled oil, 1 part.
Any of the above may be thinned with hot benzol or toluol.
(*d*) Pitch, 8 parts; resin, 6 parts; wax, 1 part; plaster, ¼ to ½ part.
(*e*) Pitch, 8 parts; resin, 7 parts; sulphur, 2 parts; stone-powder, 1 part.
Compositions (*d*) and (*e*) are used to unite slate slabs and stoneware for engineering and chemical purposes.
The following are plastic cements for caulking:—
(*f*) Pitch, 3 parts; shellac, 2 parts; pure crude rubber, 1 part.
(*g*) Pitch, 1 part; shellac, 1 part; rubber substitute, 1 part.
(*f*) and (*g*) are mixed by melting over a burner.

Resin, Shellac, and Wax.

A strong stone cement having little body and applied in layers.
(*a*) Resin, 8 parts; wax, 1 part; turpentine, 1 part. For nitric and hydrochloric acid vapours.
(*b*) Resin, 1 part; sulphur, 1 part; fireclay, 2 parts. Sulphur gives great hardness and permanency in resin cements.
Good waterproofing cements are:—
(*c*) Resin, 1 part; wax, 1 part; powdered stone, 2 parts.
(*d*) Shellac, 5 parts; wax, 1 part; turpentine, 1 part; chalk, 8 to 10 parts.
For a soft airtight paste for ground glass surfaces:—
(*e*) Wax, 1 part; vaseline, 1 part.
A strong cement without body for metals (not copper), porcelain and glass.
(*f*) Powdered shellac, 1 part; ammonia water, 10 parts. Allow to stand until solution is effected.

Rubber.

As a leather cement:—
(*a*) Asphalt, 1 part; resin, 1 part; gutta percha, 4 parts; carbon disulphide, 20 parts.
As a resistant to acid vapours:—
(*b*) Rubber, 1 part; linseed oil, 2 parts; fireclay, 3 parts.
A plain rubber cement:—
(*c*) Cut crude rubber in small pieces and then add carbon disulphide or benzol, allowing the rubber to dissolve.
Corks and wood are made impervious to water by soaking them in the above solution.

Linseed Oil.

For aqueous vapours:—
(*a*) China clay and linseed oil.
(*b*) Lime and linseed oil, forming the well-known putty.
(*c*) Red or white lead and linseed oil.
The above mixtures become very strong when set, and are best diluted with powdered glass, clay, or graphite.
(*d*) Oxide of iron and linseed oil.

Casein, Albumen, and Glue.

Cements of this nature are resistant to moderate heat and oil vapours but not to acid fumes.
(*a*) Finely-powdered casein, 12 parts; fresh slaked lime, 50 parts; fine sand, 50 parts; and enough water to make a thick mass.
A strong cement for ground unions standing a moderate heat.
(*b*) Casein in fine powder, 1 part; rubbed with silicate of soda, 3 parts.
(*c*) White of egg made into a paste with slaked lime. This should be used immediately after being made up.
A composition for soaking corks, wood packing, etc., to render impervious to oil vapours:—
(*d*) Gelatine, 2 parts; glycerine, 1 part; water, 6 parts.

Silicate and Oxychloride Cements.

For oil vapours standing highest heat:—
(*a*) Paste of sodium silicate and asbestos.
For gaskets for superheated steam retorts, furnaces, etc.:—
(*b*) Sodium silicate and glass.
(*c*) Sodium silicate, 50 parts; asbestos, 15 parts; slaked lime, 10 parts.
A metal cement:—
(*d*) Sodium silicate, 1 part; oxides of zinc, lead, or iron, singly or mixed, 1 part.
(*e*) Zinc oxide, 2 parts; zinc chloride, 1 part; water to make a paste.
(*f*) Magnesium oxide, 2 parts; magnesium chloride, 1 part; water to make a paste.

Flour and Starch.

(*a*) Flaxseed makes a very tough cement, but does not withstand water.
(*b*) Flour and molasses to a stiff paste.

(2.)

Tallow, 8 lbs.; palm oil, 10 lbs. Heat to 212° F., and well stir.

Antifriction Grease.

(1.)

Tallow, 100 lbs.; palm oil, 70 lbs. Boil together, and when cooled to 80°F. strain through a sieve and mix with 28 lbs. common soda and 1½ gallon of water.

(2.)

Blacklead, 1 part; lard, 4 parts.

Rosin-Oil Soap.

90 lbs. powdered slaked lime, stirred into 100 lbs. rosin oil. Heat the mixture, constantly stirring it until a uniform paste of the consistence of syrup is obtained. This rosin oil is a component of all the patent wagon greases.

Blue Patent Grease.

2 lbs. powdered slaked lime, heated in 550 lbs. of crude rosin oil for 1 hour, and then allowed to cool. Skim the oil, and stir in 10 to 12 lbs. of rosin-oil soap, until the compound is of a buttery consistency and of a blue colour.

Yellow Patent Grease.

1 part turpentine, 20 parts caustic lye. Add to 350 parts of blue grease.

Black Patent Grease.

2 parts lampblack, 110 parts blue grease.

Patent Palm-Oil Wagon Grease.

Melt 10 lbs. rosin-oil soap in 10 lbs. palm oil; add 550 lbs. rosin oil, with as much rosin-oil soap as will give the whole the consistence of butter; finally, add 7½ to 10 lbs. of caustic soda lye.

Adhesive Grease for Machine Belts.

Lubricate the belts with fish oil to which 10 per cent. of tallow has been added. This will make them flexible, and augment their friction on the pulleys.

Grease for Waterproofing Leather.

Oleic acid, 24 parts; crude stearic acid, 6 parts; ammoniacal soap, 18 parts; extract of tannin, 6 parts; water, 24 parts. Melt the oleic acid together with the stearic acid; then add gradually the ammoniacal soap, the extract of tannin, and finally the water. The ammoniacal soap is obtained by adding to heated oleic acid caustic ammonia until, after continued stirring, the odour of ammonia remains apparent and the whole congeals to a jelly-like mass.

Cooling Compound for Hot Bearings.

(1.)

Mercurial ointment mixed with black cylinder oil and applied every quarter of an hour, or as often as expedient. The following is also recommended as a good cooling compound for heavy bearings:—Tallow, 2 lbs.; plumbago, 6 ozs.; sugar of lead, 4 ozs. Melt the tallow with gentle heat, and add the other ingredients, stirring until cold. For lubricating gearing, wooden cogs, etc., nothing better need be used than a thin mixture of soft soap and black lead.

(2.)

For cooling a hot bearing Professor Lecocq, of the Charleroi Higher Industrial School, recommends that the oil usually employed for lubrication be dissolved in an equal quantity of petroleum spirit, the evaporation of which latter will, he says, afford the cooling desired.

Watchmaker's Oil.

Expose the best olive oil to a temperature a few degrees below the freezing point, which will cause all foreign substances to separate. Pour off carefully the supernatant clear oil, and filter through a cup of linden wood or pith of elder wood. By this process an oil is obtained which will remain liquid for several years, and does not attack the delicate machinery.

Neat's-foot oil treated in the above manner furnishes a less useful oil, since it loses much fatty matter by exposure to cold.

A very useful oil is obtained by dissolving 1 part of pure neat's-foot oil in 3 of pure benzine. Allow the compound to remain for several days in a closed vessel; then filter, and expose the solution to a temperature of 40° F., at which it is again filtered, and the benzine distilled off. The oil should be kept in small, dark vials protected from the air.

A very fine lubricant for clocks and watches is, according to Artemus, obtained by mixing 2 parts of solar oil with 1 of rape-seed oil.

To test the fitness of Oils for Lubricating Watches and Clocks.

Pour a drop of the oil to be tested upon different metal plates, as iron, brass, tin, lead, etc.; keep them in a place free from dust, and examine the drops during 8 to 14 days in regard to their liquidity. Oil remaining liquid after the lapse of this time can be safely used.

Viscosity of Various Standard Oils.

Description.	Viscosity.	
	At 70° F.	At 120° F.
Sperm oil	100	45
Whale oil	190	70
Olive oil	213	75
Lard oil	225	78
Neatsfoot oil	247	80
Rape-seed oil	250	88
Axle oil	600	120
Valve oil	—	550
Cylinder oil	—	700

In the above table sperm oil is taken as the standard for viscosity at 70° F.

The viscosity of thick oils can be greatly reduced by adding 8 per cent. of naphthalene to the oil.

An objectionable characteristic in an oil is its tendency to become resinous with use, due to the oil undergoing the process of oxidation. This change in the oil indicates, to some extent, the degree of refining process the oil has undergone. A simple test can be made in the following way:—Place a small quantity of oil in a glass beaker and put in a nearly equal amount of nitric acid. Should the oil have no tendency to gum, the acid and oil will combine and get very thick, while should there be any objectionable characteristic the oil will remain thin.

CLEANING AND PRESERVATIVE COMPOSITIONS.

To clean Brass.

Oxalic acid, 1 oz.; Rotten stone, 6 oz.; powdered gum arabic, ½ oz.; sweet oil, 1 oz. Rub on with piece of rag.

Soap for cleaning Metal-work.

The soaps used for cleaning metal-work usually consist of mixtures of vaseline, oleic acid, and fat, mixed with a small quantity of rouge. When freshly prepared they leave nothing to be desired; but, unfortunately, such mixtures soon turn rancid and become unfit for use. A newer soap for metal-work, which is stated to be free from this objection, is made from cocoanut butter in the following way:—2·5 kilogrammes of the butter are melted in an iron vessel, together with a little water, and to the mixture is added, with constant stirring, 180 grammes of chalk, 87·5 grammes of alum, 87·5 grammes of cream of tartar, and 87·5 grammes of white lead. This mixture is then poured into moulds and allowed to solidify. The soap so obtained is made into a paste with water, rubbed over the metal to be cleaned, and finally removed by a dry rag or chamois leather.

To clean Grease from Paper.

(1.)

Warm the spotted part, and press blotting-paper upon it until all the grease is extracted that is practicable by this method; then with a brush apply very hot turpentine, and wash off with alcohol.

(2.)

Apply benzine collas freely to the spot.

To clean Marble.

Powdered chalk, 1 part; powdered pumice stone, 1 part; soda, 2 parts. Mix with water. Paint over marble; then clean, and wash off with soap and water.

To clean Grease from Stone or Marble.

Soft soap, 1 part; fuller's earth, 2 parts; potash, 1 part. Mix with boiling water. Lay it on the spots, and let it remain for a few hours.

A Solvent for Rust.

It is often very difficult, and sometimes impossible, to remove rust from articles made of iron. Those which are very thickly coated are most easily cleaned by being immersed in a solution (nearly saturated) of chloride of tin. The length of time they remain in this bath is determined by the thickness of the coating of rust. Generally twelve to twenty-four hours is long enough.

To cleanse Paint Brushes from Dried-in Paint.

Suspend the brush in a tumbler containing a solution of 1 part of crystallised sodium carbonate in 3 of water, in such a manner that it hangs several inches from the bottom of the tumbler. Let it stand from 12 to 24 hours in a moderately warm place (140° to 150° F.). The dried paint will be softened so much that it can be easily washed out with soap and water. Brushes which have become as hard as stone can be restored by this process.

To Remove Rust from Iron.

(1.)

Freely apply turpentine or paraffin oil, leave for twelve hours, and then rub with the finest emery cloth.

(2.)

Dip in strong hot potash bath, for about ½ hour. Then immerse in a cold muriatic acid pickling solution—2 parts water, 1 acid. This removes rust in a few minutes, the metal being attacked but very little. Without the potash it will take about 65 minutes against 4 when both baths are used. The appearance of the rust when treated is black and soft and it can almost be entirely rubbed off with the hands. The metal so treated has a smooth, glossy finish.

(3.)

A dip of 40 parts of muriatic acid and 60 parts of water is effective for removing rust. After the rust has been removed, it is necessary to dip the steel in a strong alkaline bath to remove every trace of acid. The alkaline solution usually employed for this purpose is composed of 2 oz. each of soda ash, sodium cyanide, and caustic lime.

To Remove Rust from Iron Electrically.

A very simple and effective way of cleaning rusted iron articles, no matter how badly they are rusted, consists in attaching a piece of ordinary zinc to the articles, and then letting them lie in water to which a little sulphuric acid is added. They should be left immersed for several days, or a week, until the rust has entirely disappeared, the time depending on how deeply they were rusted. If there is much rust, a little sulphuric acid should be added occasionally. The essential part of the process is that the zinc must be in good electrical contact with the iron; a good way is to twist an iron wire tightly around the object, and connect this with the zinc, for which a remnant of a battery zinc is suitable, as it has a binding post. Besides the simplicity of this process, it has the great advantage that the iron itself is not attacked in the least as long as the zinc is in good electrical contact with it. When there is only a little rust, a galvanised iron wire wrapped around the object will take the place of the zinc, provided the acid is not too strong. The articles will come out a dark grey or black colour, and should then be washed thoroughly and oiled. The method is specially applicable to objects with sharp corners or edges, or to files and other articles on which buffing wheels ought not to be used. The rusted iron and the zinc make a short-circuited battery, the action of which reduces the rust back to iron, this action continuing as long as any rust is left.

To keep Machinery from Rusting.

Take 1 oz. of camphor, dissolve it in 1 lb. of melted lard; mix with it (after removing the scum) as much fine blacklead as will give it an iron colour. Clean the machinery, and smear it with this mixture. After 24 hours rub clean with soft linen cloth. It is stated that this mixture will keep machinery clean for months under ordinary circumstances.

To protect Iron and Steel from Rust.

The following method is but little known, although it deserves preference over many others: Add $1\frac{3}{4}$ pints of cold water to 7 ozs. of quicklime. Let the mixture stand until the supernatant fluid is entirely clear. Then pour this off, and mix it with enough olive oil to form a thick cream, or rather to the consistency of melted and recongealed butter. Grease the articles of iron or steel with this compound, and then wrap them up in paper; or, if this cannot be done, apply the mixture somewhat more thickly.

To keep Tools from Rusting.

Half-ounce camphor dissolved in 1 lb. melted lard; skim and mix in as much black-lead as will give it an iron colour. Smear tools, and after 24 hours rub clean with soft linen cloth.

Or, 6 oz. lard to 1 oz. rosin. When semi-fluid it is ready for use.

Or, use vaseline, to which, when warm, a little powdered camphor has been added.

Removing Rust from Tools.

Tools which have become very rusty should be treated with a chemical solution, instead of trying to scour the rust off by means of emery cloth. A good solution for removing rust may be made as follows. Into one quart of distilled water dissolve, little by little, sufficient chloride of tin to obtain a saturated solution, that is, until the water will not dissolve any more of the salt. Put the tool into a receptacle containing the solution and let it stand over night. In the morning rinse the solution off in running water and dry thoroughly with a piece of chamois or cloth.

(*W. S. S.*, '*Machinery.*')

Rustless Steel.

Recent research has shown that a protective influence against the rusting of steel is exerted by a copper content that would be described by an analyst as a trace. By increasing the copper content from ·01 per cent. to ·03 per cent. the corrosion is decreased by 30 to 40 per cent. Steel with a considerable excess of sulphur can be protected by a copper percentage of ·15.

Blueing Steel.

Outfit.

The outfit consists of a cast-iron kettle, one tank for boiling water, and one tank for oil (aquiline). The mixture consists of nine parts of saltpetre, by weight, and one part pyrolusite. The articles are hung in perforated baskets. A scraper is necessary for the melting kettle to stir the solution and to scrape the sediment from the bottom.

Method.

The desired temperature for treatment is obtained when all the mixture has melted and begun to boil, and when a pinch of fine sawdust thrown in bursts into flame the moment it reaches the surface. The temperature must be kept constant to give good results. In operation, the full basket may be hung on the chain at one end of a lever and lowered into the solution. The articles are left in for three minutes, then are slowly lifted out to allow the surplus solution to drain off; they are then dipped into hot water to clean off the solution; after the water has drained off, the articles are dipped into the oil and taken out as quickly as possible and allowed to drain. It is essential to note that there be no rust on the work, and that red-hot cast iron is attacked by these chemicals.

BLUEING SMALL SCREWS.

Use a boiling bath composed of:

Water	1 gallon.
Hyposulphite of soda	2 ozs.
Acetate of lead	2 „

The hyposulphite of soda and the acetate of lead are first dissolved in the water and the whole is then brought up to boiling point. The work, which must be absolutely clean and free of grease, and preferably polished, is immersed in the bath for a few seconds, and then withdrawn. At first the work will be a kind of yellow, changing to red and then to blue almost immediately. The work is rinsed in water and quickly dried. Changing the length of time during which the work is immersed in the bath will give varying depths of colour. When the desired tint is obtained note the time immersed, and give subsequent dippings the same period in the bath.

The brilliancy of the blues obtained by the above method is greatly enhanced if the work is copper plated before immersion in the colouring bath. The plating may be accomplished by the dipping process. To a quantity of distilled water add all the copper sulphate it will dissolve, then for every four ounces of distilled water add from 10 to 14 drops of sulphuric acid. Start with 10 drops in the first instance and add more sulphuric acid if required. Before coppering it is absolutely essential that the work be free from grease. It should be noted that in all colouring processes the higher the initial polish on the work the greater the brilliance of the finished work.

(*'Machinery.'*)

Blueing Small Hardened Steel Springs Without Heating.

Thoroughly clean the springs in boiling lime water and afterwards remove any remaining lime by means of a brush. Dip the springs in a nitric acid bath; wipe clean and oil; linseed oil is generally used for this purpose. (*W. R., 'Machinery.'*)

Waterproof and Fireproof Boards.

The boards are first laid in a waterglass solution of 5° to 10° Bé., where they are left 10 to 12 hours, when they are taken out and allowed to drip off. After drying, they are placed in a solution (gravity 2° to 3° Bé.) of calcium chloride, magnesium chloride, and ammonium chloride. In this they are left four to six hours, and after dripping off and drying again, they are ready for use.

COPYING PROCESSES.

Glycerine-Jelly Process.

(1.)

8 ozs. glycerine, 2 ozs. best glue; to the glue add 8 ozs. of water, and when dissolved stir in glycerine. Pour the mixture into a zinc dish, and as soon as it sets it is ready for use. Use aniline ink.

(2.)

16 ozs. glycerine, 8 ozs. golden syrup, 3 ozs. flake gelatine, 16 ozs. water. Soak gelatine in water for 10 hours; heat gently in water bath; add glycerine and golden syrup. Pour into dish. Use aniline ink.

(3.)

Gelatine, 1 lb.; water, 2 lbs.; glycerine, 5 lbs. Melt together and pour in shell dish. For the ink: aniline violet, 1 oz.; water, 5 ozs.; methylated spirit, 1 oz.

(4.)

Whiting to fill dish; glycerine in sufficient quantity to mix the whiting to the consistency of glaziers' putty. Press into dish and smooth with knife, and finally with small indiarubber squeegee. For ink use violet aniline, ½ oz.; sugar, ½ drachm; boiling water, 2 ozs.; when cold add 1 drachm each of alcohol and glycerine and 2 drops carbolic acid.

Write or draw original on dry smooth paper with a pen well filled with the aniline ink. Directly it is quite dry place it face down for 1 to 5 minutes, according to number of copies required, on composition, the surface of which must previously be moistened with water and dried with paper (newspaper will do); gently smooth down with hand to remove air bubbles. On peeling it off a negative is left on the composition. To take copies, apply to the negative sheet after sheet of any paper, smoothing them down with slight pressure, and removing them at first as quickly as possible; but as the copies become faint the paper may be left down longer on the negative, or it may be damped before putting down. The copies having been taken, sponge off the negative immediately with cold water, or tepid water if it does not come off readily. When the surface is worn and uneven, re-melt composition; a little glycerine may have to be added at each re-melting.

(5.)

The following formula for making hectograph pads is given by Mr. H. E. Smith in the 'American Engineer and Railroad Journal': Clear hide glue, 1 lb.; water, 1½ pint; glycerine, 2½ pints. The glue should be of a good quality, and the kind that comes in transparent, light-brown sheets, as the white or brown opaque glue does not give as good results. Break the glue into small pieces and soak it in the water over-night in a covered vessel. Then melt it in a water-bath, and add the glycerine, which should previously be heated to the same temperature as the melted glue. Stir only as much as is necessary to mix the glue and the glycerine, as too much stirring introduces air bubbles, which are difficult to remove. Pour the hot mixture through a cheese-cloth bag into the pans. When the pans are filled and the jelly is still quite fluid, sweep off air bubbles or impurities from the surface with the edge of a card. Let the pans stand 48 hours before using. This formula calls for much less water than usually required by other formulas, since it is preferred to secure the requisite softness by means of the glycerine, which does not evaporate and allow the pads to dry out and harden, as does the water.

In writing the original copy always use hard, glazed paper, and write with hectograph ink. In making the negative moisten the surface of the pad with a cold wet sponge, wiping off the excess of moisture. Dry off with a newspaper, and let it stand for two minutes. Place the original face down on the pad for from one to three minutes, rubbing down to a perfect contact, and then carefully remove. In printing apply a clean sheet of any kind of paper so that it touches the hectograph at all points, rubbing as little as possible. Never use hot water for removing the negative; as soon as the copies are all made, wash off with a sponge and cold water and dry off well with a newspaper. Never let the pad stand with ink in it after the copies are made, and always keep it closed when not in use.

Blakeley Process.

The following process, devised by Mr. R. W. Blakeley, of Pendleton, Manchester, is a modification of the glycerine-jelly process, but dispenses with the glycerine-jelly.

Take a pad of 10 to 12 sheets of tissue paper, damp well and screw up for a minute between damping sheets in the ordinary letter-copying press to distribute the moisture evenly. The pad should be thoroughly damp—if too dry it will not take up the ink from the original and if too wet the ink will run.

The original is drawn on any hard-surfaced paper with aniline ink, such as violet blue copying ink, and then placed face down on the damp tissue paper pad and screwed up in the press for five minutes; this gives the negative on the damp pad, from which copies are taken by screwing up blank sheets with the negative in the press. For the first copy 20 seconds in the press is enough. For the fifth or sixth 45 or 50 seconds is required.

As the negative pad loses moisture to every copy this damping cloth under the negative is redamped every half-dozen copies or so.

Autocopyist.

Tough paper is coated by means of a sponge, at a temperature of 120°F., with a gelatine (flake) 5 ozs.; glycerine, 5 drachms; water, 20 ozs.; and then allowed to dry.

The best paper to use is either prepared vegetable tracing-paper, or else vegetable-parchment paper.

The prepared paper is stretched tightly over a felted wooden block or board. The original is written or drawn on smooth paper with an ink composed of a saturated solution of alum tinged with aniline black, and then applied to the prepared paper as in the glycerine process. An inked roller (lithographic ink) is then passed over the surface, a sheet of paper laid on the latter, and a felted roller passed briskly over two or three times, and the paper taken off. One hundred to two hundred sharp, clear copies can thus be obtained. The prepared paper cannot be cleaned and used a second time.

Cyclostyle.

A stencil is formed by writing or drawing on prepared paper with a pen fitted with a revolving perforator. Copies are taken by passing over the stencil an india-rubber scraper charged with lithographic ink thinned with lard-oil.

Blue Photographic Copying-Process.

Draw design on thin paper. Brush paper over with a solution of (1), and dry in the dark.

(1.)

Double citrate of iron and ammonia, 44 grs.; water, 1 oz.

Expose under plan, which is pressed out flat by a sheet of plate-glass, and develop with solution (2).

(2.)

Ferrocyanide of potassium, 50 grs.; water, 1 oz.

Wash with water slightly acidulated with hydrochloric acid, and then in water alone, and dry.

This gives white lines on a blue ground, or a negative of the drawing.

The following gives blue lines on a white ground, or a positive print:—

Sensitising solution—

(1.)

Ferric chloride, 50 grs.; oxalic acid, 25 grs.; water, 1 oz.

Develop with

(2.)

Ferrocyanide of potassium, 80 grs.; water, 1 oz.

All the steps being the same as in the other process.

BLACK PHOTOGRAPHIC COPYING-PROCESS.—TO COPY DRAWINGS IN BLACK LINES ON WHITE GROUND.

(1.)

The following process has been patented by A. Colas, of Neuilly, France. Paper is prepared with the following solution :—½ oz. each of sulphate of iron, sesquichloride of iron, gelatine, and tartaric acid, in 10½ ozs. of distilled water. The paper, kept flat, is stored in a dark closet. When exposed to the light beneath a transparent drawing, the parts influenced by the light lose their greenish-yellow colour. It is afterwards dipped into a bath made of 7 ozs. of gallic acid, ¾ fluid oz. of alcohol, and 1 quart of water. The greenish-yellow lines turn black at once, and the sheet requires only to be rinsed in water.

(2).

The following is known as the 'Polygraphic' method :—A solution of ½ oz. of aniline colour and 8 drops of glacial acetic acid in 3½ fluid ozs. of water is used as an ink in this process. Japanese paper, a copying press, and a smooth, polished zinc plate are used for producing copies. The paper, after the corners have been moistened, is spread out upon the zinc plate. On the top of the paper is placed a linen cloth, first soaked in water and then wrung out, and on the top of this a sheet of waterproof paper. A cushion formed of ordinary paper by folding it several times together is pressed upon the zinc plate thus prepared. The side of the sheet written on is placed upon the sheet fastened on the zinc plate, and on the top of this a sheet of paper of the same size. The sheets of paper which are to receive the copy must be damped. It is now pressed ; in a few minutes the impression will be ready, which can be used at once for 20 to 25 copies. After the impression is drawn off the Japanese paper is removed and the zinc plate washed and cleansed. If 2 pages of a sheet have to be copied, the pages must be enveloped in sheets of paper, which will prevent the ink from one page depositing itself on the other.

The Ferrocyanide Process.

This process, by which it is possible to make direct positive prints, was the first step taken towards important improvements in the reproduction of drawings. The ferrocyanide paper is prepared with a sensitising solution, the nature of which varies according to the class of work to be done. The following are two formulas :

	Grammes.		Grammes.
1. Perchloride of iron	80	2. Tartaric acid	90
Gum	120	Persulphate of iron	110
Citric acid	30	Perchloride of iron	120
Water	1,000	Gum solution	1,000

This paper when prepared is of a yellow colour ; when exposed to light beneath the tracing important changes take place in the sensitised surface which is not protected by the lines of the drawing. The salts of iron are reduced, the exposed surface becomes white, and as soon as the drawing appears in yellow lines, which can be ascertained by raising the back of the frame, the paper is removed and put in a ferrocyanide or potassium bath, which immediately forms Prussian blue by combining with the iron salts that are not reduced, that is to say, in those parts of the sheet that have been protected from the light. In this way the drawing is developed in a bright blue tint. The sheet is afterwards washed, and then placed in a bleaching bath made up in the proportion of 40 grammes of sulphuric acid and 1,000 grammes of water ; finally, the sheet is subjected to a liberal washing, and any spots which do not appear to have been completely bleached are treated with a soft brush.

PHOTO-COPYING.

The simplest outfit for photo-copying consists of a flat frame, a developing bath and rubber squeegee, cutting and trimming table and knife, drying racks, and some metal tubes to hold the sensitised papers. The frame (of ash or oak) has a plate-glass front, a thick sheet of felt, back boards saw cut and battened, pressure bars and springs. In each frame there should be an equal number of boards and bars, and all bars and boards should be interchangeable.

The developing bath consists of an oblong shallow tray ; the larger sizes are fitted with outfall socket and plug. These baths are usually stocked (in zinc) up to 56 ins. by 36 ins. ; for larger sizes, wooden baths lead-lined, or simply made water-tight and provided with a glass or slate slab at the bottom, are generally used. The bath should be fixed with a fall of about ½ in. per ft., so that the water used in developing will flow off readily.

The cutting table is simply a board fitted with a strip of zinc about 6 ins. wide on the upper side, running the full length, and close to the edge. A piece of felt should be tacked to the opposite edge of the table sufficiently large to cover the whole table. This can be drawn over undeveloped prints or sensitised papers. Such a board may be very conveniently supported on trestles. It is often the practice to substitute for the trestles a cabinet of drawers, in which tracings and finished prints can be stored.

The metal tubes for holding the papers should be of tin or zinc, with sliding lids and at least twice the diameter of the roll of paper before unwrapping, otherwise, when unwrapped, it will expand and be difficult to remove. The simplest form of rack for natural drying consists of two brackets attached to a wall, about 3 ft. 6 ins. apart; clips are attached to the prints when in the bath, a rod is slipped through and the whole hung on the brackets.

A flat squeegee is frequently used for removing the superfluous moisture from the prints whilst lying in the bath. It consists of a thin strip of rubber about 10 ins. long secured in a wooden handle.

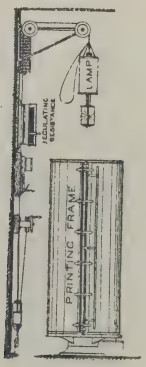

FIG. 1.

The outfit above described is suitable for offices having good daylight and no great pressure of copying work. For large and rapid outputs an electrical outfit is necessary.

Such a machine, capable of taking two tracings, is shown in fig. 1. It is made in several sizes varying from 40 ins. by 27 ins. to 60 ins. by 40 ins. The tracings are clamped closely around a glass cylinder, inside which an arc lamp is alternately raised and lowered until the prints have been fully exposed.

An improved type of copier for a considerably larger output is shown in fig. 2. It enables prints from tracings of any length up to that of a complete roll of paper (30 or 32 feet) to be produced in one piece. The paper A, fed with tracings B, travels slowly downwards between the

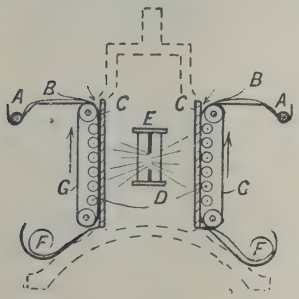

FIG. 2.

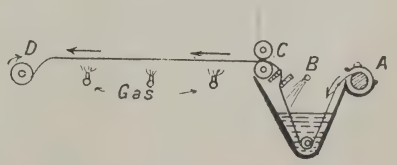

FIG. 3.

glass plate C and an endless blanket G pressed against it by the geared rollers D, passing several fixed arc lamps or one travelling one, E, after which it emerges and rolls up at F ready for trimming and washing.

Continuous printing machines, which are in two sizes, for paper either 30 or 40 ins. wide, are made single or double, the latter printing simultaneously two rolls of paper as in fig. 2. The speed can be varied from 4 feet per minute to 6 minutes per foot on either side so that fast and slow work can be done simultaneously. Fig. 3 shows a 'washing machine.' The roll of prints is placed in the trough A, passed through a running water-bath and spray B, between squeegees and rollers C, over a series of gas burners, and rolled up dry at D.

Trimming in quantities is usually effected with a guillotine for large work and a trimmer of the Merrett type for smaller sizes.

TRACING.

Place the sheet of paper over the drawing to be copied, and lightly rub it over with a ball of wool saturated with benzine; this renders the paper transparent temporarily, when the tracing can readily be made. The benzine by evaporation leaves the paper opaque as before. The benzine must be absolutely pure to secure good results.

MISCELLANEOUS.

To Prevent Rusting-in of Screws.

In machines exposed to heat or moist air the screws soon rust in, even with the use of oil, which later on renders it difficult to take the machines apart. By dipping the screws before use in a thin paste of graphite and oil they can be readily taken out, even after years.

Drilling Glass.

To drill holes in glass a common steel drill, well made and well tempered, is the best tool. Moisten with turpentine in which some camphor has been dissolved. Dilute sulphuric acid is also equally good.

To drill a large hole in thin glass, make in a piece of wood a hole of the size required, and fasten the wood with beeswax upon the glass so as to act as a guide. A piece of brass or copper tubing, of the size of the hole required, is placed in the hole in the wood and supplied with emery powder and water, and is twirled round between the fingers or by means of a bow-string. This will cut a hole in a few minutes.

To Divide Glass Bottles.

Breaking glass tubes or vessels with a clean edge by the aid of a string dipped in an inflammable oil is a well-known method, but the latter is not suitable for large vessels, such as a carboy to break such vessels, fill to point required with cold water, then pour boiling oil over surface of water: before oil has time to cool, dash cold water on outside of vessel, when a clean break is said to result. *(Engineer.)*

To Cut Glass Tubing of Large Diameter.

Nick the glass tube with a file or a cutter at the point where the fracture is desired. Wrap three or four thicknesses of blotting paper around the tube about $\frac{1}{8}$ in. from each side of the mark, the blotting paper being held in place by copper wires. Soak the blotters with water, and expose the narrow section of tube between the two wet blotters to the heat of a bunsen burner. The flame will cause a fracture starting at the file nick and extending in almost a straight line around the tube. *(Power.)*

Cutting Glass under Water.

Cutting a glass dial with a pair of scissors may seem difficult, but it is not, although the job must be done under water and both the glass and scissors must be submerged. A good way is to first cut a paper the size or shape of the glass desired; place it on the under side of the glass for a pattern. It is not expected that it is possible to cut through the centre of a large piece of glass but by trimming a little at a time a good job can be done. The cutting sensation is a good deal the same as that of cutting cardboard. *(A. Dube, 'Power.')*

To make Ivory and Bone Permanently White.

Hydrated oxide of zinc is dissolved in ammonia and the articles laid in it. To remove the yellow tint, a few drops of an aqueous solution of blue vitriol is added, until the latter, on being shaken up, turns blue; after impregnation the articles are repeatedly washed with cold water, dried in the air and polished.

Zinc-oxide of ammonia solution is prepared as follows:—40 parts by weight water mixed with 25 parts of pure zinc, with (after a quarter of an hour) 50 parts concentrated hydrochloric acid added.

To the zinc solution 150 parts hot water is added then (gradually stirring the while) caustic ammonia, until the precipitated white hydrated oxide of zinc is dissolved.

(Scientific American.)

Hard Rubber.

The finest grade of hard rubber, such as is found in a good comb or fountain pen, may contain 75 per cent. rubber and 25 per cent. sulphur, and may have been vulcanised ten hours. The specific gravity of pure hard rubber ranges from 1·12 to 1·25. The tensile strength in the finest and purest grades may be over three tons and the dielectric strength is specified by the United States Navy for sheets at 10,000 volts per $\frac{1}{32}$ in. of thickness.

Fibre.

There are three kinds of fibre in general use—viz., two kinds of vulcanised fibre, known as hard and flexible, and horn fibre.

The flexible is restricted to such uses as pump valves, washers and gaskets. The tensile strength of vulcanised fibre varies from 10,000 lbs. to 20,000 lbs. per sq. in. (as compared with 3,000 lbs. to 6,000 lbs. for leather). Its resistance to compression varies from 40,000 lbs. to 60,000 lbs. per sq. in. (for wood it varies from 3,000 lbs. to 11,000 lbs.). Its resistance to shearing varies from 9,000 lbs. to 13,000 lbs. per sq. in. (compared to wood, with the grain, 225 lbs. to 906 lbs.; to aluminium casting, 12,000 lbs.; and to aluminium forgings, 16,000 lbs.). There is no clearly defined elastic limit, but it approximates 4,000 lbs., and there is no permanent set even at rupture point. The specific gravity is about 1·3, varying from 1·2 to 1·5 (sp. gr. of pure aluminium in a cast state is 2·58; of cork, 0·24; of wood, 0·35 to 1·33). It possesses the strength and density of a metal, yet is elastic and nearly as light as hardwood. A square foot of $\frac{1}{8}$ in. fibre weighs about $\frac{7}{8}$ lb. and the same area of 1 in. stock about 7 lbs.—i.e., about 20 cub. ins. to the pound.

Vulcanised fibre is insoluble in all the ordinary solvents, and is not affected by immersion in alcohol, ammonia, benzine, or any of the animal, vegetable, or mineral oils. It absorbs water freely, and swells when wet, but is not otherwise injured.

When heated, fibre does not melt or soften, but at a high temperature it chars and loses its elasticity. Vulcanised fibre is not brittle, and will stand a great amount of pounding and rough usage. It can be machined, and will take a fine polish, but cannot be moulded.

One of the purposes to which vulcanised fibre is being applied is the thrust bearings in light, sensitive, drilling machines. Ball bearings cause endless trouble in this position if one of the balls fractures or chips, and it has been found that a fibre disc answers the purpose admirably. The permeability of the fibre to oil renders it self-lubricating, and its life under these conditions is remarkable.

To True Grindstones.

Drive at a moderate speed and true up with a piece of iron tube. Keep turning the tube, which should be held at right angles, and turn it as the edge grinds away. The stone should be *dry*, not wet.

To Face Oilstones.

Take a piece of iron with even or straight face (it ought to be planed), scatter a little emery or fine sand on the iron plate, add a little water, and rub the face of the stone, renewing the emery or sand and water as requisite, finishing with an addition of water without emery or sand.

Ink for Writing on Metal.

Chloride of platinum, $\frac{1}{4}$ oz.; soft water, 1 pint. Use with a quill pen.

Etching and Etching Fluids.

The nearest approach to a perfect ground for general purposes is beeswax of the proper consistency, which can be easily applied in any desired thickness. Before applying the wax it is important that the surface be thoroughly clean and absolutely dry, and the difference in temperature between the wax and the article to be etched should be slight. If it is necessary to dip the piece into melted wax, the article should be kept immersed for a few moments until it acquires the same temperature as the molten wax.

The following fluids have been tried on various substances and found to work satisfactorily :

Iron and Steel.—Hydrochloric acid (full strength) should be used. Nitric acid however must not be used.

Brass.—Nitric acid.

Copper.—A mixture containing 2 parts of nitric acid and 1 part sulphuric acid.

Silver.—Nitric acid, 3 parts; water, 1 part.

Gold.—A mixture containing 1 part of nitric acid and 3 parts of hydrochloric acid. This mixture should be prepared just before being applied, and should be used warm, under a hood or fume closet.

Platinum.—The same mixture as that used for gold

Lead.—Nitric acid.

Aluminium.—A 10 per cent. solution of caustic soda or potash.

Zinc.—A mixture containing equal parts of hydrochloric acid and water, used warm.

Glass.—Hydrofluoric acid. The article may be immersed in the liquid acid for a few minutes or it may be exposed to the fumes for five to fifteen minutes. Extreme caution should be used in handling this acid, using rubber gloves for the hands and a lead or hard rubber container for the acid. Contact with the skin will cause severe burns, and the action seems to be continuous, producing burns far more severe than those caused by the mineral acids.

All of the acids may be used full strength and will act instantly, but if the etching is to be of considerable depth most of them may be diluted with water before applying. This will require more time, but will produce a cleaner cut. The exception to this is the mixture of gold and platinum, which must always be used full strength and applied as warm as the melting point of the wax will permit. (*A. Schleimer*, '*Machinery.*')

To Bend Zinc Tubes.

Put a cork into one end and fill with slightly damp sand well rammed in, then close with another cork; heat the tube until it is just uncomfortably hot to the hand, and then bend round a bit of board sawn to the required curve.

To Drill Hard Steel.

Use turpentine instead of oil; it will drill readily when the drill will not touch the metal with oil.

Aluminium Working.

One of the best lubricants for cutting aluminium in the lathe is kerosine oil; this prevents tearing, and enables a better finish to be obtained.

To Clean Files.

Files clogged with tin or lead can be cleaned by a few seconds in strong nitric acid. For iron filings, use blue vitrol; rinse in water, and dip in nitric. For copper or brass, use nitric several times; for zinc, dilute sulphuric acid. After any of these treatments, rinse the files in water, brush vigorously, and dry in sawdust, or by burning alcohol on the file.

To Remove a Stubborn Nut.

Heat the spanner end and place on nut for a moment or two; this will expand the nut only, whereas using a blow-lamp, etc., heats both nut and bolt. If the above method fails the nut should be split.

Steel-Facing Electrotypes.

A film of pure iron of such hardness as to resemble steel (hence the process is named 'steel-facing') may be deposited on the face of an electrotype. The solution for the purpose is made as follows:—Dissolve 1 lb. of iron sulphate (green vitriol) in half a gallon of rain-water, and add a solution of ammonium carbonate until all the iron has been precipitated. Wash the precipitate by pouring on water and allowing to settle, finally draining off all water possible. Then dissolve the wet precipitate in just sufficient sulphuric acid to avoid having any free acid, and use this as the depositing solution in as concentrated a form as possible. As the solution has a tendency to become acid by working it, this must be corrected by using an anode plate of pure iron eight times larger than the electrotype to be faced, and placing a plate of platinum in the solution, attached to the iron anode, when the solution is not at work.

Another solution, suitable to larger operations, is made as follows:—Dissolve 56 lbs. of ammonium carbonate in 35 gallons of water. In this place a large anode of charcoal iron, and a small cathode of the same connected with a battery, and dissolve into the solution until a test strip of copper is nicely coated with iron in a few minutes. Work this, and all other iron solutions, with a weak current—a battery of Daniell cells will do—keep the anode clean, and add free ammonium carbonate as required. The voltage necessary to work any solution and give best results must be found by experience, always bearing in mind that iron solutions yield their metal in best condition at a low voltage. Iron solutions are also liable to change from atmospheric influences, the iron in solution being oxide by contact with light and air. To minimise this trouble, keep the solutions covered. If a moderately thick coat of iron is desired, the electrotype must be taken out every four or five minutes, and the face scrubbed in clean water, then replaced in the bath. When the coat is thick enough it should be well washed in hot water and rapidly dried, then oiled, and then brushed over with benzine. If not used at once it must be protected from rust by coating with a film of wax.

Silvering a Mirror.

(14 square inches area.)

Well scrub glass with brush, soap, and hot water; rinse repeatedly in cold water; soak in nitric acid for few minutes; rinse in distilled water. Do not touch surface after soap stage.

Solutions.

(*a*)

Silver nitrate	50 grs.
Distilled water	1 oz.

(*b*)

Grape sugar	50 grs.
Distilled water	1 oz.

(*c*)

Caustic potash	50 grs.
Distilled water	1 oz.

Add strong ammonia drop by drop to (*a*), when a yellowish precipitate will form, and later liquid will clear. No more ammonia must then be added; swirl after each drop. Add (*c*), when black precipitate will form; add ammonia drop by drop until solution clears; add 2½ ozs. distilled water and mix in sugar solution (*b*). *Immediately* put into dish and carefully insert glass with face (downwards) just below the surface. When sugar is added solution becomes cloudy, so it should only be added when quite ready for use. Leave glass undisturbed for 30 minutes. Remove glass and again wash in distilled water. Drain for few minutes and swish off any drops of water. If cloudy, polish with a pad of cotton wool covered with soft chamois leather and jewellers' rouge, by light circular strokes. Lacquer with No. 2 cold colourless lacquer from Messrs. Gedge, 90 St. John's Street, Clerkenwell. Back with Brunswick black.

Size of Clock Dials.

Allow 1 ft. diameter for every 10 ft. from the ground, and then add 6 ins. to this; thus, if the dial is to be 40 ft. from the ground, the diameter should be 4 ft. 6 ins.

Flow of Sand.

The velocity of flow of sand and other fine materials through openings of various shapes and in different circumstances is determined mainly by the size of the particles and of the opening, but is slightly diminished by angularity of the particles or by moisture on them. The specific gravity of the particles, the height of the material above the opening, and the shape of the upper contour of the material have little effect. If D is the diameter of the opening, *d* that of the particles, both in inches, the mean velocity of flow V in feet per second is given with sufficient accuracy for most practical purposes by the equation, $V = (D - 2d)/\sqrt{D}$.

(***Hersam***: *Journal of the Franklin Institute.*)

Wire Drawing.

With Diamond Dies.—The diamonds used are partly natural stones and partly chips from large stones used in jewellery; some of them also are stones which have proved too hard for the jeweller to polish. For a hole ·055 in. in diameter a 5-carat stone is needed, whilst stones weighing half-a-carat suffice for dies with holes from ·014 in. down to ·009 in. in diameter and under. In copper wire the smallest size made commercially is 0·002 in. in diameter. Thirteen diamonds are needed to reduce the wire from ·010 in. in diameter to 0·003 in. in diameter. Wires thinner than ·002 in. in diameter are exceedingly expensive to make. A lot drawn for exhibition purposes from ·0022 in. in diameter down to ·001 in. in diameter took 7 drafts. The life of the diamonds when drawing copper wire is six months to a year, provided the stones are of good size, hard, smooth, and well drilled. The weight produced per operator per day falls very rapidly as the size of the wire is reduced. Thus, whilst one man will produce 1,100 lbs. per day of No. 22 (B. and S. gauge), he can only draw 45 lbs. of No. 40 (B. and S.). Diamonds are also used for drawing steel, though they are not economical, nor do they produce a better quality of wire than steel die-plates; but if fine steel wire is wanted very round and true to size, the diamond dies seem necessary. A steel die will not keep to size for more than one coil of No. 33 wire or finer. The life of a diamond is much shorter on steel than on copper, averaging only about three days, when it must be polished out for the next larger size. The surface produced on steel wire is not so smooth when diamonds are used as it is with steel. The speed at which the wire is drawn appears to have little effect on the life of the diamond die, which depends solely on the length passed through. About 200 lbs. weight of steel wire can be drawn through a No. 32 (B. and S.) diamond die-plate before it is off size, 15 lbs. through holes ·005 in. to ·003 in. in diameter, and less than 1 lb. through holes smaller than ·002 in. in diameter. The smallest commercial size is ·0025 in. steel brush wire, drawn from low or medium carbon steel. Difficulty was at one time experienced in drawing hard music wire smaller than ·012 in. in diameter without breaking the diamond; but nowadays it can be drawn as small as ·005 in. in diameter, using 2 to 2½-carat diamonds for the dies. Below about ·009 in. or ·008 in. diameter, however, music wire becomes very curly, and no method of keeping it straight has yet been discovered. (*S. Barnett.*)

Cracks in Metal.

A crack in a piece of metal is prevented from extending further by the well-known means of drilling a hole where the rent ends; but when the hole is not bored on just that spot the crack is apt to continue beyond the hole. To facilitate the search for the exact point, moisten the cracked surface with petroleum, then wipe it, and immediately rub it with chalk. The oil that has penetrated into the crack exudes, and thus indicates with precision where the crack stops.

Rendering Celluloid Incombustible.

In order to overcome the undesirable quality of celluloid to ignite, a French chemist has adopted the following method: An ether-alcohol solution of celluloid is made; then an ether-alcohol solution of ferric perchloride. The two solutions are mixed, and a clear syrupy liquid is obtained, of yellow colour, yielding no precipitates. The liquid is poured into a suitable vessel and is left for spontaneous evaporation, and a substance of shell-colour is produced, which, after washing and drying, gives the desired result. The celluloid thus treated loses none of its properties of pliability and transparency, and is not only uninflammable, but it is also incombustible.

Another method by which the celluloid may be rendered uninflammable, based on the same principle, consists in mixing bromide of camphor with cotton powder, adding castor-oil to soften the substance so that it may be less brittle. This product, though more easily prepared, is, however, not incombustible like the former preparation.

Wood-worms in Westminster Hall Roof.

The extermination of the *Xestobium tessellatum* in the oak roofing of Westminster Hall has been effected by spraying the timber with a mixture of 50 per cent. tetrachlorethane, 6 per cent. cedar wood oil, 2 per cent. solvent soap, 2 per cent. paraffin wax, and 40 per cent. trichlorethylene. The tetrachlorethane is a perfect insecticide, but it is so dangerous that those who handle it must use gas masks.

It is stated that the most effective means of treating oak work when attacked with wood-worm is to give it several coats of paraffin, well soaked into the wood. This should be done by a careful workman, making quite sure that every hole has been well soaked with the paraffin; if treated with paraffin it does not damage the oak, but has a tendency to improve the colour.

Thermostatic Metal.

Thermostatic metal, manufactured by the *British Thomson-Houston Company, Ltd.*, in appearance a homogeneous metal, is formed of two metal strips having widely different coefficients of expansion. The two metals are welded together along their entire length, and are quite inseparable under normal working conditions. When the duplex strip is subjected to change of temperature, one half will expand more quickly than the other, causing the strip to bend. A single degree of temperature change is said to affect its curvature to a measurable extent, and practically instantaneously. In bending, it exerts a force sufficient for the direct operation of levers, the opening and closing of ventilators, etc. The metal can be cut, stamped, or machined. It is supplied in various thicknesses from 0·015 in. to 0·25 in.

SECTION XL

PART I

LENGTHS—SURFACES—WEIGHTS—CAPACITIES—FOREIGN MEASURES—WIRE-GAUGES—SIZES OF PAPER, etc.

(Revised by S. W. Attwell, of the National Physical Laboratory.)

The accepted relations of English Imperial to International Metric Measures are thus given by the Standards Office of the Board of Trade:

1 inch = 25·399978 mm.; 1 metre = 39·370113 inches; 1 gallon = 4·5459631 litres; 1 litre = 1·75980 pint; 1 pound = 0·453592 43 kilogram; 1 kilogram = 2·2046223 pounds.

In 1893 the United States of America recognised the metre as the fundamental standard of length, and adopted the conversion value of 1 metre = 39·37 inches.

10 penny diameters = 1 ft.; halfpenny = 1 inch; 5-shilling piece = 1½ inch. Weight of: 3 pennies, 1 five-shilling piece, or 5 shillings, each = 1 oz.

LENGTHS.

English.

The length of the standard yard of 36 inches is such that a pendulum vibrating seconds of mean time, temperature 62° F., at the level of the sea and latitude of Greenwich, has a length of 39·1393 inches.

Miles.	Furlongs.	Chains.	Rods.	Yards.	Feet.	Inches.
1	8	80	320	1,760	5,280	63,360

GUNTER'S SURVEYING CHAIN.

7·92 inches = 1 link. 100 links = 1 chain 4 rods, or 22 yards. 80 chains = 1 mile.

ROPES AND CABLES.

1 cable-length = 120 fathoms = 720 feet. 1 fathom = 6 feet.

GEOGRAPHICAL AND NAUTICAL MEASURES.

1 degree of a great circle of the earth round the equator = 69·174 statute miles = 365,239 feet. 1 nautical mile (knot) = 6,080 feet. 1 telegraph mile = 6,087 feet.

LOG-LINE.

The log-line should be about 150 fathoms long, and 10 fathoms from the log to the first knot on the line. If half-a-minute glass is used, it will be 51 feet between each succeeding knot. For 28-seconds glass it will be 47·6 feet = 7·93 fathoms per knot. This is the length of knot by calculation, but practically it is shortened to 7·5 fathoms per knot for 28-seconds glass.

The Metric Carat.

By decision of the Standards Department of the Board of Trade, the metric carat of 200 milligrams, and its necessary multiples and sub-multiples, are standard weights in the United Kingdom.

CAPACITIES.

English.

Gallon.—The standard gallon (*International Bureau of Standards, Paris*, 1921) measures 277·420 cubic inches, and contains 10 lbs. (avoir.) weight of distilled water (weighed in air against brass weights) at the temperature of 62° F., the barometer being at 30 ins.

Dry Measure.

Apothecaries' Measures.

Gallon (C) = 8 pints (O) ; 1 pint = 20 fluid ounces (oz. weight of water).
Ounce (℥) = 8 drachms (ʒ) = 480 minims (♏) = 720 drops (gtt).
One wine-glass = 4 tablespoonfuls = 16 teaspoonfuls = 2 ounces.
Symbols.—f. or fl., fluid ; ss., one half ; aa., for each. Thus, f℥ss. means ½ a fluid ounce.

Care should be taken to distinguish the difference between Stubs' Iron Wire Gauge and Stubs' Steel Wire Gauge. The former is commonly known as the English Standard Wire or Birmingham Wire Gauge, and designates the Stubs' *Soft* wire sizes.

The Stubs' Steel Wire Gauge is the one employed in measuring drawn steel wire or drill rods of Stubs' make, and is also used by some makers of American drill rods.

(*Brown and Sharpe.*)

SECTION XL

PART II

THE METRIC SYSTEM IN CONNECTION WITH INTERNATIONAL TRADE.

(*A. H. Allen, M.I.E.E.*)

The decimal multiples and submultiples of the metre (the length standard) in general use are the kilometre (1,000 m.), centimetre ($\frac{1}{100}$ m.), and millimetre ($\frac{1}{1000}$ m.); in scientific work the micron ($\frac{1}{1000000}$ m.) is used. In surface measurements the square metre, centimetre, and millimetre are used for industrial purposes, and the are (100 sq. metres), hectare (100 ares or 10,000 sq. metres), and the square kilometre (1,000,000 sq. metres), for land measurement. For the measurement of volume the principal unit is the litre ($\frac{1}{1000}$ cub. metre or 1,000 cub. centimetres); the cubic metre and the cubic centimetre ($\frac{1}{1000000}$ cub. metre) are in common use.

The units of weight are the gramme, the kilogram (1,000 grammes, or the weight of a litre of water at its maximum density), and the metric ton (1,000 kilograms): the quintal (100 kilograms) is also used in commerce, and submultiples of the gramme in laboratory work. The following are the abbreviations employed to denote the units, their metric and English equivalents, and approximate values of the latter:—

Name.	Abbn.	Metric Equivt.	English Equivt.	Approx. Value.
Millimetre	mm.	0·001 m.	0·03937 inch	$\frac{1}{25\frac{3}{8}}$ inch
Centimetre	cm.	0·01 m.	0·3937 inch	$\frac{3}{8}$ inch
Metre	m.	1·0 m.	1·0936 yard	$1\frac{1}{10}$ yard
Kilometre	km.	1,000 m.	0·6214 mile	$\frac{5}{8}$ mile
Square centimetre	cm^2.	0·0001 m^2.	0·155 square inch	$\frac{5}{32}$ square inch
Square millimetre	mm^2.	0·000001 m^2.	0·00155 square in.	$\frac{1}{645}$ square inch
Square metre	m^2.	1·0 m^2.	1·196 square yard	$1\frac{1}{6}$ square yard
Are	a.	100 m^2.	0·02471 acre	$\frac{1}{40}$ acre
Hectare	ha.	10,000 m^2.	2·471 acres	$2\frac{1}{2}$ acres
Square kilometre	km^2.	1,000,000 m^2.	0·3861 square mile	$\frac{3}{8}$ square mile
Cubic centimetre	cm^3.	$\frac{1}{1000000}$ m^3.	0·0610 cubic inch	$\frac{1}{16}$ cubic inch
Litre	l.	$\frac{1}{1000}$ m^3.	1·7598 pints	$1\frac{3}{4}$ pint
Cubic metre	m^3.	1·0 m^3.	1·308 cubic yard	$1\frac{1}{3}$ cubic yard
Gramme	gm.	$\frac{1}{1000}$ kg.	0·03527 oz.	$\frac{1}{28}$ oz.
Kilogram	kg.	1·0 kg.	2·2046 lb.	$2\frac{1}{4}$ lb.
Quintal	ql.	100 kg.	1·9684 cwt.	2 cwt.
Metric ton	t.	1,000 kg.	0·9842 ton	1 ton

Some misapprehension exists with regard to the difficulty of conversion from English to metric measures and *vice versa*. When such operations are necessary, they are readily performed with the aid of printed tables, of which many varieties are available at small cost. But, in point of fact, conversion would not be required except on rare occasions if the metric units were in general use. Under the conditions existing in this country, conversions from one English unit to another are constantly called for, as in reducing cwt. to lb., or feet to miles, involving calculations at least as arduous as the conversion from English to metric measures, but when the use of the metric system is universal similar changes will be made by simply moving the decimal point. Thus, to reduce 25·78 kilometres to metres, all that is required is to write down 25,780 metres, and to find the volume occupied by 47·31 litres one need only write down 47,310 cubic centimetres, or 0·04731 cubic metre. Only during the process of changing from the present units to the metric system would conversion be frequently necessary.

Another common error is to suppose that the convenient binary divisions of a unit, especially the half and quarter, could not, or should not, be used in connection with the metric system; on the contrary, in countries which have adopted the metric system these divisions are in common use, and there is no reason why other vulgar fractions should not be employed, if desired, except that by doing so a great deal of unnecessary labour would be incurred, as in the case of the English units at present, and one of the greatest advantages of the metric system would be needlessly sacrificed. In workshops where the inch subdivided into sixty-fourths is now used, it is necessary, in order to employ screw micrometers or verniers, to make use of printed tables for converting these awkward fractions into decimals of an inch, and in order to avoid this grave inconvenience some manufacturing firms dimension their drawings entirely in inches and mils. These difficulties are never experienced where the metric system is in vogue.

Again, in finding the weight of a body of irregular shape from the drawings, a common requirement in engineering work, it is necessary to ascertain the volume in, say, cubic inches, and multiply this by the weight of a cubic inch, which must be obtained from tables, and if the tables give the weight per cubic foot but not per cubic inch, as often happens, one or other figure must be converted with the multiplier or divisor 1,728; or if the specific gravity of the material only is obtainable, this has to be multiplied by the weight of a cubic inch of water in order to obtain the weight of a cubic inch of the material. In the metric system, on the other hand, nothing but the specific gravity is ever necessary; this multiplied into the volume in cubic centimetres at once gives the weight of the body in grammes, from which the weight in kilograms or tons is obviously obtained by shifting the decimal point three or six places to the left without any calculation.

In the engineering industries there is much to gain by the adoption of the metric system, in addition to the commercial advantage resulting from the use of the same units as our foreign customers. Drawings would be figured throughout in millimetres, thus avoiding the necessity of marking the denominations of the units, with the resulting liability to error, and the difficulties of adding up a series of dimensions involving eighths, sixteenths, and thirty-seconds correctly would be obviated, whilst much time would be saved. Where calculations were necessary, the trouble and time involved in reducing fractional dimensions to decimals would be avoided, and the liability to error in this operation would be removed. It may be argued that error will arise in placing the decimal point; if this is so, it applies equally to the English measures, for this question only arises when multiplication or division is involved, the position of the point remaining unaltered in addition and subtraction, and if an error of this kind were made it would be so large as to be readily discovered by inspection.

During the war, still more than in peace time, it has been found necessary in many workshops to use both English and metric measures side by side; no difficulty has been experienced as a result of this, works managers stating that the workmen readily adopt the metric measures, whilst in cases where jigs and gauges are used they need not even know what the dimensions are. In all work for which limit gauges are used, the dimensions are always stated in decimals, whether English or metric. In changing from one system to the other, the gauges need not be altered at all; it is the size of the part, not the name of the size, that is important. This applies also to jigs and templates. In the case of screw threads, which are usually cut with dies and taps, the Whitworth standards can be retained, as the only measurements required relate to the size of the stock, not to the threads. The dimensions of screws smaller than the smallest true Whitworth size ($\frac{1}{4}$ inch) were standardised years ago by a British Association Committee, on the metric system, and need not be changed. Metric screws can, if desired, be cut in a lathe with an English leading screw, if one wheel is added to the change wheels, having 63 or 127 teeth.

An important question is that of the metric unit which takes the place of the mil, or one-thousandth of an inch, which under modern conditions of accuracy of workmanship is very generally employed as the actual working unit of length for fitted parts, although the fact may not be so generally realised. The answer is that the one-hundredth of a millimetre admirably meets the requirements, being practically equal to four-tenths of a mil. For very fine work, dimensions are frequently stated in tenths of a mil, but are usually accompanied with a tolerance or margin of error which reduces the limit of accuracy to something like half a mil. The latter is, in fact, according to the National Physical Laboratory, in a report to the Engineering Standards Committee,* a degree of accuracy of measurement which is seldom attained in the workshop, and of course the accuracy of the work is still lower, except in the tool-room, where entirely special conditions obtain. In the report above referred to, it was shown, as the result of a long investigation, that the average error was over $1\frac{1}{2}$ mils, and individual errors amounted often to two or three mils, even in the case of high-class workmanship on plain cylindrical work. Hence the hundredth of a millimetre provides sufficient margin for all purposes in the workshop, and where extreme accuracy is necessary, as in making gauges and other tool-room operations, the thousandth of a millimetre (less than half a ten-thousandth of an inch) is the utmost that is required. As a matter of fact, a large proportion of workshop dimensions can be stated with sufficient accuracy to the nearest millimetre, and even in the case of machined and fitted parts the great majority of dimensions need not be figured to a finer subdivision than one-tenth of a millimetre. Hence

* Now the British Engineering Standard Association.

there is no necessity for a 'string of decimals,' even when converting inch measurements on a drawing to millimetres; if the metric equivalents are given to the tenth of a millimetre the departure from exactitude cannot be as great as two mils, and if they are given to the hundredth, i.e. to two decimal places, the inaccuracy cannot exceed one-fifth of a mil. On the other hand, in accurate work requiring the use of gauges, with dimensions given to a finer value than $\frac{1}{500}$ inch, decimal figures are freely used in English measures, running to the third and even the fourth place on drawings figured in inches, and lists of standard sizes and tolerances, such as those issued by the British Engineering Standards Association, absolutely bristle with decimals. Such dimensions cannot be stated in 32nds and 64ths. Thus there is no novelty in the use of the decimal system in connection with inch measurements, and those who have to use these drawings are already of necessity familiar with the handling of decimals. As a matter of fact, they are obliged to keep at hand printed tables of decimal equivalents for the binary subdivisions of the inch.

Perhaps the chief objection to the use of the metric system in British workshops is the fact that much of the raw material, such as metal rods and bars, sheets, etc., is obtainable at present only in round figures based on the inch, and the dimensions of this material in some cases control those of the machines and tools (but mainly the tools) by which they will be worked upon. As it is desirable to use round figures wherever possible, especially for stock material, the adoption of the metric system would necessitate eventually slight modifications of all such standard sizes, to make them even millimetres or decimals of a millimetre, and during the transitional stage stocks of both denominations would have to be made and sold. This, however, would be a temporary matter, and could hardly outweigh the advantages of falling into line with the vast bulk of our foreign customers in this respect.

SECTION XLI

PATENTS, TRADE MARKS, AND DESIGNS

SECTION XLI

PATENTS, TRADE MARKS, AND DESIGNS.

(Contributed by C. G. Redfern, A.M.I.Mech.E.)

PATENTS.

Application for a patent must be made by the inventor or inventors either alone or in conjunction with one or more co-applicants or a limited company. By inventor is understood either the actual inventor or a person who first introduces an invention from abroad or to whom an invention is communicated from abroad.

When an application is made it is accompanied by either a 'provisional' or a 'complete' specification. In the former case the specification must describe the nature of the invention, but need not particularly describe the same, and the applicant has the right to use and publish the invention during nine months from the date of application, which time may be employed in perfecting the invention and in applying for foreign patents. This protection against the consequences of use and publication is known as Provisional Protection. Should a complete specification not be filed within the prescribed period of nine months, the application is deemed to be abandoned, and no official publication of the provisional specification takes place. When the application is accompanied by a complete specification, full protection is obtained from the date of the acceptance, and between this date and that of the sealing of the patent the applicant has all the privileges and rights accorded by the patent, except that he will not be entitled to institute any proceeding for infringement, unless and until a patent for the invention has been granted.

When a provisional specification has been filed and it is not desired to abandon the application, a complete specification must be filed within nine months from the date of filing the provisional specification; one month's extension of this time, however, can be obtained on payment of a fee. In such a case the complete specification must describe substantially the same invention as that the nature of which is disclosed in the provisional specification; if not, the Comptroller may require the complete specification to be amended to avoid any disconformity between the two specifications.

A complete specification—whether filed with the application or after a provisional specification—must fully describe (if necessary with the assistance of drawings) the manner of carrying out the invention in practice, and at the same time clearly and correctly point out the features of novelty by a distinct statement of the invention claimed. The complete specification on being filed is submitted to an examiner who makes an investigation to ascertain whether the invention described therein has been wholly or in part claimed or described in any specification (other than a provisional specification not followed by a complete specification) published before the date of the application, and deposited pursuant to any application for a patent made in the United Kingdom within fifty years next before the date of the application, or in the complete specification of any prior application, although such complete specification may not have been filed when the application was made. If any anticipating specifications are found, the applicant will have the opportunity of amending the specification, and, if the amendment is not effected to the satisfaction of the Comptroller, the Comptroller may insert a reference to any of the prior specifications in the specification by way of notice to the public. Where the Comptroller is satisfied that the invention has been wholly and specifically claimed, he may refuse to grant a patent.

When an applicant has two or more provisional applications running concurrently and the subject-matter of such applications is of such a nature as to constitute a single invention which may properly be covered by one patent, the Comptroller may accept one complete specification in respect of the whole of such applications and grant a single patent thereon bearing the date of the earliest of such applications; in case of legal proceedings, however, the respective dates of the several applications may be considered.

Patents of addition for improvements in, or modifications of, an invention already patented may be applied for for any unexpired term of the original patent, and no renewal fees, other than those payable in respect of such original patent, will be payable.

Great Britain is a party to the International Convention for the protection of industrial property, under which an applicant for a patent in any one of the States being parties to the Convention may obtain priority in any of the other States—that is to say, an application may be made in any of such States, notwithstanding that publication of the invention may have been made therein, providing that such application be filed within twelve months from the date of the original application.

When a complete specification has been accepted such acceptance is advertised, and the specification will be open to public inspection. Notice of opposition to the grant of a patent may be given at any time within two months from the date of such advertisement, but on the following grounds only, viz. :—

(*a*) That the invention was obtained from the opponent or from a person of whom he is the legal representative.

(*b*) That the invention has been published in the complete specification of a British patent filed in the United Kingdom within fifty years before the date of application for the patent, the grant of which is being opposed, or has been made available to the public by publication in any document (other than a British specification) published in the United Kingdom prior to the application.

(*bb*) That the invention has been claimed in the complete specification of a British patent which, though not published at the date of the application for a patent, the grant of which is opposed, was deposited pursuant to an application for a patent which is, or will be, of prior date to such patent.

(*c*) That the nature of the invention or the manner in which it is to be performed is not sufficiently or fairly described in the complete specification.

(*d*) That the complete specification includes matter not in the provisional specification, and forms the subject of an application made by the opponent in the interval between the leaving of the provisional and complete specifications.

(*e*) That, in case of an application under the International Convention, the specification describes or claims an invention other than that for which protection has been applied for in a foreign state or British possession, and that such other invention forms the subject of an application made by the opponent in the interval between the leaving of the application in the foreign state or British possession and the leaving of the application in the United Kingdom.

If there is no opposition, or, in case of opposition, if the determination is in favour of the grant of a patent, the Comptroller causes a patent to be sealed.

The decision of the Comptroller in most cases is subject to appeal to the Law Officer.

Letters Patent extend to Great Britain, Ireland, and the Isle of Man, and are granted for sixteen years, subject to the payment of renewal fees commencing at 5*l.* in respect of the fifth year, and increasing 1*l.* for each succeeding year during the term of the patent, the last payment being 16*l.* These renewal fees are payable before the commencement of the year in respect of which the payment is made, but extensions of time for making these payments up to three months can be obtained, with the addition of a fine, and in the event of a patent lapsing through the non-payment of a fee, the Comptroller is empowered to revive the patent on certain conditions.

At any time after the sealing of a patent the Comptroller may, if requested by the patentee, cause the patent to be endorsed with the words 'licences of right' and any person shall then be entitled, as of right, to a licence under the patent upon such terms as, in default of agreement, may be settled by the Comptroller.

Furthermore, any person interested may apply to the Comptroller alleging that there has been an abuse of the monopoly rights under a patent and asking for relief. Such rights will be deemed to have been abused, if, after four years from the date of the patent, the invention—being capable of being worked in the United Kingdom—is not being worked on a commercial scale; or if such working is being prevented or hindered by the importation from abroad of the patented article; or if the demand for the patented article is not being met to an adequate extent and on reasonable terms; or if trade or industry is being prejudiced by refusal to grant licences, or by conditions attached by the patentee to the purchase, or use of the patented article or to the working of the patented process. If the Comptroller is satisfied that an abuse of the monopoly rights has been proved, he may order the patent to be indorsed with the words 'licences of right' and grant a licence to the applicant on such terms as he may think expedient; or he may order the patent to be revoked.

For 'PATENT SPECIFICATION DRAWINGS,' see page 176.

TRADE MARKS.

Trade marks are registered under the Trade Marks Act of 1905 as amended by the Act of 1919, which provides that a registrable Trade Mark must contain, or consist of, at least one of the following essential particulars :—

1. The name of a company, individual, or firm represented in a special or particular manner

2. The signature of the applicant for registration or some predecessor in his business.

3. An invented word or invented words.

4. A word or words having no direct reference to the character or quality of the goods, and not being, according to its ordinary signification, a geographical name or a surname.

5. Any other distinctive mark; but a name, signature or word or words, other than such as fall within the descriptions in the above paragraphs 1, 2, 3, and 4, shall not be registrable under the provisions of this paragraph except upon evidence of its distinctiveness.

Provision is also made for the registration of any special or distinctive word or words, letter, numeral, or combination of letters or numerals used as a Trade Mark by the applicant or his predecessors in business before the 13th August, 1875, and which has continued to be used down to the date of the application for registration.

The Trade Marks Act of 1905 as amended by the Act of 1919 provides for a new kind of registration of Trade Marks whereby certain marks, not registrable under the principal Act, can now be registered, provided they have been in *bona-fide* use in the United Kingdom for not less than two years. For this purpose the Register is divided into two parts called Part A and Part B, the new kind of marks being registered in Part B.

An application for registration is made on a form bearing the necessary stamp and should be accompanied by four additional representations of the mark properly mounted. The application is then examined and the mark compared with other marks on record in the Trade Marks Office (this provision may be dispensed with in the case of application to register in Part B), and if, in the opinion of the registrar, any mark or marks be found having such resemblance to the mark sought to be registered as to be calculated to deceive, the applicant will be notified of the conflicting mark or marks, and if, within one month from the date of issuing such notice, no action is taken by the applicant the application will be deemed to be abandoned. Should, however, the applicant so desire, the registrar will appoint a hearing in order that the applicant may attend before him, when the registrar will decide whether the application can proceed. Appeal can be taken from the decision of the registrar to the Board of Trade.

When an application is allowed the mark is advertised in the Official Journal of the Trade Marks Office. The application is then open to opposition for one month from the date of the Journal in which the advertisement appears, and should no opposition be entered the registrar will, upon payment of the registration fee, issue his certificate of registration.

The term of registration of a Trade Mark is fourteen years and may be renewed.

DESIGNS.

For articles which do not form the subject of a patent, protection may in some cases be obtained by design registration where the novelty consists of shape, pattern or ornamentation. Copyright is granted for five years and is renewable for a further similar term, and it is within the discretion of the Comptroller of Patents and Designs to extend the term of a copyright for a third period of five years.

SECTION XLII

COST OF ENGINEERING WORKS

(Contributed by John T. Rea, Author of 'How to Estimate')

SECTION XLII

COST OF ENGINEERING WORKS.*

(Contributed by John T. Rea, Author of 'How to Estimate.')

BORING.

Percussion boring by the ordinary 'English' method to depths of 500 ft. costs 10*s.* to 20*s.* per foot, advancing 2 to 6 ft. per 24 hours.

Rope boring for oil, salt, etc., holes 6 to 15 ins. diameter, 20 to 60 ft. per day, costs 2*s.* to 8*s.* per foot. Plant for a hole 2,000 ft. deep weighs 80 tons, and costs about 2,000*l.*

Diamond boring in hard rock, 5 ins. diameter, costs in this country 8*s.* per foot down to 500 ft., and 12*s.* to 18*s.* down to 1,500 ft. Advance, 5 to 10 ft. per day. Bort 'diamonds' are 2*l.* to 3*l.* per carat for the softer rocks, and carbon 6*l.* to 12*l.* per carat for the harder ones. Boreholes above 6 ins. diameter are thus almost prohibitive for expense.

Chilled shot method for relatively large boreholes, 6 in. diameter, in hard ground, costs 10*s.* to 12*s.* per foot. It is slower but cheaper than diamond boring.

Actual Costs—The following are from practical pre-war experience :—	Per ft. s.	d.
Rope boring at Middlesbrough, 8 ins. diameter, to depths of 1,000 ft., at rate of 60 ft. per day	8	0
Ditto. in Pennsylvania and Ohio, 6 to 15 ins. diameter, at rate of 20 ft. per day, average contract price	6	0
Diamond boring in Scotland, 5 ins. diameter, to depth of 1,800 ft., advancing about 6 ft. per day	6	4
Ditto. in British Columbia, 2,200 ft. deep, at rate of 10 ft. per day	8	6
Ditto. in Nova Scotia, 2 ins. diameter, sunk by the Government in fairly hard ground to depths of 200 to 400 ft. in 1913, averaged	9	0
Ditto. in Victoria, also sunk by the Government, averaged in the coal measures in 1912	9	3
Ditto ditto. in the harder rocks	14	0
Chilled shot 6 in. Government boreholes in Nova Scotia in 1913, averaged	10	6
Some important boreholes of the world—		
Bezuidenville, Transvaal, 5,800 ft.	42	0
Czechow, Rybnik, Upper Silesia, 7,350 ft.	43	4
Paruschowitz, Silesia, 6,572 ft. (12 in. bore decreasing to 2¾ in.)	11	6
Schladebach, Prussia, 5,737 ft.	21	2

BREAKWATERS.

Breakwaters formed of large rough blocks of stone as a foundation with heavy masonry walls above, forming a harbour. Average width 300 ft., and average depth 50 ft. below low-water mark. 150*l.* to 300*l.* per foot run complete.

Alderney.—Composite type of rubble mound and upright wall above. Mound terminates 12 to 15 ft. below low water. 338 ft. wide at base and 36 ft. at top. 90 ft. mean depth of water. 259*l.* per foot run.

Algiers.—Mound type, with large random concrete blocks surrounding the rubble. 50 ft. mean depth of water. 122*l.* per foot run.

Bizerta.—Composite type, with wall built on caisson system. 58 ft. mean depth of water. 60*l.* per foot run.

* All prices mentioned are pre-war figures unless otherwise stated.

Colombo.—South-west breakwater, 1874–85, is 4,212 ft. long, built of concrete blocks weighing 18 to 30 tons, on the sloping bond system, and cost 705,200*l.*, or 167*l.* per foot run. Extension to ditto as a further protective arm, 1907–12, is 1,800 ft. long, also of concrete blocks, and cost 380,000*l.*, or 211*l.* per foot run.

North-east breakwater, 1894–7, is 1,100 ft. long, and constructed as a rubble embankment; the north-west or island breakwater, 1900–6, is 2,657 ft. long, and made of concrete; the two together cost 500,000*l.*, or 133*l.* per foot run.

Total length of the four breakwaters about 9,770 ft., with five lighthouses on them, and total cost 1,585,200*l.*, or an average of 162*l.* per foot run. Depth of sea, 30 to 36 ft. at low water. Rise of tide at Ceylon is only 2 ft. Engineers, Sir John Coode, Son, and Mathews.

Dover.—Wall type, composed of concrete blocks weighing 26 to 40 tons, 82 ft. wide at base and 40 ft. at top. Depth of water, 61 ft. high; 42 ft. low. 415*l.* per foot run.

Holyhead.—Composite type, with very predominant mound of rough rubble stone, 400 ft. average width at base and 40 ft. at top. Sea and harbour walls built upon the mound. 54 ft. mean depth of water. 163*l.* per foot run.

Marseilles.—Mound type. Outer casing of concrete blocks, 25 tons each, and average thickness 14 to 20 ft. Inner casing of rubble stones, 2 to 5 tons weight, about 12 ft. thick. Rubble hearting, ½ to 2 tons stones, and 6 ft. thick. 35 ft. mean depth of water. Joliette section, 72*l.* per foot run, and new section, 109*l.* per foot run.

Naples.—Composite type. 93 ft. mean depth of water. 186*l.* per foot run.

Plymouth (1811–48).—Rubble mound with walls on top, nearly a mile long. Slope of 5 to 1 seawards. 360 ft. wide at base and 43 ft. at top. Average depth, 45 ft. below low-water mark. Absorbed 3,670,440 tons of rubble and 22,150 cubic yards of masonry. Engineer, Sir John Rennie. 250*l.* per foot run.

Portland.—Mound type with large rubble blocks and heavy masonry wall above, 270 ft. wide at base. The largest of its kind in England and in two portions—inner about 2,000 ft. long and outer over 6,000 ft., with 400 ft. opening between them. Depth of water, 58 ft. high; 51 ft. low. 6 million tons of stone used. Convict labour. Total cost, 1,250,000*l.* 140*l.* per foot run.

Maintenance.—This is less for walls than for rubble mounds, as the latter are greatly affected by wave action, and need constant repair. Cost varies according to situation and exposure, and rarely exceeded 1*l.* per foot run per annum, pre-war. For some time it averaged 1*s.* 3*d.* at Holyhead, 7*s.* at Geneva, and 13*s.* at Naples.

(See also page 1324.)

BRIDGES.

Types.—(1) Arched, (2) Cantilever, (3) Girder or lattice, (4) Movable (bascule or lifting, rolling, swing, and transporter), (5) Pontoon (with barrels, boats, planks, &c.), (6) Suspension, (7) Trestle (with very high steel or wood framework piers, and (8) Viaducts or "land" bridges

Costs include foundations, piers, abutments, approaches, footpaths, machinery, etc., complete.

Description.	Span.	Number of Spans.	Cost per ft. sup.
	ft. ft.		
Brick or masonry	50 to 100	Single	£1 to £2
	50 „ 100	Multiple	£2 „ £4
Ordinary concrete	30 „ 50	Single	15*s* „ £1
	30 „ 50	Multiple	£2 „ £3
Reinforced concrete	50 „ 100	Single	10*s*. „ £1
	50 „ 100	Multiple	£1 „ £2
Steel bascule or lifting	50 „ 100	Single	£3 „ £5
	100 „ 200	Multiple	£5 „ £8
Steel girder or lattice	50 „ 100	Single	£1 „ £3
	50 „ 100	Multiple	£2 „ £5
Steel suspension	50 „ 100	Single	£1 „ £2
	100 „ 200	Multiple	£2 „ £4
Steel swing	50 „ 100	Single	£2 „ £3
	100 „ 200	Multiple	£3 „ £5

Brooklyn Bridge (1870–83).—Wire cable suspension bridge over the East River, connecting New York with Brooklyn. 5,990 ft. total length, including 1,596 ft. central span from tower to tower, two spans of 930 ft. from the towers to anchorage on either side, and the approaches of

ironwork and masonry, 1,563 ft. on New York side and 971 ft. on Brooklyn side. Width 85 ft., divided into five passage ways for vehicles, trams, and foot passengers. Clear height above high water 135 ft. in centre and 118 ft. at towers, giving a free passage to shipping. Towers 277 ft. above high water, upon rock foundation 80 ft. below surface of river and 40 ft. beneath its bed. Supporting the spans are four cables nearly 16 ins. diameter, and 3,758 ft. long, with anchorages of solid stone masonry weighing 60,000 tons each, and rising 90 ft. above river's edge. Each cable contains 5,282 galvanised steel wires in 19 separate strands, of 278 lengths, and each strand has over 200 miles of continuous wire. Wires laid parallel, not twisted, with spiral wire wrapping. Deflection of cables between towers is 128 ft. Engineer, John A. Roebling. Total cost, including approaches, 3,100,000*l.*, or 518*l.* per ft. run, or 6*l.* per ft. sup.

Forth Bridge, Scotland (1882–90).—At South Queensferry, near Edinburgh. Steel latticework, with two main cantilever spans 1,710 ft. each, and 24 land spans, 42 to 688 ft. each. Each cantilever 680 ft. long, united by a girder 350 ft. span. The steel towers supporting the cantilevers are 361 ft. high. 50,960 tons of steel employed and 6½ millions of rivets. Complete length. 8,100 ft., and with approaches, 8,300 ft.; width, 30 ft. Double line railway. Height of railroad, 152 ft. above high water. Main piers of masonry, and concrete foundations in rock, 70 ft. below high water. Central pier of granite standing on the islet of Inchgarvie. Engineers, Sir John Fowler and Sir Benjamin Baker. Contractors, Sir Wm. Arrol & Co. Total cost, including approaches, 1,700,000*l.*, or 205*l.* per ft. run, or 7*l.* per ft. sup.

Gokteik Viaduct (1901).—For a single track on the Burmah railway, and about 80 miles from Mandalay. The highest steel trestle bridge in the world, the 15 trestles varying from 250 ft. to 320 ft. in height. Comprises 10 spans of 120 ft. and 7 spans of 60 ft., or 17 spans altogether, formed with lattice or truss girders. Total length between abutments, 2,260 ft. Total cost, 61,000*l.*, or 3*l.* 10*s.* per ft. sup.

Holyhead, Britannia Tubular Bridge (1845–50).—Across the Menai Straits. Continuous double tube of wrought-iron plates, each tube 15 ft. wide by 23 ft. high at ends, and 30 ft. at centre, with one railway line in each. Two main spans of 460 ft. each, two smaller spans of 230 ft., and two shore spans of 65 ft., or a total length of 1,510 ft. Each tube weighs 4,680 tons, and is fixed 100 ft. above high water. Two abutments, and three masonry piers or towers, the highest of which is 230 ft. Complete distance, with approaches, 1,560 ft. Engineers, Robert Stephenson, assisted by Sir Wm. Fairbairn and Professor E. Hodgkinson. Total cost, including approaches 608,000*l.*, or 390*l.* per ft. run, or 13*l.* per ft. sup.

Kingston Bridge, Surrey (1825–8).—Brick and stone. Five elliptical arches: middle arch 60 ft. span, other arches 56 ft. and 52 ft. span. Ratio of piers to spans, 1 : 6. Bridge, 382 ft. long and 25 ft. wide. Bridge itself 26,800*l.*; approaches and other works, 13,200*l.* Total cost, 40,000*l.*, or 105*l.* per ft. run, or 4*l.* per ft. sup.

London Bridge (1824–31).—Stone bridge of five elliptical arches over the Thames and of handsome design, connecting the City of London with the borough of Southwark, and replacing the 12th century stone bridge Centre span 152 ft., rising 30 ft. above Trinity high-water mark, arches on each side 140 ft. spans, and abutment arches 130 ft. Total length 1,005 ft., and 56 ft. outside width. Two centre piers 24 ft. thick, exterior stones of granite and interior halt Bramley Fall and half Painshaw, Derbyshire; granite voussoirs. General depth of foundations 30 ft. below low water. Engineer, John Rennie, and completed by his son Sir John Rennie. Contractor's tender for the bridge alone was 425,081*l.*, but actual cost was 1,458,310*l.*, or 1,451*l.* per ft. run, or 26*l.* per ft. sup.

Newcastle High-level Bridge (opened 1849).—Example of a true bowstring arch in which there is no cross bracing, with six spans of 125 ft. each. Total length 1,373 ft., and 37 ft. external width. Superstructure is supported on five intermediate piers and eight land piers, four at each side, latter with arched abutments. Height of soffit above high-water, 83 ft. Arched ribs of cast iron and ties of wrought iron. 4,728 tons of cast iron and 321 tons of wrought iron were employed. A carriage roadway passes underneath the railway, the bridge supporting both. Engineer, Robert Stephenson. Total cost, 243,000*l.*, or 177*l.* per ft. run, or 5*l.* per ft. sup.

Niagara Suspension Bridge (1852–5).—Connects the United States with Canada. A wire-rope suspension bridge for road and railway, with a single span of 821 ft., centre to centre of piers and 245 ft. above the water. Superstructure is a hollow rectangular box, 24 ft. wide × 18 ft. deep, on the top of which the railway is laid, while the bottom forms a roadway for public traffic both floors being constructed of timber beams, etc. Railway floor is suspended from two wire cables, 10 ins. diameter, at intervals of 5 ft., and the lower floor by two similar cables. 120 stays. Two masonry towers at each end of the bridge, 60 ft. high, 15 ft. square at base, tapering to 8 ft. square at top, and pierced by an arch. Anchor chains embedded in masonry 7 ft. × 3 ft., and 25 to 35 ft. deep. Engineer, John A. Roebling. Total cost, 80,000*l.*, or 97*l.* per ft. run or 4*l.* per ft. sup.

Tower Bridge, London (1890–4).—Steel, with two fixed shore suspension spans 270 ft. each, and a lifting central span of 200 ft. Two large steel towers encased with stone, with two bascules or drawbridges in the centre and connected at top by a high-level footbridge, 140 ft. above high water.

Bascules weigh 1,000 tons each, and are raised and lowered by hydraulic machinery, which is contained in the chambers of the piers supporting the towers, each pier being 180 ft. long × 70 ft. wide. Staircases and hydraulic lifts are provided in the towers for foot passengers crossing the high-level bridge when the bascules are raised for the passage of shipping. Complete length, with approaches, 2,980 ft. Width of fixed spans between parapets, 60 ft., and breadth across centre span 50 ft. Engineer, Sir John Wolfe Barry. Sir Horace Jones, the City Architect, designed the architectural details. Contractors: Sir John Jackson for foundations; Sir Wm. Arrol & Co. for steelwork; and Sir W. G. Armstrong & Co. for hydraulic machinery. Total cost, including machinery and approaches, 903,000*l.*, or 303*l.* per ft. run, or 5*l.* per ft. sup.

Westminster Bridge, *London* (1853–62).—Road bridge over the Thames, with cast and wrought iron arches of 120 ft. span and 20 ft. high. 1,160 ft. long and 83 ft. wide. Engineer, Thomas Page. Contractors, Messrs. Mare. Total cost, 235,000*l.*, or 203*l.* per ft. run, or 2*l.* per ft. sup.

Bridges of Concrete.

Coulouvrenière Bridge, *Geneva* (1895–6).—Across the Rhone, 351 ft. wide, and total length of bridge over the abutments 492 ft. Width between parapets 61 ft. 4 ins., two footways 12 ft. 6 ins. each, with a carriageway 36 ft. 4 ins. between the kerbs. Two large arches with spans 131 ft. 3 ins., and rise of 17 ft. 6 ins. Arches 3 ft. 3 ins. thick at both springings and centre, about 4 ft. 6 ins. at the haunches, and steel pivoted. Two smaller arches, 35 ft. 5 ins., and 39 ft. 4 ins., but are not pivoted, being elliptical. Very handsome bridge. Arches, spandrels, 9 spandrel walls, 2 ft. thick, 12-in. top table, and filling, all of concrete, 1 to $4\frac{1}{2}$, 6, 7, and 8. Piled abutments. Facing of spandrel walls, columns, cornice, and parapet of stone. Wooden centres were used, with sand boxes for adjusting and striking. Total cost, 68,000*l.*, or 138*l.* per ft. run, or 2*l.* 5*s.* per ft. sup. of roadway and footpaths. Cost per cubic yard, including centering and scaffolding, was 3*l.* 2*s.* 3*d.*

Eyach Bridge, *Hohenzollern* (1895).—Designed by Herr Max Leibbrand, of Sigmaringen. A single span of 98 ft. 5 ins., with a rise of 9 ft. 10 ins. Concrete arch and table, 1 to $7\frac{1}{2}$, and foundations to abutments, 1 to 9, which are piled. Pivots or joints made of granite instead of iron or lead. Bridge is 143 ft. long, 12 ft. 6 ins. total width, with roadway 7 ft. 6 ins. wide, and each footpath 2 ft. 6 ins. The footpaths overhang the arch on either side, and were formed of old iron rails. Plain iron railing as parapet. Cost, 900*l.*, or 6*l.* per ft. run, or 10*s.* per ft. sup.

Kirchheim Bridge, *Württemburg* (1897).—Over the Neckar, which is 361 ft. wide at this point, with 230 ft. of foreshore, or a total of 591 ft. Designed by President von Leibbrand, chief engineer to the State of Württemburg. Length of bridge from outside to outside of abutments, 592 ft., and space between parapets 17 ft. 8 ins., including road, 12 ft. 8 ins., and two footways, 2 ft. 6 ins. each; open iron parapets. Four spans of concrete arches, 124 ft. 8 ins. each, with a rise at the centre of 18 ft. Thickness of arch at crown, 2 ft. 8 ins., increasing to 3 ft. at springing. Concrete piers 7 ft. 6 ins. thick at springing level, faced with stone at water level; cutwaters also faced with stone. Concrete in arches and abutments, 1 to $7\frac{1}{2}$, spandrel walls, tables, etc., 1 to 9, and foundations for piers, 1 to 4. Concrete on face was tooled and coloured, and concrete in piers rendered 2 ins. thick with 1 Portland cement and 2 sand. Lead joints in the centres and springings of arches 6 to 7 ins. wide, bedded and recessed in stone. Screw jacks were used for striking the centres in place of folding wedges or sand boxes. Cost, 7,000*l.*, or 12*l.* per ft. run, or 13*s.* 5*d.* per ft. sup. of bridge table. Approaches, 2,250*l.* in addition.

Munderkingen Bridge, *Württemburg* (1893).—Over the Danube. Designed by President von Leibbrand. One span only of 164 ft., and rise 16 ft. 5 ins. Thickness of arch at centre 3·28 ft., at springing 3·61 ft., and at haunches 4·26 ft. The first concrete bridge where steel pivots on bearing boxes were used, one set at each abutment and one set at the crown. Internal and external spandrel walls, abutments, horizontal and intermediate tables, cornice, and arch itself, were of concrete, 1 to $7\frac{1}{2}$, and tinted. Spandrel face of limestone, and ornamental open iron parapet. Cost of bridge, including piled abutments, 3,600*l.*, or 21*l.* per ft. run, or 13*s.* 6*d.* per ft. sup. of road and footway surface. Approaches, 1,000*l.* in addition.

Neckarhausen Bridge, *Hohenzollern* (1900).—Over the Neckar. Designed by Herr Max Leibbrand, of Sigmaringen. The handsomest concrete bridge in Germany, the concrete being coloured, and no stone used. A single concrete arch of 164 ft. clear span, with a rise of 15 ft. Arch ring 2 ft. 10 ins. thick at the centre, 3 ft. at the springing, and 4 ft. at the haunches. The arch is tapered on plan, being 1 ft. 8 ins. wider at the springing than at the centre. Concrete spandrel columns and arches over, instead of solid spandrel walls and haunches, thus reducing both material and dead load. Arches pivoted with steel pins and cast-iron brackets or bearings, and those carrying roadway were strengthened with iron rails built into the top and abutments. Concrete in arch 1 to $7\frac{1}{2}$, faced with $\frac{3}{8}$-in. spalls of limestone. Voussoirs, cornice, etc., were coloured. Width of macadam roadway 13 ft., and overhanging footpaths 2 ft. 6 ins., which is a cheap method. Centering was supported on temporary piles, with screw jacks for striking. Cost, 3,000*l.*, or 17*l.* per ft. run, or 19*s.* 5*d.* per ft. sup. Long approaches, 5,000*l.* in addition.

BRIDGES OF REINFORCED CONCRETE.

Spans, 50, 75, or 100 ft. External width, including parapets, 25 ft. Height, from mean water level to underside of elliptical arch, 13 ft. 11*s.* to 15*s.* per ft. sup.

Items.	Cost.		
	50 ft. Span.	75 ft. Span.	100 ft. Span.
	£	£	£
Excavations	70	111	184
Concrete	251	462	667
Centering	129	240	341
Reinforcing Steel	104	194	277
Preliminaries 10 per cent.	55	100	147
Contractors' Profit, etc., 15 per cent.	91	166	242
Total Cost	700	1,273	1,858

Alexandra Bridge, Pietermaritzburg (1914-15).—Reinforced concrete on the Kahn system. 170 ft. long × 30 ft. wide between the parapets, with two 5-ft. footpaths cantilevered over a 20-ft. roadway. Central arch 75 ft. span, and a half arch 38 ft. span at each end Cost, including 5 per cent. for designs and supervision, 5,906*l.* for the bridge and 4,008*l.* for the approaches = 9,914*l.* total. 52*l.* per ft. run, or 2*l.* per ft. sup.

Chatellerault Bridge, France (1900).—Across the river Vienne, and is formed entirely of ferro-concrete on the Hennebique system. Centre span 164 ft. and two side spans 135 ft. each, with rises of respectively 16 ft. and 13 ft., and a width between the parapets of 26 ft. 3 ins., excluding two cantilevered footways which overhang 3 ft. 5 ins. Spans of four arched concrete ribs, 35 ins. deep × 19 ins. wide at springings, tapering to 9 ins. square at the soffit, and extrados connected together by an arched table. Roadway and footpaths supported by spandrel pillars, 8 ins. square, and longitudinal concrete beams, the top table being 10 ins. thick at the centre, tapering to 5 ins. at kerb. The bridge only weighs 250 lbs. per ft. sup. Cost, 8,000*l.*, or 18*l.* per ft. run, or 12*s.* 6*d.* per ft. sup.

Pontypridd Bridge (1908).—Over the river Toll. Reinforced concrete on the Hennebique system, with the two piers on reinforced concrete piles. Total length 170 ft., and width 30 ft. Central river span 117 ft. Total, 3,600*l.* 21*l.* per ft. run, or 14*s.* per ft. sup.

Warrington Bridge (1913).—Over the river Mersey. Largest single-span reinforced concrete bridge in England, on the Considère system. River walls and abutments also of reinforced concrete. Clear span 134 ft., width 80 ft. between parapet walls, and ten parabolic ribs supporting uprights and cross beams on which rest 6½ in. floor slabs. Roadway has wood-block paving, and footpaths have concrete slabs. Total cost, including approaches, 24,000*l.*, or 34*s.* per ft. sup. ditto.

CANALS.

Barge or Boat Canals.

Basingstoke Canal (1794).—From Basingstoke to the river Wey. Length, 37 miles, including 29 locks. Total cost, 166,000*l.* Cost per mile, construction works only, 4,486*l.*

Bridgewater Canal (1759-61).—In Lancashire, from Worsley to Manchester. Originated by the Duke of Bridgewater to bring coal from his mines, and first length only 10 miles. 50 ft. wide and 5½ ft. deep, with vertical stone walls instead of banks. The Barton aqueduct carried the canal over the river Irwell. Engineer, James Brindley. The Bridgewater Canal has since been purchased by the Manchester Ship Canal Co. Length, 34½ miles. Total cost, 235,000*l.* Cost per mile, construction works only, 6,812*l.*

Dortmund and Ems Canal (1890-1900).—From Dortmund to the North Sea at Emden. Part of the 157 miles total length includes canalisation of the river Ems. Bottom width 59 ft., and depth 8 ft. Works include 1 canal lift, 3 masonry aqueducts, 185 bridges, and 20 masonry locks, 220 ft. long each. Artificial canal portion cost 29,000*l.* per mile, and river canalisation portion 14,000*l.* per mile. The locks were 15,000*l.* each, and the weirs 8,500*l.* each. Total cost, 3,970,000*l.*, including 400,000*l.* for land. Cost per mile, including land, 25,286*l.*, and construction works only, 22,740*l.*

Ecbing Canal.—In Holland. Length, 28 miles. Cost per mile, 7,580*l.*

Grand Junction.—Width at water level, 36 ft., and 24 ft. at bottom. Cost per mile, including land, etc., 19,500*l.*

Ulster Canal (1826-41).—Unites Lough Neagh with the Upper Lough Erne. Length, 46 miles Total cost, 200,000*l.* Cost per mile, construction works only, 4,350*l.*

Worcester and Birmingham Canal.—Original cost per mile, 20,000*l.*

Ship Canals.

Amsterdam Canal (1865–80).—Connects Amsterdam with the North Sea *via* Lake Y and Wyker Meer, in a westerly direction. Comprises a dam, 4,462 ft. long, shutting off Lake Y from the Zuider Zee. There are 5 locks, sluiceways, 3 swing bridges, and a harbour of 260 acres, with two breakwaters, 5,070 ft. long each, at the North Sea entrance. Canal is 88 ft. wide at bottom, and 23 ft. deep. 21,000,000 cubic yards of material were excavated and dredged, and 13,000 acres of land reclaimed. Engineers, Sir John C. Hawshaw and Mr. Dirke. Length, 16 miles. Whole expenditure, 3,000,000*l*; but construction works only, 2,590,000. Cost per mile respectively, 187,500*l*. and 161,875*l*.

Caledonian Canal (1804–23).—Connects Loch Eil with Inverness Firth, and Lochs Ness, Oich, and Lochy in between. The summit-level of 102 ft. is overcome by 26 locks, 13 on either side, each about 170 ft. long × 40 ft. wide. 22 miles of artificial or canal navigation, and 38 miles of natural lake navigation. Canal is 120 ft. wide at water level, 50 ft. at bottom, and 18 ft. deep. Engineer, Thomas Telford. Length, 22 miles. Total cost, 1,000,000. Cost per mile, including land, etc., 45,455*l*.

Corinth Canal (1890–3).—Between Gulf of Corinth and Gulf of Ægina. Bottom width, 72 ft., and average depth, 26 ft. Earth and soft rock. No locks. Length, 4 miles. Total cost, 1,000,000*l*. Cost per mile, construction works only, 250,000*l*.

Cronstadt and St. Petersburg Canal.—Average width, 240 ft., and average depth, 21 ft. No locks. Total length, 16 miles, including 10 miles of bay channel and 5 miles of canal proper. Total cost, 2,000,000*l*. Cost per mile of total length, 125,000*l*.

Kiel Canal (1887–95).—Or Kaiser Wilhelm Canal, from Elbe in the North Sea to Kiel in the Baltic. Mostly through marshes or shallow lakes, and river valleys, with tidal waterway throughout. Original dimensions: surface width 226 ft., bottom width 72 ft., and depth 30 ft. (since increased to 334½ ft., 144½ ft., and 36 ft. respectively). Two entrance locks, originally 492 ft. long × 82 ft. wide × 32 ft. deep over sill (now enlarged to 1,083 ft. × 147½ ft. × 45 ft., and constructed in concrete, each lock having three pairs of caissons dividing the chambers into lengths of 725 ft. and 330 ft.). The works for broadening and deepening were completed in 1914. Breakwaters at each end. Length, 61 miles. Total cost, including land purchase, 7,800,000*l*. Cost per mile, ditto, 127,870*l*.

Manchester Canal (1887–93).—From Eastham, near Liverpool, to Manchester. 15 miles canal proper, and 21 miles tidal waterway, or 36 miles total. 170 ft. wide at water level, 120 ft. at bottom, and 26 ft. minimum depth (now increased to 28 ft.). Four sets of locks, with an average lift of 15 ft. each, thus raising the water level of the canal at Manchester to 60 ft. above mean sea-level at Liverpool. The locks vary from 600 ft. × 80 ft. to 150 ft. × 30 ft., and the lock gates are moved by hydraulic machinery. The works include 160 acres of docks, with warehouses, machinery, and 95 miles of railway sidings, 6 high-level bridges, 7 swing bridges, and the Barton swing aqueduct for the Bridgewater Canal, which had to be bought. 52,000,000 cubic yards of excavation, and the plant used in construction cost 980,000*l*. Annual maintenance averages 2,000*l*. per mile of canal, and 400*l*. per acre of docks. Details of total cost:

	£
Purchase of Bridgewater Canal	1,783,000
Land and compensation	1,167,000
Constructing the canal and docks	9,000,000
Interest on capital during construction	1,050,000
Law charges, Parliamentary expenses, etc.	500,000
Total	13,500,000

Cost per mile of total length, complete, including all foregoing expenses . . 375,000
Cost per mile of ditto, construction works only, canal and docks. . . 250,000

Panama Canal (1904–15).—From Colon, on the Atlantic, to Panama on the Pacific. The Panama Canal Company was floated in 1879, with Ferdinand de Lesseps as President, and the canal begun in 1881. The French scheme was abandoned in 1889, after only 12 miles had been cut out of 54, and fifty million pounds spent, when the United States Government took over and started the American project in 1904 as now completed. Colonel (now General) G. W. Goethals, U.S.A. Engineers, was chairman of the Canal Commission which worked out the type and salient features.

Total length along axis, 50½ miles, but only 41½ miles within coastlines. The opening channel at sea-level, from Limon Bay in the Atlantic to Gatun, is 7 miles long by 500 ft. wide and 41 ft. deep. At Gatun are 3 twin locks to raise vessels to the summit canal level, 85 ft. above sea, also a dam, 8,000 ft. long, 1,500 to 2,000 ft. thick at the base, and 115 ft. high, forming the artificial Gatun Lake, 164 sq. miles area, through which ships pass in a channel 500 to 1,000 ft. wide and 45 ft. deep. After 23½ miles of Gatun Lake the Gaillard (formerly Culebra) Cut extends for 8 miles, with a channel 300 ft. wide. Then a single twin lock at Pedro Miguel to the small Miraflores Lake, where a channel, 1½ miles long by 500 ft. wide and 45 ft. deep, leads to Miriflores itself. Here two twin locks lower vessels to the Pacific sea-level, and a channel, 8 miles long,

also 500 ft. wide and 45 ft. deep, conducts them to deep water in Panama Bay. In addition there are 2⅜ miles in locks and alongside approach walls. About 26 miles are artificial canal work, out of the total distance of 50½ miles.

Width varies from 300 to 1,000 ft., and depth 40 to 45 ft. The six pairs of locks are 1,000 ft. long × 110 ft. wide, with intermediate gates to divide them into two sections of 600 ft. and 400 ft., and 6 pairs of lock gates with steel frames and plates. The gates vary from 46 ft. to 82 ft. high, and the largest weighs 730 tons. Maximum number of employees at one time was 50,000. Completed in 1914; opened in 1915.

In addition to General Goethals, other engineers were Messrs. S. B. Williamson, chief of the Pacific Division, Gaillard, Sibert, Hodges, Goldwork, Schildhauer, Cornish, Zinn, Nichols, Alfred Noble, and others.

Total cost, including purchase money, 75,000,000*l.* Cost per mile, ditto, 1,485,100*l.*

Suez Canal (1860–9).—Between Port Said on the Mediterranean and Suez on the Red Sea. M. Ferdinand de Lesseps, engineer and promoter. Total length all but 100 miles, including 60 miles through shallow lakes with and without dredging, and the rest actual canal formed by cutting. Sandy soil and a little rock. 90,000,000 cubic yards of material excavated and dredged, and 25,000 labourers employed. Canal is 420 ft. wide at water level, 108 ft. at bottom, and 39 ft. average depth. Originally 197 ft., 72 ft., and 26 ft. respectively. No locks, as the canal is level throughout. Harbour constructed at each end by breakwaters and moles, 6,000 to 7,000 ft. long, enclosing 450 acres. At the Suez entrance there is a tidal range of 6 ft. average at springs.

Total cost, including promotion, 20,000,000*l.*; but for construction works only 10,680,000*l.* Cost per mile respectively, 200,000*l.* and 106,800*l.*

(See pages 1373, 1374.)

DOCKS.

Cardiff, Liverpool, and London wet docks, including wharves, gates, locks, machinery, etc.:

20,000*l.* to 35,000*l.* per acre of water area.

Aberdeen, Glasgow, and Portsmouth, dry or graving docks for repairs, including equipment:

2*l.* to 4*l.* per yard cube of internal capacity.

Steel floating docks for repairs, in terms of lifting power	10*l.* to 15*l.* per ton.
Dock gates of greenheart, 70 to 90 ft. wide and 40 to 50 ft. high, including hydraulic machinery	40*s.* to 50*s.* per ft. sup.
Ditto of steel, ditto ditto	30*s.* to 40*s.* „
Caissons, traversing or floating, 60 to 90 ft. wide, and 30 to 40 ft. high, including hydraulic machinery	50*s.* to 100*s.* per ft. sup. of waterway.
Dock walls, of concrete, stone, or granite, with concrete backing, including digging	25*s.* to 45*s.* per yd. cube.

Actual Costs of wet docks, including dock walls, gates, locks, machinery, etc.:—

	Per acre of Water Area. £
Avonmouth Docks, near Bristol	22,500
Barry Docks, near Cardiff. Water area, 70 acres. Total cost, 900,000*l.*	12,860
Cardiff. Water area, 50 acres. Total cost, 1,500,000*l.*	30,000
„ Bute Dock Extension. Water area, 35 acres	22,000
„ West Bute Dock. Water area, 22 acres Total cost, 400,000*l*	18,180
„ Roath Dock. Water area, 33 acres. Total cost, 500,000*l.*	15,150
Glasgow, Queen's Dock	24,500
Hull, Alexandra Dock	28,900
Immingham, near Grimsby. Water area, 56 acres. Total cost, including land, railway sidings, dock sheds, coal hoists, etc., 2,600,000*l.*	46,430
Liverpool, Alexandra Dock	23,300
„ North Extension. Water area, 83 acres. Total cost, 2,640,000*l.*	31,810
London, St. Katherine's Docks	36,000
Newport, South Alexandra Docks. Water area, 20 acres. Total cost, 500,000*l.*	25,000
Swansea, Prince of Wales' Dock	18,600

Actual Costs of dry or graving docks for repairs, including equipment :—

	Per yard cube of internal capacity. £	*s.*	*d.*
Aberdeen. Internal size, 524 ft. × 73 ft. at surface level. Total 46,000*l.*	1	15	0
Belfast (1905–12). Length over all, 901 ft. Total cost, 350,000*l.*	2	1	0
Glasgow. Internal capacity, 81,555 yds. cube. Stone and concrete	2	9	0
Hartlepool. Brick and concrete, 570 ft. × 75 ft. × 17 ft. deep	1	8	0
Liverpool. Gladstone Dock (1910–13). Total cost, 500,000*l.*	1	13	0
Otago, New Zealand. Internal capacity, 37,000 yds. cube. Total 75,000*l.*	2	0	0
Portsmouth. Granite with brick and concrete backing ; 42 ft. deep	2	0	0

(See also pages 1327, 1339.)

Drainage.

4-in. and 6-in. stoneware drains, jointed in cement, including trenches 3 ft. deep and concrete bed, 6 ins. thick	2*s.* to 3*s.* per ft. run.
Ditto ditto with manholes, ventilating pipes, etc.	5*s.* to 6*s.* per ft. run.
Manholes and inspection chambers, 3 ft. × 2 ft. 6 ins. × 3 ft. 6 ins. deep, complete, including digging, concrete, brick sides, iron cover, etc.	8*l.* to 10*l.* each.
Add extra for every additional ft. in depth	16*s.* to 18*s.* per ft. deep.
Drains and sewers for estate development and town planning schemes	200*l.* to 400*l.* per acre.
Drainage and sewage disposal works for cities and towns	3*l.* to 6*l.* per inhabitant, 20*l.* to 30*l.* per house.

Reconstruction of Drainage, Stanhope Lines, Aldershot (1893).—Combined water carriage system with 4 in., 6 in., 9 in., and 12 in. glazed stoneware pipes (total, 54,670 yds. run), 2 to 6 ft. deep, 500 Jennings' latrines, 500 urinal stalls, 80 w.c.'s, with 3 gal. flushing cisterns, 200 gal. galvanised iron automatic cisterns, and 16 100-gal. brick automatic flushing tanks, with disposal of sewage by irrigation on War Department land. Occupation of barracks, 8,000 adults, 200 children, and 200 horses. Total cost, exclusive of sewage disposal works, 20,500*l.*, or 2*l.* 10*s.* per head of occupation exclusive of horses ; 7*s.* 6*d.* per yd. run of excavation.

Drainage of Land

Agricultural, or subsoil, unglazed earthenware drain pipes laid dry in 12 in. or 15 in. lengths, without jointing material and ends simply abutting. Depths and distances apart vary according to nature of soil. Cost includes digging, filling, pipes, and laying.

	Cost per acre.
In compact or heavy soils, drains 5 to 8 yds. apart, and 2 ft. 6 ins. to 3 ft. deep	6*l.* to 10*l.*
In medium soils, drains 9 to 10 yds. apart, and 3 ft. to 3 ft. 6 ins. deep	5*l.* to 6*l.*
In porous or light soils, drains 11 to 22 yds. apart, and 3 ft. 6 ins. to 4 ft. 6 ins. deep	4*l.* to 5*l.*

Dredging.

Costs include use of plant, dredging, and removing and depositing excavated material at sea. Steam dredgers cost 10,000*l.* to 40,000*l.* each ; hopper and dredger barges, 300*l.* to 1,000*l.*

Description.	Material.	Per yd. cube.	Per ton.
Bucket dredging, or 'ladder dredging'	Mud, sand, or soft clay	1*s.* to 2*s.*	9*d.* to 1*s.*
	Gravel or stiff clay	2*s.* „ 3*s.*	1*s.* „ 2*s.*
Grab dredging, or 'grapple dredging'	Mud, sand, or soft clay	2*s.* „ 4*s.*	1*s.* „ 2*s.*
	Gravel or stiff clay	3*s.* „ 5*s.*	2*s.* „ 3*s.*
Hand dredging, or 'bag and spoon dredging'	Mud, sand, or soft clay	3*s.* „ 4*s.*	2*s.* „ 3*s.*
	Gravel or stiff clay	4*s.* „ 6*s.*	3*s.* „ 4*s.*
Pump dredging, 'suction or hydraulic dredging'	Mud, sand, or peat	6*d.* „ 1*s.*	4*d.* „ 9*d.*

Blyth Harbour, Northumberland.—Actual cost of blasting and rock dredging:—

	s.	d.
Boring in hard sandstone	1	9
Explosives for blasting	1	4
Dredging, including repairs but nothing for the use of plant	3	0
Total per yard cube	6	1

Manchester.—Actual cost per yard cube of rock dredging on the Manchester Ship Canal during April 1907, by the Lobnitz rock-breaking dredgers:—The price of one rock-cutter was 6,800*l.*, and if 4 per cent. is allowed for interest, and 2½ per cent. for depreciation, the additional cost per yard cube is 2½*d.*, as added; 17,060 cubic yards were broken, the rock being sandstone, of varying hardness, with some stiff marl.

	s.	d.
Breaking, excluding cost of plant, but including maintenance and repairs	0	5½
Dredging	0	5½
Barging and tipping	0	6¾
Towage	0	2½
	1	8½
Add interest and depreciation on cost of plant	0	2½
Total per yard cube	1	10½

Similar work at Blyth cost 1*s.* 2½*d.* per yd. cube, and on the Suez Canal 1*s.* 4*d.*, average, exclusive of raising the rock by dredgers and carrying it away. Ordinary drilling, blasting, and dredging is more expensive—2*s.* 2½*d.* per yd. cube more.

Newry.—After blasting the bottom in a depth of 6 to 8 ft. at low water, the material was removed by dredging at 4*s.* to 5*s.* per yd. cube.

Severn.—Blasting and dredging the marl beds, 4*s.* per yd. cube.

Tees.—Blasting and dredging. In 1875 holes were drilled in the bed of the river Tees 7 to 9 ft. deep and 10 ft. apart, from a dredger; then dynamite blasting in 2 lb. charges. Average depth of rock blasted 4 ft. 6 ins., oolite shale. 110,000 yds. cube were blasted at 3*s.* 1*d.* per yd. cube, so as to be lifted by the dredger.

Ladder dredging in the Tees, mostly in hard boulder clay and lifting stones and tree trunks, cost 1*s.* 6¾*d.* per yd. cube.

Thames.—Contract cost of lifting ballast and clay by ladder or bucket dredgers from the Thames below London Bridge has varied from 1*s.* 4*d.* to 2*s.* 6*d.* per yd. cube, depending on distance material had to be conveyed.

Sand pump dredging 1*d.* or less per cubic yd., and grab dredging 2*d.* to 6*d.*, according to distance spoil has to be taken.

(See also pages 1348, 1349, 1350.)

ELECTRIC POWER STATIONS.

Town.	Total Cost.	Cost of Land and Buildings.	Kilowatts Housed.	Cost of Buildings per Kilowatt.	Total Cost per Kilowatt.

	£	£
Electric light installations for cities and towns, with buildings, plant, and mains complete	80 to 130	per kilowatt.
	3 „ 5	per 8 c.p. lamp.
Steam plant power stations	24	per kilowatt.
Oil plant power stations	23 „ 25	„
Capital cost of generating stations	20	„

Power and electric stations generally, brick, exclusive of plant and machinery. 10*l.* to 25*l.* per kilowatt	6*d.* to 8*d.* per f.c.
Aldershot electric lighting station (1902). Brick walls and slated roof	6½*d.* ,,
Curragh electric light generating station (1913–14). For three 100-h.p. Diesel oil engines, 66 kilowatts per engine, with a 750 ampere hour battery and accessory machinery. Contains a basement for engine beds, silencer chamber, and oil-fuel store, and above, on ground level, an engine-room, battery-room, store-room, two offices, and lavatory. Brick walls in cement mortar, 1 to 3, concrete foundations, engine beds and floors, steel sashes, steel roof, boarded and covered with asbestos slates. 99,700 ft. cube. Building only, exclusive of plant and machinery. Total, 2,080*l.*	5*d.* ,,
Building, including plant and machinery. Total, 7,456*l.*	1*s.* 6*d.* ,,
Cost of foregoing per kilowatt housed, 10*l.* to 38*l.*	
Extension to Curragh electric light station (1920–21). For one additional 100-h.p. Diesel oil engine and plant, 66 kilos, the extension of engine-room and exhaust pit being 12 ft. long, and same width and height as existing building. Construction also similar. A corrugated iron workshop, 18 ft. × 12 ft., is attached to the end of the brick extension, and included in total cost and cubing. Lump sum tender for both together. 17,600 ft. cube total. 17*l.* external services in addition. Building only, exclusive of plant and machinery. Total, 2,188*l.*	2*s.* 5¾*d.* ,,
Building, including plant and machinery. Total, 5,188*l.*	5*s.* 10¾*d.* ,,
Cost of foregoing per kilowatt housed, 33*l.* to 79*l.*	
East Ham electric power station, including tramway sheds and offices. Built by direct labour under the borough engineer. Total, 26,020*l.*	5½*d* ,,
Salisbury engine-room and boiler-house (1904). Brick walls and slated roof	6½*d.* ,,
Usual charges for current for electric lighting	2*d.* to 3*d.* per unit.
Ditto for heating and power purposes	1*d.* to 2*d.* ,,

(See also page 1898.)

Engineering Factories.

Engineering factories, brick, exclusive of machinery . . . . . 4*d.* to 7*d.* per f.c.

Material	52 per cent.
Labour	37 ,,
Power	5 ,,
Other costs	6 ,,
	100 ,,

Esplanades.

Marine Drive, Scarborough (1907).—Road 40 ft. wide, parade 20 ft. wide, and sea-wall 20 to 40 ft. high. Of concrete, on deep filling at base of cliff. Length, 1,400 yds. Total, 102,400*l.*, or 73*l.* per yd. run.

Gas Works.

Gasworks.—Gasworks complete, including buildings, plant, and distributing mains:

	Small Towns.	Large Towns or Cities.
Per head of population	30*s.* to 40*s.*	40*s.* to 50*s.*
Per ton of coal carbonised per annum	5*l.* to 6*l.*	6*l.* to 7*l.*
Per million cubic ft. of gas produced per annum	500*l.* to 600*l.*	600*l.* to 700*l.*

Land.—Area of land for the erection of works at least 2 acres per million cubic feet of gas per maximum diem.

Proportionate Capital Expenditure.—Including works, distribution plant, etc.:—

On buildings and works	38 per cent.
On district mains	55 ,,
On Parliamentary, promotion, and engineer's expenses	7 ,,
	100

Proportionate Cost of Parts.—Including buildings and plant :—

Retort house, including benches, fireclay retorts, etc.	25 per cent.
Purification buildings, with purifiers, gas scrubbers, etc.	30 ,,
Gasholders, iron or steel, with guide framing, brick-lined tanks, concrete bottoms, and excavation	40 ,,
Station meter-house, meter, and miscellaneous	5 ,,
	100

Retort-houses.—Including foundations and brickwork to benches, etc. :—

Exclusive of plant or machinery	5*d.* to 6*d.* per f.c.
Including retorts, ironwork, and fittings	1*s.* to 2*s.* ,,

Glover-West's system for vertical gas retorts, Belfast (1913) :—
70,950*l.* for a plant to carbonise 480 tons of coal per 24 hours,
=148*l.* ,, ,, 1 ton ,, ,,

Gasholders.—Steel or iron telescopic holders, including guide framing, etc. :—

	Per 1,000 cub. ft. of capacity. £ £
Single-lift holders, up to about 50,000 cub. ft.	25 to 28
If of the spiral type, 25 per cent. less	20 ,, 22
Two-lift holders, about 250,000 cub. ft. capacity	16 ,, 20
If spirally guided, about 50 per cent. less	8 ,, 10
Large holders, from 2 to 3 million cub. ft. capacity	9 ,, 12
The 10½-million holder at Manchester cost	5
The 12-million holder at East Greenwich Works cost	5 guineas

(See pages 2064, 2069, 2076, 2080.)

Harbours.

Artificial harbours complete, including reclamation of land, dredging, enclosure walls, breakwaters, landing stages, lighting, buoys, cranes, etc.

5,000*l.* to 10,000*l.* per water acre enclosed.

Colombo Harbour (1874–1914).—On the west coast of Ceylon and entirely artificial. It ranks twelfth among the greatest seaports, and there is ample space for 50 steamers besides smaller craft. The enclosed area is 650 acres (over a square mile), and depth 30 to 36 ft. at low water. Rise of tide at Ceylon is only 2 ft.

South-west breakwater, 1874–85, is 4,212 ft. long, built of concrete blocks weighing 18 to 30 tons on the sloping bond system, and cost 705,200*l.*, or 167*l.* per ft. run. Extension to ditto as a further protective arm, 1907–12, is 1,800 ft. long, also of concrete blocks, and cost 380,000*l.*, or 211*l.* per ft. run. North-east breakwater, 1894–7, is 1,100 ft. long, and constructed as a rubble embankment; the north-west or island breakwater, 1900–6, is 2,657 ft. long, and made of concrete; the two together cost 500,000*l.*, or 133*l.* per ft. run. Total length of the four breakwaters about 9,770 ft., with 5 lighthouses on them, and total cost 1,585,200*l.* Graving dock, 1900–4, is 700 ft. long, 85 ft. wide, and cost 400,000*l.*; patent slip, 1900–3, is 800 ft. long, and cost 43,000*l.*; coaling depot, on 24 acres of reclaimed land, has a frontage of 2,200 ft. with 18 jetties, and cost 163,000*l.* Other services, 821,900*l.* Total expenditure from 1874 to 1914 (forty years) was 3,013,100*l.* The small Fishery Harbour immediately to the northward has a rubble arm 800 ft. long, and cost 12,000*l.* The engineers were Sir John Coode, Son, and Mathews; and the resident engineers, Sir John Kyle, M.I.C.E., Mr. J. H. Bostock, M.I.C.E., Mr. John Kyle, M.I.C.E. (son of Sir John), and Mr. A. D. Prouse, M.I.C.E.

4,636*l.* per water acre enclosed; 162*l.* per ft. run, average of breakwaters.

Dover Harbour (1898–1909).—Original Admiralty Pier, 1,000 ft. long, was built in 1847–71. Dover Harbour Board then constructed a small commercial harbour of their own in 1890, between the existing Admiralty Pier and a new east pier, of 56 acres net area, afterwards increased to 75 acres by reclaiming the foreshore. The National Harbour was proceeded with in 1898-1909, and comprised the extension of the western breakwater, or old Admiralty Pier, from 1,000 to 3,000 ft., an eastern arm, 3,320 ft., and an isolated breakwater in the middle, 4,200 ft. Total sheltering works, 9,520 ft., or nearly 2 miles long, with two entrances 740 ft. and 650 ft. wide and 42 ft. deep at low water, enclosing 610 acres, exclusive of the 75 acres in the Commercial Harbour. Height of breakwaters from bottom of foundation to parapet top 60 to 126 ft. or an average of 90 ft., with 50 ft. average depth below low-water level, and 50 ft. average thickness, built of concrete blocks weighing 10 to 40 tons each and faced with granite above low-water level. Works include a sea-wall, 3,850 ft. long, to protect base of cliffs, a lesser sea-wall, 700 ft., and reclaiming about 20 acres of land. Engineers, Sir John Coode, Son & Mathews. Contractors, Messrs. S. Pearson & Son, Ltd. National Harbour, 610 acres, cost 4,000,000*l.*, and inside Commercial Harbour, 75 acres, 1,250,000*l.*, or a total of 685 acres and 5,250,000*l.*

National Harbour :	6,557*l.* per water acre enclosed ;	420*l.* per ft. run of breakwater.
Commercial Harbour :	16,666*l.* ,, ,, ,, ;	131*l.* ,, ,, ,,
The two combined :	7,664*l.* ,, ,, ,, ;	551*l.* ,, ,, ,,

(Breakwaters, see pages 1324, 2413.)

Heating.

The fewer the radiators, and the longer the run, the higher the cost per radiator. 15 ft. sup. of radiator should be supplied for every 1,000 cubic feet of space to be heated. Cost includes fittings complete, but is exclusive of boiler-house and buildings.

Heating buildings with boilers, pipes, and radiators . . . . . 1*l.* to 4*l.* per 1,000 f.c.
Low-pressure hot-water heating . . . . . 8*l.* „ 10*l.* per radiator.
Hot-water work inside a building . . . . . 1*s.* 6*d.* per ft. run.

(See also pp. 2104, 2115, 2116.)

Landing Slips.

Landing Slips, Milford Haven (1894).—Formed of Portland cement concrete, with shingle supplied by contractor, and 8 ft. wide × 3 ft. high, on 18-in. foundations. In tidework, and not exceeding 40 yards from shore. Excavation in boulders and shingle on beach. 30*s.* per foot run.

Lighthouses.

Lighthouses. (All of Granite).	Date.	Height of Focal Plane above High Water.	Engineer.	Total Cost.	Cubical Contents.	Cost per Ft. Cub. of Masonry.

Lighthouse, Kovilam Point, Northern Province, Ceylon (1914-16).—Tower is supported on reinforced concrete platform over hardwood piles, and built of dressed coral stone in lime mortar, cement rendered externally. Walls 2 ft. 7½ ins. thick above plinth, carried up with a uniform thickness at a batter of 1 in 48. Internal diameter of tower 8 ft. 3 ins., and height from top of foundation to reinforced concrete cap 91 ft. Fourth order light visible for 16 miles, and focal plane 97½ ft. above mean sea level. Cost, exclusive of lantern and ironwork above the cap, 1,730*l.*, or 1*s.* 6*d.* per foot cube.

Lighting.—A complete gasworks plant for a lighthouse costs about 800*l.*
Annual expenditure for gas lighting, where works are installed . . . . 72*l.* per light.
„ „ „ „ where gas is supplied from elsewhere . 32*l.* „

A first-class electric lighthouse installation, including optical apparatus, lantern, dynamos, engines, air compressor, siren, etc., but not buildings, costs about 6,000*l.*

Maintenance.—Average annual cost of maintenance of an English shore lighthouse, with two keepers, is 280*l.*

Average annual cost of maintenance of an English shore lighthouse, with three keepers and a siren fog signal, is 450*l.*

Annual maintenance of a rock lighthouse, with four keepers and an explosive fog signal, is about 800*l.*; and of an electric light station 1,100*l.*

Lightships.—Steel lightships, of average size, with power driven compressed air siren, cost about 16,000*l.*

Annual maintenance of ditto, including periodical overhaul, 1,320*l.*

Usual limits.—Length	80 to 114 ft.
Beam	20 „ 24 „
Depth moulded	13 „ 16 „
Tonnage	155 „ 280 „

(See also page 1356.)

LIGHTING.

Buildings.—Cost of gas and electric lighting inside buildings, including service pipes, stop-cocks, ordinary brackets, pendants, switches, wiring, and other articles, fixed complete, but excluding meters, external gas mains, generators, etc.

	s.	*s.*	
Acetylene	20 to	40	per light.
Coal gas	30 „	50	„
Electric	25 „	50	„

Wiring, including all necessary wire, switches, fuses, lamps, holders, casings, etc., but not electroliers or shades, 15*s.* to 40*s.* per lamp.

Installing artificial lighting per 100 points, including oil-engine, dynamo, wires, lamps, etc., but excluding buildings :

Acetylene.	Petrol Gas.	Electric Light.
100*l.* to 200*l.*	150*l.* to 200*l.*	200*l.* to 300*l.*

Acetylene.—Cost of upkeep consists mainly in the purchase of carbide with occasional renewal of burners. A 25 c.p. burner of ordinary type consumes about 1 f.c. of gas per hour, which demands $\frac{1}{6}$ lb. carbide. With calcium carbide at 15*s.* per cwt. the cost of such a burner works out at $\frac{1}{2}d.$ per hour. Total upkeep of a 100-light installation is between 20*l.* and 30*l.*, according to number of hours lights are used.

Gas Lighting of the Castle, Carlisle (1896).—Supply from City of Carlisle Gas Company's mains through a 600-light dry meter supplied by Company. 4 in., 3 in., and 2 in. cast-iron mains and 1½ in. to ¼ in. galvanised wrought-iron service pipes, underground pipes 3 to 3½ ft. deep. Fittings include 19 governors, 10 valves, 20 stopcocks, 10 dry meters, 572 burners, 10 Wenham lights, 12 Schulke lights, 20 Deimel lights, 18 Welsbach incandescent lights, 12 Sugg's lights, etc. Occupation of barracks, 731 adults and 72 married quarters.

Total, 1,144*l.* 36*s.* per light or point. 28*s.* per head.

Gas Lighting of Strensall Camp, near York.—Completed 1915, in extension of the York Gas Co.'s mains. Cost includes 3-in. external steel mains, 2-in to ¾-in. wrought-iron branches, brick meter-house and meters, siphons, stopcocks, burners, excavation, fixing, etc., complete, in huts and 40 married quarters for about 1,260, total of officers, N.C.O.'s, and men. 376 incandescent burners and 584 flat-flame burners, or 960 lights altogether.

Total, 1,780*l.* 37*s.* per light or point. 28*s.* per head.

Electric Lighting, Army Pay Offices, York.—Feb. 1915. 84 electric lights, mostly of 100 c.p. each, including opal glass shades, wiring, cords, switches, fuses, etc., but not cable into building or any plant, as taken from the Corporation electric main in road. 18 officers and 300 clerks.

Total, 91*l.* 22*s.* per light or point. 6*s.* per head.

Electric Lighting, Army Pay Offices Extension, York.—Aug. 1916. One-storey corrugated iron building, lined with plaster slabs. 136 electric lights, mostly of 100 c.p. and 50 c.p. metal filament lamps, including pendants, opal and holophane glass shades, wiring, cords, 109 switches, fuses, distribution boards, etc. Direct-current supply on the three-wire system taken from the Corporation electric main in adjacent road. 24 officers and 400 clerks.

Total, 137*l.* 20*s.* per light or point. 6*s.* 6*d.* per head.

Railway Coaches.—	£
Cost of fitting a railway coach with electric light	130
„ „ „ „ incandescent gas	34
Annual maintenance of an electric lit railway coach	13
„ „ a gas „ „	7

STREET LIGHTING AT CROYDON.

(1910.)

Type of Lamp.	Number of Lamps.	Distance Apart.	Total Cost.	Average c.p. per Mile.	Cost per c.p. per Annum.
	No.	Yds.	£	c.p.	*d.*
Incandescent gas .	2,137	80	7,062	839	15·86
Incandescent electric	90	66	288	1,373	13·71
Electric arcs . .	428	65	7,212	10,537	11·32

LOCKS.

Including foundations, invert, walls, gates, sills, machinery, lock-keeper's cottage, etc.

Brick and concrete	Per yd.cu. of internal capacity 30*s.* to 50*s.*
Stone and concrete	" " " " 40*s.* " 60*s.*
Canal locks	each 5,000*l.* to 15,000*l.*
River locks	" 15,000*l.* " 30,000*l.*

MARINE PIERS.

Timber and iron piers for seaside places, with creosoted fir or iron screw piles, averaging 40 ft. long and driven up to 15 ft. in sand or shingle, including braces, ties, timber decking, railings, tarring, gates, seats, etc.

Gangway or promenade portion	8*s.* to 12*s.* per ft. sup.
Landing stage or head to pier	10*s.* " 16*s.* "

Military Pier, Tilbury (1896).—450 ft. long by 16 ft. wide, or 7,200 ft. sup. Height above h.w.o.s.t. level, 4 ft., and above l.w.o.s.t. level, 20 ft. Foundation, 3 ft. of mud over 20 ft. of chalk, the distance bored. Substructure of wrought-iron piles, 10 ft. apart, with rod iron braces, on which are fixed wrought-iron girders with intermediate joists supporting timber decking. 18-in. gauge tramway rails, 24 lbs. per yard, and steam crane to lift 10 tons. Total cost, including 500*l.* for hoisting machinery, 3,200*l.*, or 8*s.* 11*d.* per ft. sup.

Batticaloa Jetty, Eastern Province, Ceylon (1900).—Timber pier, 50 ft. long, with return portion 22 ft. long, and 10 ft. wide. Cost, 5*s.* 6*d.* per ft. sup.

Galle Jetty, Southern Province, Ceylon (1916).—Jetty is 162 ft. long × 20 ft. wide, carried on concrete cylinders 6 ft. diameter, spaced 20 ft. centre to centre longitudinally and 14 ft. transversely, end pair being taken down to a depth of 20 ft. Special cylinders, 8 ft. diameter, form seats for two 3-ton cranes. Jetty is roofed for a length of 137 ft. Cost, 4,923*l.*, or 1*l.* 10*s.* per ft. sup. Cost of cylinders sunk, 6 ft. diameter, 3*l.* 19*s.*, and 8 ft. diameter, 5*l.* 3*s.*, per ft. run.

Kalkudah Jetty, Eastern Province, Ceylon (1901).—Jetty of iron, with wooden joists and planking, 165 ft. long × 28 ft. wide, and landings. Piles of H-iron section, 9 ins. × 7 ins., carried through a stratum of sand about 8 ft. into the coral bed of 1 to 2 ft. thick. Cross bracing, walings, fenders, etc. Corrugated iron roof over 122 ft. of length, supported on iron principals carried by H-iron standards, 8 ins. × 6 ins. Water 8 ft. deep at end of pier. Cost, including crane seat, 2,516*l.*, or 11*s.* per ft. sup. of platform area.

Paddiruppu Jetty, Eastern Province, Ceylon (1900).—70 ft. long with a tee head 30 ft. × 6 ft. wide, constructed of Palu timber with brick abutment. Cost, 8*s.* per ft. sup.

MINING.

(See Section XXXVI., page 2153.)

PILE DRIVING

(See page 502.)

RAILWAYS.

Average cost of railways, main lines, 4 ft. 8½ in. gauge, double track, total capital expenditure, including land and all charges :—

	£	£
In England	35,000 to	45,000 per mile.
„ Scotland	25,000 „	35,000 „
„ Ireland (5 ft. 3 in. gauge)	20,000 „	25,000 „
„ Europe	15,000 „	25,000 „
„ India (5 ft. 6 in. and metre gauge)	12,000 „	25,000 „
„ Norway, light railways, 3 ft. 6 in. gauge	5,000 „	10,000 „
„ Queensland „ „ „	7,000 „	15,000 „
„ United States	8,000 „	12,000 „
Single line railways in poor districts of Scotland and Ireland	5,000 „	7,000 „

(See also page 653.)

PROPORTIONATE COST OF PARTS.

Earthworks	24 per cent.
Tunnels	10 „
Permanent way, including ballast	12 „
Sidings	3 „
Junctions and signals	1 „
Bridges and viaducts	9 „
Culverts and drainage	5 „
Stations and buildings	6 „
Construction only	70 „
Land and compensation	15 „
Rolling stock	10 „
Legal expenses	5 „
	100

	£	£
Main lines, construction work and stations only	10,000 to	20,000 per mile.
Light railways „ „ „ „	1,000 „	3,000 „
Permanent way, single line, light construction, 4 ft. 8½ in. gauge, in flat country, cuttings and banks averaging 3 ft., rails 55 lbs. per yard, ballast 15 ins. deep, including stations and permanent works, but excluding land and rolling stock	5,000 „	6,000 „
Ditto, heavy construction, 75-lb. rails, and 24 ins. ballast	6,000 „	8,000 „
Yearly maintenance of permanent way	200 „	250 „
Rolling stock, single line, depends on kind of traffic	700 „	1,000 „
Permanent way, double line, in excess of above figures	50 „	75 per cent.
Rolling stock „ „ „ „	10 „	30 „

Working expenses in England average 50 per cent. of the gross receipts.
„ „ Scotland „ 45 „ „ „
„ „ Ireland „ 40 „ „ „
Average gross receipts, 4*s.* to 6*s.* per train mile.

Railway Footbridges.—Of iron or steel, including foundations, supports, girders, floor, staircases, lattice sides, etc., erected complete, 5 ft. wide.
250*l.* to 350*l.* each, 30 to 40 ft. span, or 15*s.* to 20*s.* per ft. sup.

Railway Viaducts.—On the Great Western Railway there are a great many viaducts, especially in Cornwall, commencing at 50 to 60 ft. deep, and being as much as 90 or 100 ft., and even up to 150 ft., in the centre of the gorge. They are, as a rule, about 60 ft. spans between the piers, which is found to be the economical width. Segmental arches nearly, but not quite, semi-circular, 3 ft. thick at centre, and 3 ft. 9 ins. at the springing. Piers, 7 ft. 6 ins. wide at the top, tapering on every side at 1 in 32. This gives a pressure of about 8 tons per square foot on the masonry. The cost comes out for such a structure, carrying two lines of way, at 1*l.* per yard forward per foot high, measured from ground to rail. That is, for example, a viaduct 200 yards long, and averaging 70 ft. in depth, will cost 14,000*l.*

Avon Viaduct.—On the Midland Railway, and of brick. 720 ft. long, 51 ft. high, and 11 arches of 50 ft. span. Cost, 14,000*l.*, or 19*l.* per ft. run.

Congleton Viaduct.—On the Manchester and Birmingham Railway, and of stone. 3,080 ft. long, or over ½ mile, and 106 ft. high. Cost, 113,000*l.*, or 37*l.* per ft. run.

Dove Viaduct.—On the same line, and of brick. 1,716 ft. long, 88 ft. high, and 23 arches of 63 ft. span. Cost, 54,000*l.*, or 32*l.* per ft. run.

Viaduct over the River Eye, Berwickshire (1889).—Six openings of 50 ft. clear span, 55 ft. 3 ins. between centres of piers, and extreme height above bed of stream 60 ft. Total length of bridge 331 ft. and 15 ft. wide; single track. Abutments of 1 to 7 concrete. Five piers, 45 ft. high and 12 ft. wide at top, with 9-in. and 18-in. brick face and concrete hearting, and 9-in. brick wall up the centre. Superstructure of lattice main girders 8 ft. apart, with cross girders of 10-in. × 5-in. rolled iron joists, 40 lbs. per ft. run. Flooring of 4-in. planking, and the rails carried by longitudinal beams, 14 ins. × 12 ins. Cost, 3,700*l.*, or 11*l.* per ft. run, or 15*s.* per ft. sup.

Viaduct on the Gifford Light Railway, Haddingtonshire (1900).—Four spans of 42 ft. 8 ins., centre to centre of three piers, with 1 to 6 concrete foundations. Height to rail level above the bed of stream is 50 ft., and length over all 194 ft. by 18 ft. wide; single track. Masonry piers, haunches, and abutments, and brick arches over openings. Cost, 2,043*l.*, or 11*l.* per ft. run, or 12*s.* per ft. sup.

New York Elevated Railroad (1872-80).—Steam traction. Two lines of way supported on square wrought-iron lattice-work columns, let into cast-iron base blocks founded on brickwork and concrete, at distances of 37 to 44 ft. apart. Rails of Vignoles or flange pattern, of Bessemer steel, weighing 50 lbs. per yd. run, spiked to cross timber sleepers and guarded by longitudinal timbers. Sharpest curve is 90-ft. radius. Steepest gradient, 1 in 50 for a length of 800 yds. Stations about ¼ mile apart, with platforms 200 ft. long and 13 ft wide. No payment was made for way-leave along the streets, nor for compensation to frontages. Length, 35 miles. Total cost, 2,870,000*l.* Cost per mile of double track :—

	£
Foundations, columns, girders, superstructure, and permanent way	57,696
Railway stations and platforms	12,000
Rolling stock, 5 locomotives and 12 cars	11,680
Per mile of double track	81,376

Tube or Underground Railways.—Electric traction, as constructed in London. Two tracks, 4 ft. 8½ in. gauge, each laid in a separate tunnel, 11 to 12 ft. diameter. 300,000*l.* to 600,000*l.* per mile of double track.

	£	
London (Central), 6 miles. 13 stations	580,000	per mile of double track.
London (Waterloo and City), 1½ miles	340,000	„ „ „

Steam Traction.—Two tracks, 4-ft. 8½-in. gauge, laid in elliptical tunnel, 29 ft. wide and 17 ft. high, of 27-in. brickwork on concrete foundations.

	£	
London (Metropolitan), 1860-84	600,000	per mile of double track.
London (Metropolitan District)	250,000	„ „ „

Both the foregoing have since been converted to electric traction.

Cost of electrification only, exclusive of power stations, sub-stations, rolling stock, etc., 5,000*l.* to 10,000*l.* per mile of double track.

Cost of Indian Railways.—For the year 1895 the capital cost (rupee at 1*s.* 3¼*d.*) of Indian railways was :—

	£	
Standard gauge, 5 ft. 6 ins.	10,095	average cost per mile.
Metre gauge, 3 ft. 3⅜ ins.	4,519	„ „
Special gauges, 2 ft. 6 ins. and 2 ft.	2,093	„ „

London Railway Stations.

3 0	12	2	30	3,000 „ 3,500
3 3½	17	3	40	3,500 „ 4,500
3 6	20	3½	50	4,000 „ 5,000

Belgium.—Over 1,000 miles of minor lines have been constructed at a cost, including rolling stock and all outlay, of rather less than 3,000*l.* a mile. These are generally on the metre gauge (3 ft. 3⅜ ins.), and as many of them appear to be laid on the roads the cost of land is very small. They earn about 6*l.* per mile per week, and working expenses are 66 per cent., or 4*l.* per mile per week. Net earnings of 2*l.* per mile per week give a return for over 3 per cent. per annum on the capital.

England.—In England a line on the standard gauge, with no heavy works, would cost twice as much as the Belgian metre gauge railways, or say 6,000*l.* per mile. As regards land, a light railway can seldom do with less than an average width of 1 chain (66 ft.) or 8 acres per mile, and this at 100*l.* per acre comes to 800*l.* per mile. Hence to run the line on a strip of green alongside a road would save a good deal of expense, but this might involve bad gradients and sharp curves and the maximum speed would be reduced. The following are some actual costs :—

Clogher Valley Railway, Ireland.—Length 37 miles, 3 ft. gauge, 45-lb. rail, and runs for the most part on the side of the road. Cost, 3,500*l.* per mile. It earns about 4*l.* per mile per week, but this is mostly absorbed in working expenses.

Wisbech and Upwell Light Railway, Cambridgeshire.—Length 5¾ miles, with 2 miles of sidings, standard gauge, 50-lb. rail, and runs mostly on the edge of the road. Cost, excluding sidings, 7,000*l.* per mile of line. The earnings are about 9*l.*, and the expenses 7*l.* per mile per week.

Agrails.—The Decauville tracks of the new light railways, or 'agrails' as they are called, did admirable service at the front, both in France and Belgium. They can be laid at a cost of 2,500*l.* per mile, and are now being put forward as a rival or as an adjunct to motor lorry traffic, to save the costly wear and tear of roads and to relieve congestion. They can be run on the edge of existing roads, with sidings on the various farms, but are only suitable for comparatively flat districts. The old narrow-gauge railways were too solidly and expensively built, but the agrails are of very light construction and should prove most useful.

River Canalisation, see page 1373.

River Regulation, see page 1371.

Roads.

	£ £	
Main roads, 30 to 40 ft. wide, for heavy traffic, constructed complete, including bottoming, metalling, gravelling, watering, and steam rolling	3,000 to 5,000	per mile.
By-roads, 20 to 30 ft. wide, for light traffic, and ditto ditto ditto	1,000 „ 3,000	„

Maintenance of Roads.

	£ £

Wood-block " "	1 0	" 1 6	" "
Ordinary macadam "	1 0	" 2 0	" "
Tarred macadam "	0 4	" 0 9	" "

Cost per Head.—Cost per head of population for maintenance, repair, and improvements to roads, 6*s.* to 7*s.* per annum.

Damages.—Cost of maintenance has increased about 30 per cent. within recent years owing to traction engine and motor traffic. Damage through traction engines, steam lorries or carts is often assessed at 1*d.* to 2*d.* per ton per mile conveyed over the road. Damage by 'extraordinary traffic' sometimes 2*l.* to 3*l.* per mile.

Supervision.—Cost of supervision, including county surveyor's and clerk's salaries, office expenses, audit of urban accounts, etc., 3 to 6 per cent. on cost of maintenance.

(See also 'Roads,' Section XIV, p. 701.)

ROOFS.

	£ £	
Roofs, light, corrugated iron, 18 to 22 gauge, exclusive of iron or steel trusses	2 to 3	per square.
Roofs for light cheap sheds and buildings, including trusses, corrugated sheeting, gutters, etc., fixed complete	5 " 8	"
Roofs, ordinary steel and iron, including purlins, boarding, gutters, etc.	5 " 10	"
Roofs, railway station platform, with glass	10 " 20	"
" " termini, over 150 ft. span, fixed complete	30 " 45	"

Victoria Station and Charing Cross Station have since been entirely rebuilt.

SEWAGE WORKS.

Sewage disposal works for cities and towns	3*l.* to 6*l.* per inhabitant.
Bacteria filter-beds with earth embankments and floors, completed with clay puddle, and filled in with clinker or coke breeze 3 ft. deep	5*s.* to 10*s.* per yd. sup.
Ditto with concrete walls, and clinker or coke breeze 4 ft. deep	20*s.* to 30*s.* "

Precipitation and sludge tanks in the north-west of England, to treat a million gallons of sewage daily, built in 1910. From actual tenders received.

	£
Scheme with cast-iron tank plates	7,000
" " brickwork in cement	6,000
" " reinforced concrete	4,500

Strensall Camp Sewage Works, near York (1914–16).—For 1,000 nominal number of troops at 20 gals. per head per day, or 20,000 gals. sewage per day. Lift system, ground being low and sandy. Drainage connections comprised replacing 86 e.c.'s by w.c.'s, 18 additional w.c.'s, or 104 total w.c.'s, 234 gullies, and 80 manholes, with 4-in. and 6-in. stoneware drains gravitating to the ejectors. Brick engine shed, 15 ft. by 14 ft., for air compressor plant with 2 gas engines, and 4 ejector pits, with 12-in. concrete walls lined with $\frac{3}{8}$-in. cast-iron plates, and concrete floors with expanded metal: pits octagonal in plan, 12 ft. internal diameter and 12 ft. average depth,

containing 5 pneumatic ejectors, 25 gallons each, 1 pit holding 2 ejectors. 2½ in. steel compressed air mains from engine-house to ejectors, which raise sewage to the 5-in. and 6-in. cast-iron rising main drains and thence 1,700 yards (about a mile) to the outfall works. Total lift for sewage 19 feet. Outfall works include two reinforced 6-in. concrete tanks, 20 ft. × 10 ft. × 6 ft. each, containing 7,500 gallons, or 15,000 gallons altogether; two brick sludge beds, 20 ft. × 10 ft. × 3 ft. each, with 10-in. screened ashes at bottom and 4-in. agricultural drains on 6-in. concrete floor; two circular filter beds, 46 ft. diameter, with rubble sides and reinforced concrete floors filled with 5-ft. furnace clinker, ½-in. to 4-in. gauge, the liquid sewage being distributed by a revolving sprinkler delivering 84,000 gallons per day. Special filter tiles on floor for aeration, concrete surface channel all round, and effluent then taken by waterways for land irrigation prior to discharging into existing ditch. Cost under five separate contracts:—

	£
Drainage connections, w.c.'s, stoneware drains, and manholes	2,710
Brick engine shed, and four concrete and iron ejector pits	775
Five ejectors, compressors, two gas engines, 2½-in. steel air mains, and 5-in. and 6-in. cast-iron main drains	1,837
Outfall works, including tool house, wire fence, and entrance road	2,035
Preparation of 13 acres of land, waterways and ditches for effluent	493
Total cost	7,850

Cost per head, 7*l.* 17*s.*, or 892*l.* 10*s.* per 1,000 gals. per day treated.

Steam Excavating.

The 'Ruston Crane Navvy' is made in five standard sizes with bucket capacities varying from ⅝ to 4 cubic yards capacity and weighing from 16 to 120 tons net, and will do the work of from 30 to 200 men. The cost may be reckoned from 2*d.* to 6*d.* per yard cube; the harder the material the greater the saving. A medium size machine fitted with a 2¾ cubic yard bucket will readily excavate and load into wagons 800 to 1,000 tons of ironstone or stiff clay per day of 8 hours at a pre-war cost of 2*d.* per cubic yard, or 3*d.* including interest, depreciation and repairs. The following can be reckoned upon as a fair average output under ordinarily good working conditions in a day of 8 hours:

Machine with	⅝	cubic yard bucket	200	in medium clay	to 450 in sand
,,	1½	,, ,,	300	,, boulder clay	,, 800 ,,
,,	2	,, ,,	400	,, well-blasted rock	,, 1,000 ,,
,,	2¾	,, ,,	500	,, ,,	,, 1,500 ,,
,,	4	,, ,,	800	,, ,,	,, 2,500 ,,

A 'Wilson' excavator will dig 400 to 630 yards cube per working day, at a rate of 1*d.* to 6*d.* per yard delivered into wagons, a gang of 14 men being required.

A 'Whitaker' machine will do as much as 720 yards cube per day, but the average is 500 yards at a price of ¾*d.* per yard. The buckets are 1½ yard cube capacity, the crane 10 tons, and the total weight of the machine 32 tons.

French and German endless bucket excavators are particularly useful for digging in light soil or stiff clay, and to a depth of 16 or 20 ft. at a time. The average day's work is 1,200 to 1,500 yards cube at a cost of 5*d.* per yard. They need 35 men in attendance.

Stationary or travelling steam cranes may be employed to work iron or wooden skips, which are like large buckets or boxes respectively, and hold ½, ¾, or 1 yard cube, made to discharge from the crane over a wagon Woodford's patent steel skips are best, self-righting, and with safety catch.

In working grabs, the cost in some cases may be taken as about half the price of hand labour, the saving is greater when under water. When dredging Limerick harbour with a Priestman's grab the average cost of dredging and discharging was 1¾*d.* per ton.

Tanks.

Tanks, cast-iron, 5,000 to 10,000 gals., supplied only.	1*s.* 6*d.* to 2*s.* per f.c.,	3*d.* to 4*d.* per gal.
,, wrot.-iron ,, ,, ,, ,,	2*s.* to 2*s.* 6*d.* ,,	4*d.* ,, 5*d.* ,,
Galvanised wrot.-iron square cisterns, 14 W.G., 50 to 500 gals. capacity, exclusive of fixing	2*s.* 6*d.* to 4*s.* ,,	5*d.* ,, 8*d.* ,,
Add if covered in at top	6*d.* to 1*s.* ,,	1*d.* ,, 2*d.* ,,

Telephones.

Providing and fixing complete, including copper line weighing 150 lbs. per mile, with poles, brackets, insulators, etc.

25*l.* for ¼ mile; 30*l.* for ½ mile; 38*l.* for 1 mile; and beyond, 30*l.* per mile.

Tramways.

Approximate Cost per Mile.	Single Track. £ £	Double Track. £ £
Electric tramways, overhead trolley system, with span wires, including buildings and equipment, but exclusive of generating station for electricity	9,000 to 12,000	15,000 to 20,000
Ditto, ditto, with side brackets or centre poles	7,000 „ 10,000	14,000 „ 18,000
Overhead equipment, including supports :—

The Peak Cable Tramway, Hong-Kong (1888).—Rises 1,207 ft. in a total length of 4,690 ft. Maximum gradient 1 in 2, and minimum 1 in 25. Three intermediate stations, and top and bottom termini. Single track 5 ft. gauge of two 30-lb. rails, and steel sleepers 24 lbs. per yard. Midway crossing place 130 ft. in the clear, above which the track is formed of three rails. Power-house at summit, with two engines, boilers, etc. Steel haulage cable, 3½ in. circumference, weighing 2 lbs. per ft. run. Rolling stock consists of two cars, each holding 45 passengers, and one ascends while the other descends, 9 minutes per trip. Total cost, 20,000*l.*, or at the rate of 22,516*l.* per mile.

(See also page 677.)

Tunnels.

Chab Tunnel (1897–8).—On the Mari-Attock Railway, Punjab, India. Constructed between June, 1897, and July, 1898, through sandstone. Length, 1,312 ft., or about ¼ mile, of which 312 ft. were cut and cover. Average progress per day, 1½ yds. Total cost, 18,690*l.* (equivalent to 74,760*l.* per mile), or 43*l.* per yard run. Maximum altitude above sea-level 1,350 ft., and greatest depth of axis beneath surface 150 ft.

Single track in horseshoe-shaped tunnel, lined with brickwork 5 to 6 bricks thick, or 26 to 31 ins., internal diameter at centre 15 ft., and internal height 19 ft. Backing of round stones found on the local hill slopes.

Tunnel Maintenance.—Cost of reinstating five 3 to 6-ring double-track railway tunnels, Clayton, Cliftonville, Balcombe, Rotherfield or Crowborough, and Mickleham, in chalk, clay, and sand, in the south of England, built between 1837 and 1875 and repaired between 1887 and 1917, including cutting out the inner ring and replacing by a brindle ring in cement, sometimes an additional ring, or part of the tunnel inverted, toe wall built to the footings, parts of the wall re-lined, or spaces behind walls and over arches filled with concrete, etc., the work being carried out day and night during traffic by contract or departmentally, a single line being run at night, and taking various periods of from three to eight years to complete.

11*l.* to 20*l.* per lineal yard.

Other tunnels requiring more extensive repairs, such as shoring, bad portions cut out, and completely rebuilt, use of cement gun, etc.

30*l.* to 250*l.* per lineal yard.

Water Towers.

Water towers, brick, exclusive of tanks and pipes, 1*s.* to 1*s.* 4*d.* per ft. cu. 2*s.* to 5*s.* per gal.
Water supply inside a building, including service pipes, taps, etc. 2*l.* 10*s.* to 3*l.* per tap.

Beverley Water Tower, Yorkshire (1915).—Built of reinforced concrete on the Hennebique system. Two circular tanks, one within the other, the inner one holding 4,000 gals. and the other

Mont Cenis	1857–71	14	7½	3	3,000,000	400,000	227	4,248	4,090	France to Italy. One tunnel, 26 ft. 3 ins. wide × 24 ft. 7 ins. high, with double track. Through solid granite, and lined with brick and stone.
Rotherhithe	1904–08	4	1⅓	1⅔	1,250,000	1,041,700	587	—	—	One tube, 30 ft. diameter. Top 7 ft. below bed of Thames. Fitzmaurice, engineer. 4,863 ft. between portals, and 1,400 ft. directly under the river. Max. progress in 1 day 10½ ft.
Severn .	1873–86	13	4½	2	2,000,000	444,400	252	—	100	Width 26 ft. × 25 ft. high. Double track. Water-logged ground and expensive pumping. Hawshaw, Hayter, and Richardson, engineers.
Simplon .	1898–1905	7	2⅓	10	3,120,000	253,000	144	2,313	7,005	Switzerland to Italy. Two single-track tunnels, each 16 ft. 5 ins. wide × 19 ft. 6 ins. high, 56 ft. apart, axis to axis. Enlarged 1911, at a cost of 1,600,000*l.* A. Brandt, engineer.
St. Gothard	1872–82	10	9⅓	6	9,080,000	972,900	553	3,787	6,076	Switzerland to Italy. Two lines of way in a single tunnel, 26 ft. 3 ins. wide × 24 ft. 7 ins. high, in granite, lined with masonry. Louis Favre, engineer.
Thames .	1825–43	18	½	⅓	482,000	1,928,000	1,300	—	—	Between Rotherhithe and Wapping. Brunel, engineer. Delay in completion due to water difficulties. Foot subway, with spiral stairways at each end. Used since 1865 as a tunnel by East London Electric Rly., and lengthened to 1¼ mile.

It is generally cheaper to tunnel than to make a cutting over 50 ft. in depth, but a good deal depends upon whether earth is required

7,200 gals., or a total of 11,200 gals. Extreme diameter 34 ft., and 10 ft. internal depth, with three 6-in. cast-iron outlets, 4-in. sides, 2-in. curved dome top, 4-in. bottom, with beams under, supported on three 12-in. × 12-in. columns or legs, 30 ft. high, with 12-in. × 8-in. braces to latter and half-way up. Total height from ground level to top of tank, 42 ft. 6 ins. Concrete foundations, 2 ft. deep. Cost, including materials and erection, 312*l.*, or 27*l.* 17*s.* per 1,000 gals.

Bramham Moor Water Tower, near Tadcaster, Yorkshire (1916).—Designed by the Trussed Concrete Steel Co. Two united rectangular tanks, 4,000 gals. and 6,000 gals., or a total of 10,000 gals.; two iron ladders inside the tanks for cleaning purposes, and 3-in. cast-iron outlets; 5-in. sides, 3½-in. flat top, 6-in. bottom, with 24-in. × 10-in. beams under, supported on four 10-in. × 10-in. columns or legs, 20 ft. high, with 10-in. × 6-in. braces to latter and half-way up. Foundations 2 ft. 6 ins. deep in addition. Cost, including materials and erection, 298*l.*, or 29*l.* 16*s.* per 1,000 gals.

Curragh Water Tower (1900).—Heavily built, 34 ft. square externally and 94 ft. high above ground. 6 stories. Concrete foundations 6 ft. thick, brick walls in cement 45 ins. thick below to 22 ins. at top. Flat concrete roof, asphalted. Contains two cast-iron tanks, 20,000 gals. each, or 40,000 gals. total. Lower floors used as a fire engine station. Building only, 9,300*l.*; cast-iron tanks and pipes, 1,630*l.*; special fittings, 70*l.* Total, 11,000*l.*

1*s.* 4*d.* per ft. cu. 275*l.* per 1,000 gals

WATERWORKS.

Waterworks, comprising reservoirs, filter beds, mains, valves, hydrants, etc., complete :

	£		
Birmingham	3	per head of population	
Dublin	2	,,	,,
Edinburgh	3½	,,	,,
Glasgow	3	,,	,,
Liverpool	4	,,	,,
Manchester	3	,,	,,
Generally speaking	2*l.* to 4	,,	,,
Small waterworks in Ireland (20 to 25 galls. per head.)	2*l.* to 2½	,,	,,

Batticaloa Water Supply, Eastern Province, Ceylon (1915–16).—Supplies a population of 6,000 with about 20 gals. per head per day. One central well 10 ft. diameter, and two auxiliary wells same diameter, connected by adits 500 ft. long, yielding 180,000 gals. per day. From the central well the water is pumped through a 7-in. steel delivery main to the reservoir, 4 miles distant, from which the town is supplied by gravitation by 2-in. and 1½-in. distributing mains to 75 standpipes. 11¼ miles of pumping and service mains altogether. Pumping machinery in duplicate, 3-in. centrifugal pumps, belt-driven by 18 B.H.P. oil engines, each pump capable of delivering 10,000 gals. per hour against a total head of 60 ft., or a total pumping capacity of 100,000 gals. per diem working 10 hours. Wells lined with 12-in. concrete, roofed with concrete slabs. Storage reservoir of 100,000 gals., with concrete walls faced in brick cement rendered and roofed with corrugated iron on steel trusses. Cost, 9,533*l.*, or 95*l.* per 1,000 gals., or 1*l.* 12*s.* per head of population supplied.

New Magdalen Barracks Water Supply, Oxford (1896).—Supply from City of Oxford Water Company's mains, constant service, Siemens' meter supplied by Company. Davey's lift and force pump worked by steam power, and 6 in. cast-iron mains, 3 in. cast-iron domestic supply mains, and 1½ in., 1 in., ¾ in., and ½ in. galvanised wrought-iron service pipes, 3 to 4½ ft. deep. Reserve tank of 13,000 gals. for fire purposes, 60 ft. high on Armoury roof, 18 fire hydrants, 20 sluice valves, 40 stop valves, 280 bib valves, 50 3-gal. flushing cisterns to w.c.'s, and 6 200-gal. cisterns to latrines. Occupation of barracks, 500 adults, 100 children, and 5 horses. Total cost, including 80*l.* for machinery and erection, 3,500*l.*, or 5*l.* 16*s.* 8*d.* per head of occupation, exclusive of horses. 6*s.* 6*d.* per yd. run of excavation, exclusive of machinery, but inclusive of all fitments.

(See also page 1297.)

IMPOUNDING RESERVOIRS.

Impounding reservoirs for gravitation waterworks to large towns, including excavations, embankments, etc.

200*l.* to 700*l.* per million gallons storage.

	£		
Arnfield, for Manchester waterworks	432	per million gals. storage.	
Crowden ,, ,,	561	,,	,,
Hollingworth ,, ,,	458	,,	,,
Tellowfold ,, ,,	722	,,	,,
Monmouth	912	,,	,,
Rooden, for Oldham	491	,,	,,
Sheffield waterworks, structures only	210	,,	,,
Ditto, including Parliamentary expenses, payments for compensation, etc.	485	,,	,,
Swansea	550	,,	,,
Swinshaw, for Ashton-under-Lyne and Stalybridge	405	,,	,,
Walshaw Dean, for Halifax	469	,,	,,

Scraping Water Mains.

Various Towns.—Actual cost by pipe scraper driven by water pressure and supplied by Glenfield & Kennedy, Ltd., Kilmarnock:—

Year.	Place.	Diam. of Main.	Length of Main.	Total Cost.	Cost per Mile.	Cost per Yd. Run.	Obstructions removed, other than corrosion.	Gain in Delivery after Scraping.
		Ins.	Miles. yds.	£	£ s. d.	s. d.		Per cent.
1880	Bradford	18	4 1,100	634	137 1 7	1 $6\frac{3}{4}$	Stones, lead, crowbar, etc.	56
1883	Whitehaven	11	3 1,223	516	81 19 5	$11\frac{1}{2}$	Mussels, stones, and lead	28

1902	Pelotas, Brazil	12	9 830	450	47 10 2	$6\frac{1}{2}$	Large stones, etc.	

Curragh Old Waterworks Pumping Station.—Different dates, 1859, 1907, 1915, and 1921. Includes concrete reservoir, corrugated iron fence, brick engine house, boiler house, chimney shaft, workshop, coal yard, engineer's cottage, and new corrugated iron engine shed, engineer's hut, concrete tanks, old and new wells with bored Artesian tubes, 112 ft. and 276 ft. total depths respectively, barbed wire fencing, water-main connections, and 1,550*l.* worth of machinery, complete . . . . . 9,550*l.* total cost.

13½-in. Artesian bored tube well (1907), including boring 52 ft. deep sunk in sand and gravel from the bottom of existing dug well which is 8½ ft. diameter and 59 ft. deep . . . . . 3*l.* 5*s.* per ft. in depth.

Ditto including men's time, fixing plant, testing, and carriage, and hire of compressor . . . . . 7*l.* 10*s.* ditto.

(The cost of this Artesian well is included in the 9,550*l.* total.)

Curragh Old Waterworks Reservoir (1887–93). In connection with pumping station. Uncovered, with puddle clay embankments, stone-lined. Steel fence all round. Size, 320 ft. × 260 ft. × 6 ft. deep, and holds 3,100,000 gals. Total, 2,760*l.* 1½*d.* per foot cube. Reservoir now disused . . . . . 18*s.* per 1,000 gals.

Selby Waterworks Reservoir (1908). 800,000 gals. 12-in. concrete floor, brick walls, 50½ ins. thick at base and 22½ ins. at top, 6-in. concrete roof in arches of 7 ft. span. Total, 4,800*l.* . . . . . 6*l.* per 1,000 gals.

In the London Metropolitan area—

Cost of pumping averages 43 per cent. of the entire maintenance expenditure.
Cost of pumping alone averages 50*s.* per million gallons.
Repairs and renewals of water-mains and pipes, 34*s.* per million gallons.
Maintenance of water-mains or pipe-way, 24*l.* per mile.
Cost of filtration, 7*s.* 5*d.* per million gallons.

Assuan Dam (1902–12).—Built for irrigation purposes at the head of the first cataract of the Nile, about 600 miles above Cairo. The original dam was of granite rubble masonry founded on a similar rock, which has dykes of softer igneous material. It was 1½ miles long, 100 ft. thick at base, with a maximum height from its foundation of 130 ft. The greatest difference of level of water above and below dam is 67 ft. Dam of local granite in Portland cement, and total weight of masonry is over a million tons. 180 sluice openings, closed by steel gates. When full the reservoir affects the depth of river for 140 miles above dam. Navigation is provided by a ladder of five locks, each 260 ft. long and 32 ft. wide. First dam was finished in 1902, and held 220,000 million gallons, at a cost of 2,500,000*l.*, or 11*l.* 7*s.* 3*d.* per million gallons. Engineer, Sir Wm. Willcocks, and contractor, Sir John Aird.

Between 1907 and 1912 the dam was raised 26 ft., and also thickened by 16 ft. on the downstream side, so as to contain an extra 310,000 million gallons, at a cost of 1,500,000*l.*, or 4*l.* 16*s.* 9*d.* per additional million gallons. Sir Benjamin Baker, consulting engineer.

Total capacity, 530,000 million gallons, and total cost, 4,000,000*l.*, or 7*l.* 10*s.* 7*d.* per million gallons as finally completed.

Scraping Water Mains.

Ayr.—Scraping 14-in. and 16-in. cast-iron water mains, 14½ miles long, at Ayr, between Loch Findas and the service reservoir at Dairymple, in 1915. Pipes laid 28 years before, but incrustation reduced capacity by 30 per cent. Scraper weighed 3 cwts., and was driven by a pressure of 15 ft. head of water. When this pressure was unobtainable the instrument was pulled through by a chain. Pipes were divided into sections with inspection boxes, and each section was done twice, the scraper travelling at the rate of 2 miles an hour. Capacity of mains was at once increased by 37 per cent.

For 14-in. pipes the scraping alone cost 13*l.* 8*s.* per mile, or 2*d.* per yd. run.
„ 16-in. „ „ „ 12*l.* „ „ 1⅞*d.* „
„ 14-in. pipes the total cost was 34*l.* 5*s.* „ „ 4¾*d.* „
„ 16-in. „ „ „ 46*l.* 10*s.* „ „ 6½*d.* „

Srcaping is necessary every 3 years, owing to rapid reincrustation.

SECTION XLIII

LEGAL NOTES FOR ENGINEERS

Contributed by W. Valentine Ball, O.B.E., M.A., of the North-Eastern Circuit, Barrister-at-Law.

Author of 'The Law Affecting Engineers' (Constable & Co.); 'The National Form of Building Contract' (published by The Local Government Journal), and Joint Editor of 'Emden's Building Contracts,' 4th Edition (Butterworth & Co.)

SECTION XLIII

LEGAL NOTES FOR ENGINEERS.*

(Contributed by W. Valentine Ball, O.B.E., M A., Barrister-at-Law.)

(1) Legal Status of an Engineer. (2) Fees. (3) Employment of an Engineer. (i.) *Generally*; (ii.) *Employment Abroad*; (iii.) *Wrongful Dismissal*; (iv.) *The Restrictive Covenant*; (v.) *Engineers and Compensation for Accidents*; (vi.) *Engineers and the National Insurance Act*; (vii.) *Effect of War on Contracts.* (4) Secret Commissions. (5) Disclosure of Secrets. (6) Rights of an Engineer to the Inventions of a Servant. (7) The Engineer as Witness. (i.) *Generally*; (ii.) *Arrangements as to Fees*; (iii.) *Evidence before Parliamentary Committees.* (8) Liability for Negligence. (9) Rights, Powers, and Duties of an Engineer under a Contract for Works. (i.) *Generally*; (ii.) *Specifications*; (iii.) *Plans and Drawings*; (iv.) *Extras*; (v.) *Certificates*; (vi.) *Penalties and Bonuses*; (vii.) *Defects, Repairs, and Maintenance*; (viii.) *Subcontractors and Specialists*; (ix.) *Whether the Employer's Engineer can act as Arbitrator in Relation to Disputes Arising under a Contract.* (10) The Engineer as Arbitrator. (i.) *Generally*; (ii.) *Who may be Arbitrator*; (iii.) *Proceedings before the Arbitrator*; (iv.) *The Award*; (v.) *Time for Making the Award*; (vi.) *The Fees of an Arbitrator*; (vii.) *Stating a Case for the Opinion of the Court*; (viii.) *Costs of a Reference.* (11) Notes on Sale and Purchase of Machinery. (12) Relief when Contract Difficult to Perform because of the War.

(1) LEGAL STATUS OF AN ENGINEER.

Any person may describe himself or practise as an engineer, as the word engineer is not a term of art in the legal sense. Although the Institution of Civil Engineers may make rules of professional etiquette to be observed by its members, compliance with such rules will not be enforced in a court of law, save in so far as they involve a restatement of the ordinary law. For instance a rule which states that no consulting engineer shall advertise could not be enforced, whereas infringement of a rule that 'he shall not pay by commission or otherwise anyone who introduces clients' might offend against the common law (*Panama Telegraph Co.* v. *India Rubber Co.* (1875) L. R. 10 Ch. 515) or against the Secret Commissions Act.

(2) FEES.

If an engineer is consulted, there is an implied contract to pay him reasonable remuneration (*Manson* v. *Baillie* (1855) 2 Mac. H. L. Cas. 80). It is more satisfactory, however, to provide for payment of fees beforehand. In the case of a contract to design and supervise erection of works it is well to provide for payment of $\frac{1}{3}$ on signing the contract, $\frac{1}{3}$ when half the contract price has been paid to the contractor, and $\frac{1}{3}$ when the contractor has been fully paid. Provision should also be made for (1) payment for plans and drawings in case the works are abandoned; (2) travelling and hotel expenses. There is, of course, no fixed scale of remuneration for the engineer, but in deciding what is a reasonable charge, the Court would have regard to (i.) the standing of the engineer; (ii.) the nature and extent of the work undertaken and carried out. It is no answer to a claim for fees (*a*) that a particular undertaking has proved to be a failure if the failure was not due to any fault of the engineer—as where, for instance, an engineer is employed merely to *supervise* the erection of a dam which bursts on completion; or where an engineer is employed to draw plans for a newly invented machine which fails to work (*aliter* if the employer was relying on the engineer's skill and judgment: *Duncan* v. *Blundell* (1820) 3 Stark. N.P. 6); (*b*) that the work in question is not completed, if the failure to complete is not due to the engineer. Where an engineer is to be paid on completion and the work is abandoned before the time, the engineer is entitled to what is due for services rendered, and to what he has lost by not being allowed to complete the contract (*Horton* v. *Hemsley* (1908) *Times*, February 19).

* See also 'Legal Points for Road Engineers,' p. 704.

(3) EMPLOYMENT OF AN ENGINEER.

(i.) **Generally.**—Where an engineer is to be employed for more than a year certain, the agreement must be in writing; and this is so, even if the employment is terminable at any time by six months' notice on either side (*Hanau* v. *Ehrlich* (1912), A.C. 39). The document must set forth all the terms. It is safer, however, to have the terms of an agreement always put into writing. Special care should be taken to (*a*) specify the times when the salary is to be paid; (*b*) provide for the contingency of illness, as illness does not necessarily determine the contract, nor will it justify dismissal without regular notice, unless the employee is so smitten with disease that he can never be expected to work again (*Cuckson* v. *Stones* (1858) 1 E. & E. 248); (*c*) provide for the notice which may be given on either side to determine the contract. If nothing is specified in the agreement, an engineer employed at a yearly salary is entitled to a year's notice (*Buckingham* v. *Surrey and Hants Canal Co.* (1882) 46 L. T. 885). An engineer wrongfully quitting his employment without notice forfeits the salary due for the part of the current year which he has served. The fact that a contract of employment for an indefinite period contains no express term as to notice to be given for its determination does not exclude the implication that such a notice is required (*Payzu* v. *Hannaford* 34 T. L. R. 442). The suspension of servant from his duties which prevents his earning his commission may amount to a wrongful dismissal (*Rubel* v. *Vos* 34 T. L. R. 171). Dismissal without notice is only justifiable in a case of gross misconduct. If the 'employer' is a company or a municipal corporation or other local authority it is safer to insist that the contract be under seal. The Public Health Act, 1875, s. 174 (1) provides that every contract made by an urban authority whereof the value or amount exceeds 50*l.* shall be in writing and sealed with the common seal of such authority. A surveyor who prepared plans for a local board under a verbal contract was held entitled to recover nothing (*Hunt* v. *Wimbledon Local Board* (1878) L. R. 4 C. D. D. 48). Close examination of a contract between an engineer and a local authority may, however, show that it is not within this section (see *Douglass* v. *Rhyl U.D.C.* (1913) 2 Ch. 407). Where the engineer is in the employment of a local authority he must have no interest in any contract into which that body enters (see *Melliss* v. *Shirley Local Board* (1885) L. R. 14 Q.B.D. 911). An attempt was recently made to raise the question whether a consulting engineer is liable to pay excess profits duty under s. 39 of the Finance Act, 1915, but the Court of Chancery refused to decide the point, leaving it to the King's Bench Division (*Smeeton* v. *Attorney-General* 35 T. L. R. 706).

(ii.) **Employment Abroad.**—Where an engineer is about to accept employment abroad, he should be careful to see that provision is made for the payment of travelling and other expenses. No agreement to pay travelling expenses would be implied from an undertaking, say, to employ an engineer at a salary of 1,000*l.* a year at Malacca as from January 1, 1913. It is also well to provide in the agreement that any disputes which may arise shall be determined either by arbitration or according to English law.

(iii.) **Wrongful Dismissal.**—If an engineer is wrongfully dismissed, it is his duty to reduce the damages as far as possible by taking other employment if he can procure it (see *Storey* v. *Fulham Steel Works* (1908) 23 T. L. R. 306). The damages are then ascertained by subtracting what he has earned from what he would have earned.

(iv.) **The Restrictive Covenant.**—When employing an assistant, an engineer may find it necessary to bind him not to set up close by in competition. A restrictive covenant is legal, if it is not too wide; it must be only what is reasonably necessary for the protection of the parties. A covenant to prevent a dentist practising within 200 miles of York was held to be too wide (*Horner* v. *Graves*, 7 Bing. 735). On the other hand, a covenant which bound a canvasser not to enter an employment 'within twenty-five miles of London where the plaintiffs carry on business' was held by the House of Lords to be unreasonable (*Provident Clothing and Supply Co.* v. *Mason* (1913) 29 T. L. R. 727). Care should be taken not to make the restriction perpetual unless that is absolutely necessary, for the Court criticises a perpetual covenant more closely (*Eastes* v. *Russ* (1915) 30 T. L. R. 237). In a recent case the validity of a covenant affecting a man who was employed as works engineer at a bottleworks was considered (*Forsters* v. *Suggett* 35 T. L. R. 87).

(v.) **Engineers and Compensation for Accidents.**—An engineer whose remuneration (e.g. money, board and lodging, etc.) amounts to less than 250*l.* in the service of an employer is probably entitled to the benefits of the Workmen's Compensation Act, 1906.

(vi.) **Engineers and the National Insurance Act.**—A nice question may arise as to whether, say, a station engineer must be treated as an employed contributor within the meaning of the National Insurance Act, 1911. That act covers employment in any contract of service subject to the proviso that persons earning more than 160*l.** otherwise than in manual labour need not be insured. It is submitted that the station engineer earning less than 160*l.* must be insured, but that the consulting engineer who receives an annual fee of 100*l.* for advising a firm or company need not be insured. His is a contract not 'of service' but 'for services'—a distinction which has been drawn in the Court of Appeal.

* By the National Health Insurance Act, 1919, now raised to 250*l.*

(vii.) **Effect of War on Contracts.**—Contracts entered into during the war, between British citizens and the citizens of States at war with Great Britain, were illegal and could not be enforced, unless a licence to trade was granted to one of the belligerents. Subject, however, to certain exceptions, contracts entered into by the citizens of one belligerent State with citizens of another belligerent State before the outbreak of hostilities between their respective states are not dissolved by the outbreak of war but suspended until the war is over. During suspension no performance of the contract is permitted, nor will any action on it be entertained in English Courts, even though the cause of action arose before the war. But the war being now over the mutual obligations of performance and the rights of action revive. The exceptions are (*a*) Contracts entered into before the outbreak of hostilities which will inure to the aid of the enemy or which involve any dealing with the enemy (see *Furtado* v. *Rogers*, 3 Bos. & P. 91); and (*b*) Contracts entered into before the outbreak of hostilities which from their nature cannot be merely suspended (*Griswold* v. *Waddington* (1818) 16 Johnson's Rep. 438).

(4) SECRET COMMISSIONS.

The receipt of a secret commission or a bribe by an engineer would clearly justify his dismissal (*Boston Deep Sea Fishing Co.* v. *Ansell* (1888) 39 Ch. D. 339). In such a case there is a presumption that he was influenced, against his employers' interest, by the bribe (see *Hovenden* v. *Millhoff* (1900) 83 L. T. 11).

(5) DISCLOSURE OF SECRETS.

An engineer may be employed to do work of a confidential nature for others; or he may have to employ workmen to do confidential work for him (e.g. by employing a workman to make a model of a new and patentable machine). The law implies an agreement by the servant to keep his master's secrets, and he may be restrained by injunction from disclosing them (*Alperton Rubber Co.* v. *Manning and Others* (1917) 116 L. T. 499; 33 T. L. R. 205).

(6) RIGHTS OF AN ENGINEER TO THE INVENTIONS OF A SERVANT.

If a servant invents a machine in his employer's time and even when using his employer's materials, the invention does not become the property of the employer so as to prevent the servant taking out a patent for it (*Heald's Case*, 8 R. P. C. 430). But if the servant were to steal an idea and endeavour to patent it either before or after the termination of the service, the employer could oppose the grant of a patent in respect of it (*Thwaites' Application*, 9 R. P. C. 515). And if the servant obtains a grant of a patent in respect of the invention, he can only hold it as trustee for his employers (*British Reinforced Concrete Engineering Co.* v. *Lind* (1917) 33 T. L. R. 170). The engineer when employing a servant should take care to provide, by the agreement, that the inventions of the servant shall belong to him; but when himself entering into a contract of service he should be careful to sign nothing which will abrogate his rights.

(7) THE ENGINEER AS WITNESS.

(i.) **Generally.**—As the engineer frequently comes into contact with the law and the lawyers in the capacity of a *witness*, a few notes of a practical character on the duties of a witness may be found useful.

When invited to give evidence as an expert the engineer should: (*a*) arrange for a qualifying fee to be paid in any event; (*b*) examine the plans and documents, and, if necessary, obtain a view of the *locus in quo* before consenting to give evidence; (*c*) warn the parties consulting him of all the difficulties which are manifest to him; (*d*) ascertain, if possible, the contentions which are going to be put forward by the other side, and make himself familiar with any views which they may have published upon the matters in dispute. Having consented to give evidence, the engineer should (*a*) be ready to satisfy the lawyers with regard to any technical point which may be raised in consultation; (*b*) listen to the arguments and evidence in Court, and be prepared to deal with any points made by witnesses on the other side; (*c*) bring with him any entries in his diary or any notes which he may have made *at the time* with reference to the matters in dispute, for he may use such notes to refresh his memory. Thus, if an engineer has to report as to the condition of a structure, he may use in the witness box the notes which he made on the spot. But he could not use a copy of such notes unless he was prepared to produce the original; (*d*) make and bring to court a plan or model of the structure or machine under discussion, as this will save much wordy explanation; (*e*) search in libraries and in the published proceedings of the various institutions for any books and papers dealing with the matters in hand—especially any papers written by himself, in order that he may not be confronted with an adverse opinion given on a former occasion. A witness should bear in mind that it is his duty to state facts and express opinions, not to advocate the cause. As soon as he appears to be taking a biassed view or attempting to fight the case it is more than likely that the tribunal will pay little heed to his evidence. A candid answer to an awkward question is often less dangerous than a long and evasive statement. In *Crosfield and Sons, Ltd.* v. *Techno-Chemical Laboratories Ltd.* (1913) 29 T. L. R. 378 Neville, J., expressed some views as to the function of an expert witness which may be thus summarised:—

(*a*) It is not competent in any action for witnesses to express their opinion upon any of the issues, whether of law or fact, which the Court or a jury has to determine.

(*b*) In patent cases, expert evidence is often necessary (i) to explain words or terms of science or art, or to inform the Court in case the import of a word in a document to be construed differs from its popular meaning; (ii) to instruct the Court in the laws of science; (iii) to describe the state of public knowledge at the date of the patent. 'It is rare,' added his lordship, 'to find any substantial difference of opinion between eminent experts upon matters of science whenever it is possible to dissociate the question from immediate connection with the issues in the action.'

(ii.) **Arrangements as to Fees.**—On being *subpœnaed* one is bound to attend as a witness provided sufficient conduct money is paid with the subpœna. Failure to attend might lead to an action for damages, while in the County Court the judge has power to fine a witness for non-attendance. A witness may refuse to give evidence until his expenses have been paid (*Newton* v. *Harland* (1840) 1 M. & G. 956). It should be noticed that the person liable to pay the fees is the party to the litigation, not the solicitor, unless he has expressly made himself liable (*Lee* v. *Everest* (1857) 26 L. J. Ex. 334). In order to save trouble it is best to arrange for and if possible secure payment of fees in advance. The fees 'allowed on taxation,' that is to say, the fees which an unsuccessful litigant will be ordered to pay in respect of witnesses called by the other side, are very small, but the party calling the witness will have to pay his agreed fee whatever it is. Where a case is tried at assizes in the town where the engineer lives or in London (when the engineer lives in London), the fee allowed is 1*l.* 1*s.* *per diem*, or where the engineer lives away from the town 1*l.* 1*s.* to 3*l.* 3*s.* But the taxing masters may also allow a qualifying fee of so much a day varying with the magnitude of the case. In 1875 a fee of 7*l.* 7*s.* was not considered excessive payment to a scientific witness. It is probable that a larger sum would be allowed at the present day. In addition he is allowed the travelling expenses reasonably and actually paid. In County Courts the fee allowed for qualifying to give evidence on Scale B is 1*l.* 1*s.* to 3*l.* 3*s.*; on Scale C, 1*l.* 1*s.* to 5*l.* 5*s.*; for attending Court on trial (*per diem*), Scale B, 1*l.* 1*s.* to 2*l.* 2*s.*; Scale C, 1*l.* 1*s.* to 3*l.* 3*s.*

The above scales were fixed before the war, and have not been altered. So far as they can the taxing masters will probably grant the maximum owing to high prices.

(iii.) **Evidence before Parliamentary Committees.**—When an engineer is summoned to appear as a witness before a committee of either House of Parliament he looks for his fees to the party who summons him—whether he is the promoter or an opponent. According to May's 'Parliamentary Practice' (1906) p. 434, an engineer summoned as a witness before a committee should report himself to the committee clerk on his arrival in London, or he will not be allowed his expenses for residence prior to the day of making his report; 3*l.* 3*s.* a day is the parliamentary allowance, but of course as between the engineer and the party summoning him the *quantum* of the fee is a matter of agreement.

(8) LIABILITY FOR NEGLIGENCE.

The liability of an engineer for negligence is similar to that of any other professional man. To render him liable it is not enough that there has been a less degree of skill than some other professional man might have shown. A fair average degree of skill is all that can be insisted upon (*Lamphier* v. *Phipos* (1838) 8 Car. & P. 475). If an engineer were so careless in the preparation of a tender that the cost of the works was grossly underestimated, he would probably be liable to pay damages, and he certainly could not recover his fees (*Moneypenny* v. *Hartland* (1826) 2 C. & P. 379). An engineer should be acquainted with any local bye-laws appertaining to the work in hand (*Monks* v. *Dillon* (1884) 12 L. R. Ir. 321). On the principle of *respondeat superior*, an engineer is responsible for the acts or defaults of assistants employed by him (*Mackersy* v. *Ramsays* (1842) 9 C. & F. 818). The question 'To whom is the engineer liable for negligence?' depends upon the conditions of employment. If he is engineer in relation to a large contract, he is not liable for anything done by him in his capacity as arbitrator between the employer and the contractor; but he is liable for damage resulting from negligence in supervision, e.g., failure to examine and test work before it is hidden from view (*Leicester Guardians* v. *Trollope* (1911) 75 J. P. 197). The contractor, however, could not sue the engineer for an error in the specifications on the basis of which he made his tender. Where, however, the 'quantities' are prepared by the engineer, and his fees for their preparation are paid by the contractor, it is conceived that he could be sued for damages resulting from an error in those quantities (*Bolt* v. *Thomas*, 'The Law Affecting Engineers,' p. 58). If an engineer order extras without authority, the contractor may possibly sue him for damages for breach of warranty of authority (*Randall* v. *Trimen* (1856) 18 C.B. 786). The amount of damages recoverable for negligence is to be measured by the loss which the plaintiff has suffered. In *Saunders* v. *Broadstairs Local Board* (1890) 2 H. B. C. 160, two engineers claimed fees for preparing surveys, obtaining tenders, and superintending the execution of a contract for certain drainage works. The board counterclaimed for negligence and were awarded 2,046*l.*, the amount overpaid to the contractor by reason of the negligence of the engineers in over-certifying the quantities; 2,400*l.* estimated cost of doing bad work over again; 240*l.* actual cost of repairs already done to defective work. Damages recovered by a workman against his employer for an accident might also be recovered from the engineer if it were shown that the accident was caused by the engineer's negligence (*Mosdell* v. *Mitchell*, 'Times,' January 20, 1891).

(9) RIGHTS, POWERS, AND DUTIES OF AN ENGINEER UNDER A CONTRACT FOR WORKS.

(i.) **Generally.**—Common forms of contract for large works usually set forth the powers, etc., of the engineer very clearly. The preparation of the contract is generally left to a lawyer, but the engineer should be on his guard against allowing a common printed form to be applied indiscriminately to the construction of works of a special nature. When difficulties arise it may be found that the common form does not provide for their elucidation.

(ii.) **Specifications.**—The contract should contain a clause providing that the employer will not be responsible for any mistakes or inaccuracies in the specifications which form part of the contract. Such a clause will, in the absence of fraud, afford him protection (*Pearson* v. *Dublin Corporation* (1907) A. C. 357). There should also be a clause calling the would-be contractor's attention to the fact that he must make surveys and borings for himself before making his tender. In that case, if unforeseen difficulties are met with the employer will not be responsible (*Thorn* v. *Mayor of London* (1876) L. R. 1 A.C. 120). Again, where a man undertakes to make e.g. sound hydraulic cylinders according to a specification, capable of withstanding a certain pressure, he takes upon himself the risk of the cylinders being able to withstand the named pressure when made according to the specification (*Hydraulic Co.* v. *Spencer* (1886) 2 T. L. R. 554). Carelessness in the preparation of a specification may involve the employer in added expense, for which the engineer may be liable (*Moneypenny* v. *Hartland* (1828) 2 C. & P. 378).

(iii.) **Plans and Drawings.**—These form part of the contract, and may, in the absence of a disclaiming clause, operate as a warranty that dimensions, measurements, etc., are correct. A clause disclaiming responsibility for accuracy should therefore be inserted in the contract. The engineer has no implied authority to alter plans and drawings so as to increase or lessen the burden imposed upon the contractor (*Cooper* v. *Langdon* (1841) 9 M. & W. 60). Delay in supplying the necessary plans and drawings may excuse the contractor from carrying out the work within the contract time (*Roberts* v. *Bury Commissioners* (1869) L. R. 5 C. P. 310). It is for the engineer who prepares them to see that they conform to local bye-laws (*Cubitt* v. *Smith* (1864) 11 L. T. 298). Plans and drawings made for the purpose of carrying out works are the property of the employer—not of the engineer (*Gibbon* v. *Pease* (1905) 1 K.B. 810). As to copyright in plans, see the Copyright Act, 1911, s. 5.

(iv.) **Extras.**—The duty of deciding what are 'extras' within the meaning of the contract is usually entrusted to the engineer. He has no implied authority to order extras (*Cooper* v. *Langdon* (1841) 9 M. & W. 60), although an agreement to work *to the satisfaction* of an engineer has been held to give him implied authority to order extras (*Robertson* v. *Jarvie* (1910) 45 S. L. R. 260). It has been held, however, that where the plaintiffs were employed by an architect (whose functions, for this purpose, correspond to those of an engineer) to supply door handles and door furniture for a building, and shortly before the delivery of the goods he informed the defendants, who were the builders, that the goods were being supplied by the plaintiffs, the defendants who used the goods in the building were liable to pay for them (*Ramsden* v. *Chessum* (1914) 78 J. P. 49). Extras should be authorised in the manner provided by the contract, which usually provides that all extras shall be ordered in writing (*Russell* v. *Sa da Baudeira* (1862) 13 C. B. N. S. 149); but, in the case of a contract with a local authority, which must be under seal, the order for extras need not be under seal (*Williams* v. *Barmouth Urban Council* (1897) 77 L. T. 383). If a written certificate is rendered necessary by the contract, nothing else will suffice; but in a recent case a contractor proceeded with extra work as required by an engineer without any written order. On his claiming payment, an arbitrator found that the engineer was wrong and unreasonable, and that the work and materials required by him were not included in the contract. After much litigation the House of Lords eventually held that this decision was correct (*Brodie* v. *Cardiff Corporation* (1919) 120 L. T. 417). Although the whole scheme of works cannot be altered by virtue of the extra clause (*R.* v. *Peto*, 1 Y. & J. 37) power to *vary* the work will give the engineer authority to substitute one piece of machinery for another of which it is well known to be the mechanical equivalent (*Stevens* v. *Mewes & Davies*, Court of Appeal, June 7, 1910; Emden's 'Building Contracts,' Supplement 1911). The engineer should therefore see that he has power to *vary* the work. The engineer's decision as to what are extras may or may not be subject to revision in accordance with the arbitration clause. So far as the contractor is concerned, the fact that the engineer has given his final certificate (see *sub. tit. Certificates post*) may involve a final decision as to what is and what is not an extra (*Connor* v. *Belfast Water Commissioners* (1871) 5 L. R. Ir. C. L. 55). Power to extend the time for completion is generally given to the engineer. It may be that owing to the action of the Government acting under the Defence of the Realm Acts, the performance of a contract for works becomes illegal during the continuance of the War. In such a case it is conceived that no extension of time by the engineer will avail to keep the contract alive (see *Metropolitan Water Board* v. *Dick, Kerr & Co.* 34 T. L. R. 111).

(v.) **Certificates.**—It is the duty of an engineer in relation to a contract for large works to grant or withhold the certificates upon which the contractor is paid. 'Progress certificates' are given from time to time as the work proceeds. They generally authorise payment to the extent of

80 per cent. upon the contract value of the work done from time to time. The remaining 20 per cent. is kept back usually, as to 15 per cent. until the final certificate is granted and as to 5 per cent. until the end of some stated period after the final certificate. This 20 per cent. is called the retention money (see *West Yorkshire Bank Ltd.* v. *Isherwood Bros.* (1912) 28 T. L. R. 593). The 'final certificate' is granted when the work is finished to the satisfaction of the engineer, and the contractor can sue for nothing until it has been granted (*Wallace* v. *Brandon and Byshottles U.D.C.* (1905) 2 K. B. C. 392). In deciding as to certificates the engineer acts as an arbitrator, and his decisions cannot be called in question (*Wadsworth* v. *Smith* (1871) L. R. 6 Q.B. 322); nor can he be compelled, and is better advised not to give reasons for his decision (*Stevenson* v. *Watson* (1879) L. R. 4 C.P. D. 148). No action lies against him for negligence in relation to certificates (*ib.*) (but see the case of *Goddard* v. *Ferguson*, *infra*). In exercising his discretion he must act as an arbitrator between employer and contractor (*Chambers* v. *Goldthorpe* (1901) 1 K.B. 624). It may, however, be that the decision of the engineer as to a certificate is subject to the arbitration clause, which has been held to be the case in relation to the form of contract approved by the Royal Institute of British Architects (*Robins* v. *Goddard* (1905) 1 K.B. 294). A fraudulent agreement between the employer and the engineer would however affect the validity of a certificate (*Kellett* v. *New Mills U.D.C.* (1900) 2 H. B. C. 330). The certificate of the engineer may be made a condition precedent to the contractor's right of action against the employer. If so an action cannot be maintained unless there has been improper dealing between the engineer and the employer (*Eaglesham* v. *McMaster* (1920) 2 K. B. 169). The statement that an engineer is not liable for negligence in relation to a certificate does not appear to be supported by the case of *Goddard* v. *Ferguson* (referred to by Mr. Saxon Snell in a paper read by him at the Royal Institute of British Architects, April 15, 1912). It was there held that an architect who grants a certificate which is successfully challenged by an employer in an action brought against him by a builder to recover the amount so certified to be due to him, is liable to repay to the employer the costs incurred by him in resisting the builder's claim. The Official Referee held the architect liable on the ground that when acting as agent for the building owner in granting certificates, he must be held responsible for the reasonable and probable consequences of giving a certificate subsequently held to be inaccurate or excessive. Certificates should always be given in writing in a formal manner. No engineer should pass any contract which does not contain a provision to this effect. As to when an engineer is disqualified from granting certificates, see paragraph ix., *infra*. An engineer has no right to delegate the power to grant a certificate to a subordinate, e.g. to the resident engineer (*Freeman & Sons* v. *Middleton Electric Traction Co.*, per Hamilton, J., July 15, 1910; Court of Appeal, January, 1911; Emden's 'Building Contracts,' Supplement, 1911).

(vi.) **Penalties and Bonuses.**—The question whether the contractor must pay penalties or not depends almost entirely upon the engineer. Penalties are imposed if the work is not carried out in accordance with the provisions of the contract as to time. The fact that extras are ordered will excuse the contractor from compliance with the conditions as to time (*Dodd* v. *Churton* (1897) 1 Q.B. 562), but the jurisdiction of the engineer does not extend to deciding this point (*Gallivan* v. *Killarney Urban Council* (1912) 2 Ir. R. 356). To avoid complication, however, it is best to insert a clause in the contract giving the engineer power to extend the time. With regard to the penalty clause generally nice questions sometimes arise as to whether it is capable of enforcement. If it is unreasonable on the ground that the punishment is too severe, the Court may refuse to enforce it; and it is for this reason that the words 'the sums to be regarded as liquidated damages and not as a penalty' are usually inserted after the sum named. The breach of an engineering contract involves damage of so uncertain a nature that the courts will generally treat the sum which the parties themselves have named as liquidated damages. Penalties will not be imposed if (*a*) the delay was caused by the act or default of the employer (*Thornhill* v. *Neats* (1860) 8 C. B. N. S. 831); (*b*) if there is delay in setting out the site or in delivering plans (*Roberts* v. *Bury Improvement Commissioners* (1870) L. R. 5 C. P. 310). The fact that the contractor has been delayed by a strike of his workmen, however, affords no excuse for delay (*Budgett* v. *Rimington & Co.* (1890) 25 Q.B. D. 320), nor, apparently, is the employer to be held liable for the acts of third parties causing delay (*Porter* v. *Tottenham U.C.* (1915) 1 K. B. 776). While a penalty clause is usually optional, it is obligatory in contracts made with certain local authorities (see Public Health Act (1875) s. 174 (2)). A bonus clause is sometimes inserted by virtue of which a contractor is enabled so much extra for expedition. If a contract contains such a clause, and the engineer has power to extend the time, it seems that his power to extend must be exercised not to enable the contractor to earn the bonus but only to avoid penalties (*Ware* v. *Lyttelton Harbour Board* (1882) 1 N. Z. R. 191).

(vii.) **Defects, Repairs, and Maintenance.**—In contracts relating to the erection of machinery clauses should be inserted providing for any defects which appear either before or after the issue of the final certificate. A useful form of this clause will be found in the printed conditions of contract issued by the Institution of Electrical Engineers. Its importance will be recognised when it is pointed out that when it is absent the final certificate of the engineer may possibly bar any further claim by the employer (*Lord Bateman* v. *Thompson* (1875) 2 H. B. C. 25). The time for the remedy of defects should be prolonged as much as possible, inasmuch as the very fact of there being a defects clause impliedly releases the contractor from liability for defects appearing after the stated time (*Sharp* v. *Great Western Railway Co.* (1841) 11 L. J. Ex. 17). The contractor can only be called upon to repair and maintain when compelled to do so by a repairing clause and a maintenance clause. The employer must give notice of want of repair. Mainte-

nance should be provided for in cases where the machinery or work is of a special character which is best known to the contractor. In the absence of any clause relating to defects and maintenance, it does not follow that on payment of the full price the employer thereby waives all claim for damages for work improperly done. It is a question of fact having regard to all the circumstances of the case whether the settlement was final and complete.

(viii.) **Subcontractors and Specialists**.—Most modern contracts involve the employment of subcontractors or specialists. A clause should be inserted in the head contract prohibiting the employment of any subcontractor or specialist unless approved by the engineer. In the absence of such a clause, the contractor might, possibly, farm out portions of the work to all and sundry (*British Waggon Co.* v. *Lea* (1880) 5 Q.B. D. 149). The engineer, apparently, has no implied authority to employ subcontractors (*Cowan* v. *Goderich* (1859) 10 U. C. C. P. 87). It is often well to specify the names of manufacturers of the raw materials which are to be used in the body of the contract. In order to preserve his right to supervise the work of any subcontractor or specialist, the engineer should secure the insertion in the head contract of a clause providing that payments to subcontractors shall be made by the contractor only upon the certificates of the engineer. It is also well to secure the insertion of a clause to the effect that, in the event of the contractor becoming insolvent, the subcontractor or specialist may be paid directly by the employer. All responsibility for delay or negligence on the part of a subcontractor is generally by a special clause, placed upon the contractor (see, generally, *Crittall* v. *L. C. C.* (1910) 75 J. P. 203; *Hampton* v. *Glamorgan County Council* (1916) 115 L. T. R. 426, and the case of *Ramsden* v. *Chessum*, cited, *supra*, s. (9) (v) (i.)).

(ix.) **Whether the Employer's Engineer can act as Arbitrator in Relation to Disputes Arising under a Contract.**—The position of the engineer in relation to a large contract has been rendered very difficult by certain recent decisions of the courts. In theory he is agent for the employer in the preparation of plans and specifications and in the supervision of the work, and he is arbitrator or *quasi* arbitrator between the employer and contractor in granting certificates, approving work done, granting extensions of time, etc. Sometimes he is made sole arbitrator to decide all disputes between the employer and the contractor, and a serious question has arisen in several recent cases as to how far a contractor can be forced to accept his decision whether in the matter of granting certificates, etc., or as arbitrator. In *Jackson* v. *Barry Railway Co.* (1893) 1 Ch. 238, it was held that the fact of the employer's engineer having expressed a view of the matter in dispute hostile to the contractor was not a sufficient justification for refusing to allow him to act as arbitrator in relation to that dispute. The Court of Appeal pointed out that the contractors had agreed to this form of reference, and what they relied on was the professional honour, practice, and intelligence of the engineer. There was nothing in the circumstances of the case to render it improbable that he would not arrive at an honest decision.

In *Ives* v. *Willans* (1894, 2 Ch. 478) the same result was arrived at, although, in giving judgment Lord Justice Davey said: 'No doubt in a sense the engineer will be the judge of his own conduct, and no doubt that is a position which *prima facie* raises some surprise in a judicial mind: but that is the contract of the parties.' As already indicated later decisions appear to have practically altered the law, although the judges always took care to say that *Ives* v. *Willans* is still good law. The result of the recent cases may be thus summarised. A contractor will not be bound to submit to the arbitrament of the employer's engineer (*a*) if the matter in issue is an unseemly personal dispute raising a vindictive feeling between the engineer and the contractor, and the engineer has so strongly expressed his view that it amounts to a prejudgment (*Nuttall* v. *Manchester Corporation* (1893) 8 T. L. R. 513); (*b*) if the nature of the dispute is such that the cross-examination of the engineer is essential (*Freeman* v. *Chester R. D. C.* (1911) 1 K.B. 783); (*c*) if the matter in issue is something outside the original agreement, e.g., a dispute as to whether the engineer and contractor had agreed to vary the original agreement (*Aird* v. *Bristol Corporation* (1913) A. C. 241); (*d*) if the conduct of the engineer himself is practically the only point in dispute (*Blackwell* v. *Derby Corporation* (1909) 75 J. P. 129). Finally, it was held in *Roberts* v. *Hickman* (1913) A. C. 229 that the grant of a certificate by an architect will not be a condition precedent to the builder's right to sue if, by writing letters to the employer, and allowing himself to be influenced by their views, the architect has disqualified himself from acting judicially although guilty of no fraud or improper conduct.

If the method of arbitration provided for in many existing forms of contract is declared to be impossible for any of the above reasons the only alternative is litigation, a method of settling disputes which employers, contractors, and engineers always seem to desire to avoid. What can be done to avoid such a calamity in relation to future contracts? The following courses are open. Insert a clause (*a*) referring all disputes to an arbitrator to be mutually agreed or to be nominated by the president of one of the Institutes (see, e.g., the form approved by the Institution of Electrical Engineers, clause 47); or (*b*) referring disputes to a *named* arbitrator; or (*c*) refer disputes to the president of one of the Institutes whoever he may be. The first of these suggestions appears to offer the best practical solution of the difficulty. The writer, however ventures to make the following suggestion which might possibly work in practice. Frame the arbitration clause so as to leave the decision of every question arising under the contract to the engineer but subject to a proviso that should it appear to the Court on an application to stay any action or proceeding brought in relation to the contract that the engineer is disqualified from acting as arbitrator the matters in dispute will be referred to an engineer to be agreed between

the parties, or failing agreement to be nominated by the president of the Institution of Civil Engineers. Another alternative is suggested by Mr. E. J. Rimmer in his Arbitration Clause in Engineering Contracts' (Constable & Co.). It is that a proviso should be added to the arbitration clause stating that if any action is brought the defendant may either (*a*) have the action stayed or (*b*) have the matter referred to an independent arbitrator appointed in one or other of the manners above suggested.

(10) THE ENGINEER AS ARBITRATOR.

(i.) **Generally.**—Engineers are frequently called upon to act as arbitrators to decide disputes of a technical nature wholly unconnected with any contract in which the engineer has been employed. Arbitrations are conducted in accordance with the provisions of the Arbitration Act, 1889. An arbitrator may be appointed (*a*) by the Court; (*b*) by the terms of the contract itself; or (*c*) by a person nominated for that purpose in the contract, e.g., the president of the Institution of Civil Engineers. As to appointment by the Court, this occasionally takes place when a prolonged scientific enquiry is necessary. A 'referee' of this kind may have power either to wholly dispose of the dispute or make an enquiry and report to the Court, in which latter case the Court itself gives the judgment after considering the report. As references of this kind are rare in practice they will not be further dealt with.

As a rule the engineer finds himself made arbitrator pursuant to the arbitration clause in an agreement. Any dispute arising under any contract may thus be referred, and the parties will as a general rule be bound to proceed to arbitration for the purpose of settling a dispute instead of bringing an action at law. Where a contract contains an arbitration clause, if one party commences an action, the other may apply to the Court to stay the action pending a reference, and the action will generally be stayed, unless there is some good reason for not allowing the arbitration to proceed. For instance, in a recent case a contractor alleged that he had been induced by fraudulent representations as to the nature of the soil to enter into a particular sewerage contract, and brought an action for fraudulent misrepresentation. It was held that such an action ought not to be sent to arbitration (*Monro* v. *Bognor Urban District Council* (1915) 84 L.J. K. B. 1091). (See also par. 9, ix. *supra*.)

(ii.) **Who may be Arbitrator.**—Any person upon whom the parties agree may act as arbitrator. Thus if in contract with a local authority it is specified that the borough engineer shall be arbitrator there is no objection to his so acting, and the contractor can be compelled to accept his award (*Ives* v. *Willans, supra*, 2 Ch. 478). That is the broad rule, but the Court, as has been shown, always has power to refuse to enforce the arbitration clause in a case where it is obvious that the arbitrator ought not to act owing to bias, etc. Frequently the clause provides for the appointment of an arbitrator by each party with power to the arbitrators in case of differences to appoint an umpire. When this is done the umpire and arbitrators generally find it convenient to sit together to decide the case.

(iii.) **Proceedings before the Arbitrator.**—Witnesses must be sworn in the usual way. Due notice must be given to either party of the time when it is proposed to hold the sitting. In a case of great complexity it is well to have a preliminary sitting in order to require the parties to formulate the points in difference between them. By this means the issues may be considerably narrowed. The arbitrator should hear both sides, who may be represented by solicitor or counsel. He must never hold private communication with one party on the subject matter of the reference. He has no power to examine witnesses in the absence of the parties. An arbitrator who takes evidence in the absence of, and without notice to, a tenant, is guilty of legal misconduct, for which his award may be set aside (*In re O'Connor*, 88 L. J. K. B. 1242). It is for the arbitrator to decide every question whether of law or fact. He may, however, consult a solicitor or, for that matter, any other expert on legal points. Indeed the writer was recently concerned in a case in which, with the consent of the parties, the arbitrator had his solicitor sitting by his side. He should take full notes of the evidence, unless, as is frequently the case, the parties agree to have a shorthand note.

(iv.) **The Award.**—If the case is complex, the engineer is well advised to consult his solicitor as to the form of the award. The following are the features of a valid award, which should be in writing. (*a*) *It must not exceed the submission.* Thus if the question submitted was whether the stone used for building a dam was according to specification, the arbitrator would have no power to award that the stone used was better than as specified and that the employer must pay for it. (*b*) *It must extend to all matters in dispute.* If several distinct questions are referred and the arbitrator omits to decide upon any one of them, the whole award is bad. If in the case mentioned he were asked to decide (i.) was the stone as specified; (ii.) was it suitable for the purpose, he would have to decide both questions. (*c*) *It must be certain.* The award must be so framed that its meaning is clear to the parties; but according to a legal maxim, that is certain which is capable of being rendered certain. Thus to award that A. and B. shall pay a debt in the proportion in which A. and B. hold shares in a ship is a sufficiently definite award (*Watson* v. *Watson* (1671)

Sty. 28). (*d*) *It must be final.* The award must peremptorily state the arbitrator's finding. A mere expression of opinion that A. ought to pay B. such sum as C. thinks proper would not be a final award. Finally (*e*) *it must not be impossible, unreasonable, inconsistent,* or *illegal.* An award which directed that one party should do something illegal, e.g. trespass upon the land of another would be invalid.

(v.) **Time for Making an Award.**—In the absence of agreement, an award must be made (*a*) within three months of the date of entering on the reference, or (*b*) within three months after having been called on to act by notice in writing from one of the parties, or (*c*) on or before any later day to which the arbitrator may by writing under his hand extend the time for making the award (Arbitration Act, 1889, Schedule 1 (c)). The power to extend the time is important in the case of a long and complicated reference, but it must be exercised within the period of three months above referred to. Unless the arbitrator extends the time, or the parties agree to allow him to do so, an application must be made to the Court to extend the time ; and such an application may be made whether the time for making the award has expired or not (*ib.*, s. 9).

(vi.) **The Fees of an Arbitrator.**—The arbitrator should name his fee beforehand. It is best fixed at so much *per diem* for the hearing. If no preliminary arrangement is made, he is entitled to charge what is fair and reasonable, and he can keep back his award until the fees are paid (*Ponsford* v. *Swain*, J. & H. 433). When deciding in the award as to costs he should state who is to pay his fees ; but he may insist upon their being paid by the party who takes up the award. He should not reveal his decision until after these formalities have been observed. Sometimes the *quantum* of an arbitrator's fees is left to the decision of a taxing master. On such a taxation, if the evidence goes to show that, in the opinion of persons in the same profession as the arbitrator, that his charges are fair and reasonable, the taxing master must allow them. In *Mason* v. *Lovatt* (1907, 23 T. L. R. 486) a quantity surveyor was allowed to charge 527*l.* 10*s.* for a reference which lasted 22 days, the arbitrator subsequently taking 13 days to consider his opinion. In *Llandrindod Wells Water Co.* v. *Hawksley* (1904, 20 T. L. R. 241) the fees of an umpire and two arbitrators all being engineers were allowed at 476*l.* 12*s.*, in respect of a reference which lasted 2 days. The arbitrator should state how his fees are made up.

(vii.) **Stating a Case for the Opinion of the Court.**—Where a specific question is referred to an arbitrator, and he decides it, the fact that his decision is erroneous in point of law does not make the award bad on its face so as to admit of its being set aside (*In re King and Duveen* (1913) 2 K. B. 32) ; nor will the mere fact that the dispute involves questions of law induce the Court to stay a reference to arbitration (*Rowe* v. *Crossley* (1913) 108 L. T. 11). But where a point of law arises during a reference, the arbitrator, if he does not care to decide it, may state a case for the opinion of the Court (Arbitration Act, 1889, s. 19), or the Court may compel him to state a case (*ib.*). He can also make his award in the form of a special case, leaving it to the Court to decide how the judgment shall be entered.

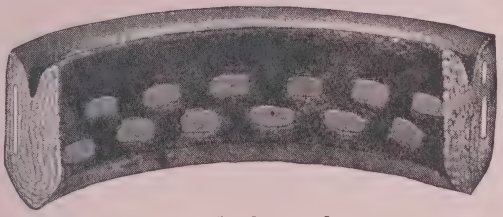
(viii.) **Costs of a Reference.**—The question of costs should be carefully considered, as the expenses of a reference are often wholly out of proportion to the sum in dispute. In litigation the general rule is ' costs follow the event '—an application of the maxim *væ victis.* Unless the submission contains some special term as to costs, the arbitrator has full power to decide who is to pay them. He may award costs to be taxed ' as between solicitor and client '—which means that the successful party is nearly indemnified—or he may award costs to be taxed as between litigants in the ordinary way. He may also, in his discretion, award a fixed sum for costs (Arbitration Act, 1889, Schedule I. (i)), or he may declare that each party shall pay his own costs. In deciding whether to make a defendant pay costs, the arbitrator should (it is submitted) consider the nature of any offer made before the proceedings were commenced. Thus supposing a contractor claimed 5,000*l.* and the building owner made a firm offer of 4,000*l.* which was refused. After hearing the evidence, the arbitrator awards 4,000*l.* or less. In such a case he would be justified in disallowing the contractor any costs. An arbitrator can only make a successful plaintiff pay costs in exceptional circumstances as when (e.g.) it appears that although successful he should not have prosecuted his claim. It was held, however, in a case arising under the Small Holdings Act, 1908, the arbitrator in the exercise of his powers under that Act had wider powers in the matter of costs than a High Court judge (*Gray* v. *Baron Ashburton*, 115 L. T. R. 729).

(11) NOTES ON SALE AND PURCHASE OF MACHINERY.

The question which most frequently arises on the sale of machinery, motor cars, etc., is what is the warranty of fitness ? Sometimes, of course, there is an express written warranty, but in the absence of that the matter is regulated by section 14 of the Sale of Goods Act, 1893, which provides (in effect) that there is no implied warranty or condition as to the quality or fitness for any particular purpose of goods supplied under a contract of sale, except (1) where the buyer expressly makes known the purpose for which the goods are required so as to show that the buyer relies on the seller's skill or judgment and the goods are of a description which it is in the

course of the seller's business to supply (whether he be the manufacturer or not) there is an implied condition that the goods shall be reasonably fit for such purpose; provided that in the case of the sale of a specified article under its patent or other trade name, there is no implied condition as to its fitness for any particular purpose; (2) where the goods are bought by description from a seller who deals in goods of that description (whether he be the manufacturer or not) there is an implied condition that the goods shall be of merchantable quality; provided that if the buyer has examined the goods there shall be no implied condition as regards defects which such examination ought to have revealed; (3) an implied warranty or condition as to quality or fitness for a particular purpose may be annexed by the usage of trade; (4) an express warranty or condition does not negative a warranty or condition implied by the Sale of Goods Act unless inconsistent therewith. The result of these provisions is that in certain cases the vendor is made liable for latent defects, that is to say, for defects which would not be discoverable on an ordinary examination of the article. Sometimes a contract for the sale of machinery contains provisions for payment of the price by instalments after production of the certificate of the engineer that such instalments are due and payable. It was held in a Scotch case (*Howden* v. *Powell Duffryn Steam Coal Co.* (1912), S. C. 920 Ct. of Sess.) that where, in such circumstances, part of the machinery was rejected, but the manufacturers refused to accept the rejection, the production of the engineer's certificate was not a condition precedent to the right to recover payment.

(12) RELIEF WHEN CONTRACT DIFFICULT TO PERFORM BECAUSE OF THE WAR.



By an Act passed on July 10, 1917 (The Courts (Emergency Powers) Act, 1917, s. 1), a measure of relief is expressly given to persons who are unable to perform certain agreements in consequence of the war. This Act was considerably extended by the Courts (Emergency Powers) Act, 1919, by s. 1 (1) (*a*), of which upon an application by any party to a contract made before January 1, 1917, if the Court is satisfied that owing to the prevention or restriction of, or the delay in the supply or delivery of materials, or the diversion or insufficiency of labour or the shortage of shipping, or the alteration of trade conditions, occasioned by the war the contract cannot be enforced according to its terms without serious hardship, the Court may, after considering all the circumstances of the case and the position of all the parties to the contract and any offer which may have been made by any party for a variation of the contract, suspend or annul or with the consent of the parties amend as from such date as the Court may think fit, or stay any proceedings for the enforcement of, the contract or any term thereof or any rights arising thereunder on such conditions as the Court may think fit. The phrase 'alteration of trade conditions' includes an alteration which is due to the rise in the cost of materials and labour. This was decided in *North Metropolitan Electric Power Supply Co.* v. *Stoke Newington Boro Council* (1921), 37 T.L.R. 196, a case in which Mr. Justice Lawrence annulled certain agreements entered into for the supply of electrical energy. The word 'enforced' is not confined to enforced by action, but means put in force or given effect to (*United States Cable Co.* v. *Western Union Teleg. Co.*, 123 L.T. 232). The second class referred in s. 1 (2) of the Act of 1917 (as amended by the Act of 1919) comprises any contract whatever, any term of which cannot be enforced without serious hardship owing to any restriction or direction imposed or given by or in pursuance of any enactment relating to the defence of the realm or any regulation made thereunder, or owing to the acquisition or user by or on behalf of the Crown for the purposes of the war of any ship or other property. With regard to this class of contract, it has been held that where administrative action has had the effect of raising the price of goods in the open market, but has had no other effect, there is no serious hardship within the meaning of the Act (*Wauters* v. *Association Internationale*, 34 T.L.R. 577). Where, however, the defendant was under contract to pay a rent of 2,100*l.* for a building the erection of which was discontinued pursuant to an order of the Ministry of Munitions, the Court granted relief, and reduced the rent to 500*l.* (*Electric Pavilions, Marble Arch, Ltd.*, v. *Lorden*, 34 T.L.R. 542).

JAMES WALKER & Co.
LIMITED

WALKER'S TRADE MARK LION PACKING

'LION' Patent Expanding STEAM PACKING

The King of Packings

It holds the highest place among Packings. . . . . .
The Metal Pins form an anti-friction wearing surface and reduce friction to a minimum. . . . . .
It expands automatically to the varying pressures of steam. . . . .
The Materials used in the manufacture are of the finest possible quality.

JAMES WALKER & Co.
LIMITED

WALKER'S LION PACKING TRADE MARK

'LION' Patent Automatic Hydraulic Packing

The King of Packings

It acts like a ram leather.

The only packing that offers at the same time highest packing efficiency and longest wearing quality.

There is no packing to equal it for Accumulators, Presses, Pumps, and all Hydraulic Work.

'Screwol,' 967
Screws, 1031
——— prevent rusting in, 2374
——— small, heads for, 1042
——— steel, for rail chairs, specification for, 538
——— threads of, 1031
——— weight of, 243
——— wood, 1040, 1041
Scribe marks, 365
Scrubbers, gas, 2067
Scullery sink, 1263
Sea, distance of objects at, 164
—— level, to reduce a measured base to, 148
——, temperature of the, 190
Seam inspection blocks and covers, asbestos cushioned, 1429
Seamless brass tubes, weight of, 238
——— copper tubes, weight of, 236
——— soft copper jointings, Hulburd's, 601
Seasoning timber, 214, 365
—— —— ——— shrinkage by, 368
—— —— woods, increase of strength by, 263
Seating block, asbestos cushioned, Pearson's, 1429
Secret commissions, 2443
——— joints in flooring boards, 342
Secrets, disclosure of, 2443
Sectional dock, pontoon, 1341
Sectioning, electric tramways, trolleys, 683
Sections, British standard, 315
——— conic, 27
——— railway, House of Commons rules for, 664
Seewer Pelton wheel regulator, 1205
Seger cones, 2268
Segments of a circle, 49, 56
Sellers' bolts and nuts, 1045
——— screw threads, 1031, 1037
Semi bauxite bricks, 426
Semicircle, angles at circumference of, 20
Semi-Diesel engines (*see* Oil engines)
Semi-rotary pump, Willcox, 1138
——— —— 'Ubel,' 1139
Semi-steel, 2279
Sentinel pyrometers, 2269
Separators, oil, 1456
——— steam and water, 1527
Series, 13
——— wound direct-current motors, 1905
Service reservoirs, 1291
'Servo' steam regulators, 1455
Setting, boiler, 1427
——— out arches, 520
——— stones, 385
Settings, boiler, leaky, 1431
Sewage, bacterial treatment of, 1255
——— disposal, Royal Commission on, standard of purity for sewage effluents, 1262
——— effluents, standard of purity, 1262
——— hourly variation of flow of, 1252
——— land treatment of, 1254
——— Local Government Board's requirements, 1258

SEW

Sewage pipes, British standard, 245
——— sludge, 1254
——— ——— activated process, 1261
——— treatment of, 1252
——— works, cost of, 2430
Sewerage systems, 1250
Sewers, 1245
——— brickwork for, 1288
——— circular, 1245
——— discharging capacity of, 1245
——— egg-shaped, 1248
——— expanded steel concrete, 349
——— flushing, 1250
——— rate at which rainfall reaches, 1245
——— salt-glazed pipes for, 425, 1246
——— storm water, discharge of, 1283
——— ventilation of, 1251
Sextant, box, 157
Seymour's resilient steel gears, 884
Shaft furnaces, 2236
——— pillars, 2177
——— sinking, mining, 2169, 2172, 2173, 2174
Shafting, 919
——— diameter of, 920, 922
——— horse-power of, 920
——— lubrication of, 910
——— speed of, 921, 922
——— steam turbine, 924, 927
——— steel, 921
——— supports of, 920
——— wrought-iron, 919, 922
Shafts, chimney, stability of, 515
——— crane, 794
——— crank, 925
——— for paddle engines, 927
——— hollow, 920
——— mine, 2169
——— deep, 2175
——— oil engine, 1699
——— propeller, tunnel, and thrust, Bureau Véritas rules, 927
——— steamship, 924
——— Board of Trade rules for, 923
——— Bureau Véritas rules for, 925
——— Lloyd's rules for, 924
——— twisting angle of, 260
——— ventilating, 2136
Shale oil, 1809
Shaping and slotting machines, power for, 973
Sharpening angles of wood machine cutters, 990
——— files, 998
——— steel mining bits, 2162
Shaw, Hele-, friction clutch, 855
Shear reinforcement, 438
Shearing machines, power for, 974
——— stresses, 292, 454
Sheet aluminium, weight of, 223
——— brass, weight of, 220
——— copper, weight of, 220
——— iron, galvanised corrugated, 308, 311
——— weight of, 215
——— lead, weight of, 220, 221
——— reinforced, 252
——— metals, specification of, 221
——— weights of, 215, 216, 220
——— steel piling, 499

SHO

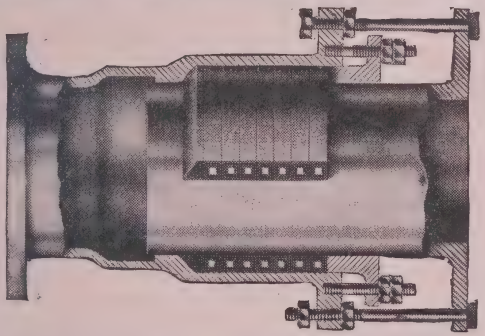
WALKER'S 'WALLICO'
CONE GAUGE GLASS RINGS

Do not become hard.

—

Can be used again and again.



Easily replaceable.

—

Send for free Sample Ring.

'EMERALD' EXPANSION GLAND PACKING

RESILIENT

DURABLE

A positive cure for one of the most troublesome joints with which Engineers have to contend.

JAMES WALKER & CO. LTD.

LION WORKS, GARFORD STREET,
WEST INDIA DOCK RD., LONDON, E.14.

Telephone: East 4253 (3 lines). Telegrams: 'Lioncelle, Pop, London.'

THE ENGINEER'S YEAR-BOOK CLASSIFIED DIRECTORY OF LEADING ENGINEERING AND ALLIED FIRMS ADVERTISING IN THE 1922 EDITION.

A RELIABLE GUIDE FOR THE USE OF BUYERS OF ENGINEERING MATERIALS, MACHINERY, TOOLS, PLANT, APPLIANCES, ETC.

For Advertisers' Addresses, and Positions of their Announcements in the 'Year-Book,' consult foregoing Alphabetical List, pages 2521 to 2538.

The aim of the Proprietors of 'The Engineer's Year-Book' is to include in this publication only the most reputable firms' announcements, so that readers desiring to order, or specify, the various specialities advertised, may do so with confidence.

***** French, Italian, Spanish, and Russian translations of the terms used in this Directory are given on pages 2613 to 2698.**

RÉPERTOIRE ANALYTIQUE DES ANNONCEURS POUR 1922.

Guide pratique des acheteurs de matériaux pour constructions mécaniques, de machines, d'outils, outillages, appareils, etc.

Les propriétaires de 'The Engineer's Year-Book' (L'Annuaire de l'Ingénieur) se sont efforcés de ne faire figurer dans la présente publication que les annonces des maisons les mieux réputées ; les lecteurs désireux de commander ou de spécifier les différentes spécialités annoncées peuvent donc le faire en toute confiance.

On trouvera pages 2613-2632 la liste des équivalents de ces termes en Français.

Pour les adresses des Annonceurs et les renvois à leurs annonces dans l'Annuaire, voir l'Index alphabétique ci-dessus, pages 2521-2538.

GUIDA CLASSIFICATA DELLE DITTE DI MAGGIOR IMPORTANZA CHE HANNO DEGLI ANNUNCI NELL' EDIZIONE DEL 1922.

Ai compratori di materiale per la meccanica, e di macchinario in genere, questa Guida è assai utile.

I proprietari della 'Engineer's Year-Book' (l' Annuario dell' Ingegnere) si sono limitati a pubblicare in questa guida solo i nomi delle case più rinomate ; i lettori che desiderano ordinare o specificare specialità comprese in questi annunci lo possono quindi fare con tutta sicurezza.

A pagina 2633-2652 trovasi la traduzione in italiano dei termini usati in questo elenco.

Per gli indirizzi delle ditte aventi degli annunci ed il posto dove detti annunci appaiono nella guida vedesi l' elenco alfabetico a pagine 2521-2538.

GUÍA CLASIFICADA DE ANUNCIADORES PARA 1922

Esta Guía es muy conveniente para los compradores de materiales de ingeniería, maquinaria, herramientas, instalaciones, utensilios, etc.

La aspiración de los propietarios de 'The Engineer's Year-Book' ('El Anuario del Ingeniero') es incluir en esta publicación solamente los anuncios de las casas de la mejor reputación ; así es que los lectores que deseen pedir ó especificar cualquiera de los diversos artículos anunciados pueden hacerlo así con confianza.

Una traducción de los términos equivalentes en Castellano se hallará en la lista, páginas 2653-2673.

Para señas de anunciadores y referencias á sus anuncios, consúltese la precedente Lista alfabética, paginas 2521-2538.

ПОДРОБНЫЙ УКАЗАТЕЛЬ СПЕЦІАЛЬНОСТЕЙ АНОНСОДАТЕЛЕЙ 1922 г.

Удобное Руководство для Покупателей Инженерныхъ матеріаловъ, инструментовъ, машинъ, приспособленій, принадлежностей и пр. и пр.

Редакція 'The Engineer's Year-Book' (Инженерный Ежегодникъ) въ настоящемъ изданіи включила объявленія лишь первоклассныхъ фирмъ, такъ что читатель можетъ съ полной увѣренностью снестись съ любой изъ этихъ фирмъ или помѣстить свои заказы на любыя изъ указанныхъ спеціальностей.

Переводъ терминовъ данъ также на Французскомъ и Италіянскомъ и Испанскомъ и Русскомъ языкахъ— см. стр. 2675-2698.

Адреса фирмъ и свѣдѣнія объ ихъ спеціальностяхъ въ 'The Engineer's Year Book' (Инженерный Ежегодникъ)—см. предыдущій алфавитный списокъ— стр. 2521–2538.

Printed in England at THE BALLANTYNE PRESS
SPOTTISWOODE, BALLANTYNE & CO. LTD.
Colchester, London & Eton

ON ADMIRALTY LIST.

Label: Lilac and Gold.

Label: Silver and Red.

'BIG J' BRAND
HIGH-SPEED TOOL STEEL and
'JACKSBERG' (Reg. No. 310,963-4599S),
Water Hardening HIGHER Speed Tool Steel
for Heavy and Quick Turning, Boring, Planing, Slotting and Shaping Tools, Drills, Milling Cutters, &c.

GRADE D.C.S.
Label: Pale Blue and Chocolate.

DIAMOND CAST STEEL.
For Turning Hard Chilled Rolls, Cutters, Turning, Planing and Finishing Tools, Drawing Dies, &c.

GRADE 1.
Label: Deep Yellow and Black.

SILVER CAST STEEL.
For Dies, Taps, Drills, Cutters, Turning, Boring, Planing and Slotting Tools, Chasers, Hobs, Reamers, Chisels, Mill Bills, Cups, Snaps, Punches, Milling Cutters, Shear Blades, &c.

GRADE 2.
Label: Light Yellow and Red.

BEST CAST STEEL.
For all kinds of Mechanical Engineering, Boilermaking, Shipbuilding, Railway and Mining purposes.

GRADE 3
Label: Deep Green & White.

WARRANTED CAST STEEL.
For Miners' Drills, Quarrying, Stone Planing and Smiths Tools, Coal Cutters, &c.

GRADE 4.
Label: Deep Red and White.

CAST STEEL.
For Miner's Drills, Jumpers, Wedges, Spindles, Masons' Tools, Hammers, Picks, Smiths' Tools, Drifts, &c.

'JACKMANIZED' STEEL.
(Registered Nos. 288, 733-4262 S.)

GRADE J.Z.
Label: Red, White and Blue.

For Dredger Bucket Pins, Bushes, Tumbler Shafts, Cross-head, Gudgeon, Crank, Sheave, Gallows, Bollard and Cam Roller Pins, Conveyor Bolts and Spindles, Disintegrator and Slide Bars, &c.
(This material is a substitute for Case-hardened Iron and Steel.)

SHEAR, BLISTER, WELDING, SPRING, TENACIOUS, VANADIUM, NICKEL-CHROME, BESSEMER, AND SIEMENS STEEL.

NOTE.—When ordering Steel DO NOT OMIT TO SPECIFY THE CLASS OF TOOL FOR WHICH IT IS REQUIRED.
In Heating Steel for the purpose of Forging and Hardening, DO NOT FORGET that it appears hotter than it really is on a dull day, or in a dark place, and much cooler on a bright day or in a very light place.

The Voice of a Great Industry

To-day, every man engaged in an industry and who desires to maintain or improve his position in that industry must keep himself fully up to date in regard to its latest phases.

The aim of the Electrical Review is to provide that information in the fullest degree and at the same time to assist the expansion and development of the British Electrical Industry in every possible way.

Manufacturers are reminded that quite apart from the immense circulation of the Electrical Review in the home market, it is also to be found in every civilized country where electrical development is in progress or may be expected.

An advertisement in its pages will secure circulation ALL OVER THE WORLD and there is literally no other method of publicity which is one half so effective for so small a cost.

The Electrical Review has devoted itself for nearly 50 years to the interests of the Electrical Industry and it has no other interests outside that industry. Not without reason, therefore, has it been called 'The Voice of the Industry' and you may rest assured that whatever position you may occcupy in the electrical world you will secure the latest and most authoritative information in regard to all that is taking place, from the pages of

ENGINEERING TRAINING

Imperial College of Science and Technology.

VISITOR—H.M. THE KING.

CITY & GUILDS (ENGINEERING) COLLEGE,

Exhibition Road, South Kensington, London, S.W. 7.

The City and Guilds (Engineering) College, the Engineering Section of the Imperial College, provides complete Courses of Instruction leading up to, and including, the highest specialised instruction with the object of fitting Students to take leading positions in the industrial world as Civil, Mechanical or Electrical Engineers, Scientific Advisers, Investigators or Experts in the Engineering industries, and for those already qualified who desire to take up more advanced courses of training and research in connection with the branches of Engineering in which they are specially interested.

The Departments of the College are as follow :—

ENGINEERING, MECHANICAL, AND MOTIVE POWER INCLUDING AERONAUTICAL—

Under the direction of Prof. Dalby, F.R.S., M.Inst.C.E.

ENGINEERING, CIVIL, AND SURVEYING—

Under the direction of Prof. Dixon, M.Inst.C.E.

ENGINEERING, ELECTRICAL—

Under the direction of Prof. Mather, F.R.S., M.I.E.E.

MECHANICS AND MATHEMATICS—

Under the direction of Prof. Forsyth, F.R.S.

The following Diplomas are awarded to Students who satisfactorily complete a full Course of from two to four years :—

The Associateship of the City and Guilds of London Institute (A.C.G.I.).

For admission to the Courses qualifying for this Diploma candidates are required to pass the Entrance or Matriculation Examination of the College held in September (application to be made not later than the first Monday) ; or to have passed the Matriculation of the University of London in certain subjects.

The Diploma of the Imperial College (D.I.C.).

(For advanced specialised or fourth-year work.)

Further information and the Prospectus of the College may be obtained on application to the Registrar.

LONDON

ENGINEERING TRAINING

UNIVERSITY OF LONDON, KING'S COLLEGE.

FACULTY OF ENGINEERING.

Complete COURSES of STUDY, extending over either three or four years, are arranged in

CIVIL, MECHANICAL, and ELECTRICAL ENGINEERING

for the Engineering Degrees of the University of London and for the Diploma and Certificate of the College.

The four years' course provides, in addition to the academic training, opportunity for practical training in 'Works.'

HEADS OF DEPARTMENTS.

Professor G. COOK, D.Sc., A.M.Inst.C.E., A.M.I.Mech.E., Mechanical Engineering.
Professor A. H. JAMESON, M.Sc., M.Inst.C.E., Civil Engineering.
Professor E. WILSON, M.Inst.C.E., M.I.E.E. (*Dean*), Electrical Engineering.
Professor S. A. F. WHITE, M.A.
Professor J. B. Dale, M.A. } Mathematics.
Professor SAMUEL SMILES, O.B.E., D.Sc., F.I.C.,
Prof. A. J. ALLMAND, M.C., D.Sc., F.I.C. [F.R.S.] } Chemistry.
Professor O. W. RICHARDSON, D.Sc., F.R.S., Physics.
Professor W. T. GORDON, D.Sc., F.R.S.E., Geology.

Considerable extensions have been made to the Engineering Department. These include large additional drawing-office, lecture room and laboratory for Strength of Materials and Hydraulics for the Civil and Mechanical Departments, and Research Rooms, including Wireless Telegraphy, for the Electrical Engineering Department. Large additions have been made to the equipment of the Laboratories in the three Departments for purposes of teaching and research.

For full information apply to the Secretary, King's College, Strand, W.C. 2.

ENGINEERING TRAINING

The Crystal Palace School of Practical Engineering

Founded 1872.

Mechanical, Civil, Colonial and other Divisions.

Principal—
J. W. WILSON,
M.Inst.C.E., M.Inst.Mech.E., F.S.E.

Vice-Principal—
MAURICE WILSON
A.M.Inst.C.E., F.S.E.

ASSISTED BY A STAFF OF LECTURERS AND INSTRUCTORS.

The School may be Inspected on application to the Principal, from whom all further information may be obtained.

This School was established for the purpose of providing Students of any branch of Engineering with thorough practical and theoretical instruction in the rudiments of the profession and in the manipulation of materials. The institution has since been largely extended.

The School is approved by the Council of the Institution of Civil Engineers, and Students who pass through its complete course and otherwise comply with the current regulations of the Institution are eligible for their Examinations; they are also eligible for election as Graduates of the Institution of Mechanical Engineers, Associates of the Society of Engineers, Students of the Institution of Electrical Engineers, etc.

The usual age for admission to the School is 16 to 17 years, but there is no limit as to the age of Students. They may commence work at the beginning of any term.

Mechanical Engineering (First Year).

The Students spend one Term each in the Drawing Office, the Pattern Shop and Foundry, and the Fitting and Smith's Shop, besides attending Lectures on 'Steam and the Steam Engine,' 'Railways: their Construction and Appliances,' 'Materials and their Manufacture,' etc.

Civil Engineering (Second Year).

The first Term in this section is devoted to Practical Preparation by actual Levelling, Surveying, Theodolite work, etc., of Plans for a complete Public Work, and the necessary Plans, Estimates, etc., for Parliament.

The second Term is devoted to the Preparation of Working Plans, Calculations, Estimates, etc., of the said Work for the Contractors.

The third Term is utilised for Original Designing, Theory of Structures, and other necessary Calculations, Specifications, etc., for Bridge, Re-inforced Concrete and other Work, and reporting upon existing Engineering Works.

Debates are held to afford Students an opportunity of gaining confidence in public professional speaking.

At the meetings of the 'Crystal Palace Engineering Society' (affiliated to the Society of Engineers) Students read and discuss papers on Professional subjects. Professional visits to Engineering Works are made from time to time.

Of the Students who have passed through the School, many have obtained appointments as Chief Engineers at home and abroad; and over 1,200 are employed in Engineering Work in various Countries in the World.

LONDON

ENGINEERING TRAINING

University of Birmingham.

Chancellor—THE RT. HON. LORD ROBERT CECIL, K.C., M.P.
Vice-Chancellor—SIR GILBERT BARLING, C.B., F.R.C.S.
Principal—C. GRANT ROBERTSON, M.A., C.V.O.
Vice-Principal—SIR WILLIAM ASHLEY, M.A., M.Com.
Secretary—GEO. H. MORLEY, M.Com.

Departments of Civil, Mechanical & Electrical Engineering.

The FULL COURSES EXTEND OVER FOUR YEARS, and students who enter after Matriculation and who pass successfully the Examinations at the end of each year WILL BE ENTITLED to the DEGREE of BACHELOR OF SCIENCE in the branch of Engineering to which they devote themselves.

The Technical Engineering Classes include:—

Lectures on the Strength of Materials, Theory of Steam, Gas, and other Heat Engines, Hydraulics, Machine Design, Strength of Structures, Distribution of Power.

Drawing: Design of Tools, Prime Motors, Dynamos, and other forms of Machinery.

Courses in Civil Engineering, including Constructional Work in Masonry and Steel, Railway Work, Dams, Bridges, and Water Engineering.

Field Work: Practical Surveying in the Field throughout the Summer Term.

Engineering Laboratory: Determination of the Strength of Materials, including Compressive, Bending, Tensile, and Torsion Tests, Experimental Study of the Steam Engine and Boiler, Frictional Efficiency Tests, the Flow of Water over Weirs and through Orifices, etc.

Lectures and Demonstrations on all branches of Electrical Engineering.

Electrical Laboratory: Testing of Continuous and Alternate Current Machinery: Electrical Instruments, Meters, Lamps and Batteries: Insulation and Magnetic Testing Work.

The Courses also include Instruction in Mathematics, Physics, Chemistry, Geology, and Metallurgy.

For detailed Syllabus, with full particulars of University Regulations, Lecture and Laboratory Courses, Fees, Scholarships, etc., apply to the Secretary.

BIRMINGHAM

5 H 2

ENGINEERING TRAINING

DEPARTMENT OF AGRICULTURE & TECHNICAL INSTRUCTION FOR IRELAND.

Royal College of Science

FOR IRELAND, DUBLIN.

FACULTY OF ENGINEERING.

The course for the Associateship in Engineering extends for a period of four years, or, in special circumstances, three years.

The course includes all subjects necessary for a thorough education in the general scientific principles common to all branches of Engineering, but special emphasis is laid on Mechanical and Electrical work.

The College is equipped with workshops and laboratories containing a most comprehensive and modern installation of machines, engines, etc.

The fees for the four years' course total £75.

Several Scholarships, entitling the holder to a maintenance allowance for four years with free tuition, are attached to the College.

Special facilities and Studentships are available for qualified students desirous of carrying on research.

Full particulars may be had on application to the Registrar, Royal College of Science, Upper Merrion Street, Dublin.

DUBLIN

ENGINEERING TRAINING

Heriot-Watt College,

EDINBURGH.

Governors—THE GOVERNORS OF GEORGE HERIOT'S TRUST.

Chairman—THE RIGHT HON. THE LORD PROVOST.

Convener of Heriot-Watt College Committee—JUDGE ALEXANDER BARRIE, J.P.

Principal—A. P. LAURIE, M.A., D.Sc., F.R.S.E., sometime Fellow of King's College, Cambridge.

DAY TECHNICAL COLLEGE

COURSES OF INSTRUCTION IN

MECHANICAL ENGINEERING, ELECTRICAL ENGINEERING, APPLIED CHEMISTRY, MINING.

The Heriot-Watt College offers complete Courses of Instruction in these subjects, and a Diploma or Certificate at the end of the Course.

The complete Diploma Courses in Mechanical Engineering and Electrical Engineering last over three years, and in Applied and Analytical Chemistry over four years.

The Diploma Course in Mining (Coal, Metalliferous and Oil) lasts over three years.

Many of the Classes are recognised by the **UNIVERSITY OF EDINBURGH** as qualifying for the Degree of B.Sc. in Pure Science and Engineering, so that a student can qualify for these Degrees by taking the necessary additional Courses at the University and passing the University Examinations.

The Lectures and Laboratory Work in Elementary Chemistry, running through the Winter and the Summer Session, qualify for the first B.Sc. in Chemistry, and the further Chemistry instruction for the B.Sc. can be had at the Heriot-Watt College.

The College is also recognised by the **INSTITUTE OF CHEMISTRY**, and complete Courses of Instruction are provided for students who wish to prepare for the examination of the Institute. In the Chemistry Department there are also Courses in Bio-Chemistry, and in Pharmaceutics for the Professional Examinations of the Pharmaceutical Society.

Special arrangements have been made for **POST-GRADUATE COURSES** in **ELECTRICAL ENGINEERING, PRIME MOVERS,** and **APPLIED CHEMISTRY.** Students wishing to take these post-graduate Courses must either hold the B.Sc. of some University or the Diploma of the Heriot-Watt College or of the Royal Technical College, Glasgow.

There is also a Course extending over two Winter Sessions for Clerks of Works, Builders' Clerks, and Surveyors' Apprentices.

EVENING CLASSES.—Advanced Classes in various Departments of Pure and Applied Science, Commerce, and Languages, which will prove of use to students who have already taken a Degree or who are studying for a Degree, are held in the College in the Evening.

FEES.—Day Classes. Composition Fees for Diploma Courses, £23 to £31 10*s.* per annum. **Evening Classes,** 7*s.* 6*d.* to £3 3*s.*

All particulars regarding the College Classes, both Day and Evening, can be obtained from the PRINCIPAL at the College.

For the Scheme for Degrees in Civil, Electrical, Mechanical, and Mining Engineering, arranged with the University of Edinburgh, see University Calendar, or the Calendar of Heriot-Watt College.

EDINBURGH

ENGINEERING TRAINING

The Royal Technical College, GLASGOW.

The College is affiliated to the University of Glasgow, and the Degrees of the University in Engineering and Applied Chemistry are open to its students.

The Diploma of the College is granted in the following Departments :—

CIVIL ENGINEERING.
Professor GEORGE MONCUR, B.Sc., M.Inst.C.E.

MECHANICAL ENGINEERING.
Professor of Mechanics, JOHN G. LONGBOTTOM, A.R.C.S.
Professor of Mechanical Engineering, A. L. MELLANBY, D.Sc.

ENGINEERING TRAINING

LOUGHBOROUGH COLLEGE,

LEICESTERSHIRE,

H. SCHOFIELD, M.B.E., B.Sc.(Hons.)Lond., A.R.C.Sc.Lond., Assoc.M.Inst.C.E., Principal.

DEPARTMENTS OF MECHANICAL, CIVIL, AUTOMOBILE AND ELECTRICAL ENGINEERING AND CHEMICAL TECHNOLOGY.

DEGREE AND DIPLOMA COURSES are arranged in the Theory and Practice of Engineering.

The Workshops of the College provide accommodation for 500 Students working at the same time.

The equipment is on most modern and comprehensive lines, and comprises Plant for Turning, Fitting, Milling, Grinding, Automatic Lathe Operating and Tool Setting, Tool and Gauge Making, Foundry Work, Pattern Making, Drawing Office Work, Heat Treatment, Viewing and Testing of all kinds, including Micrography and Radiography.

None but first-class work of a productive character is undertaken by the Students, working under the skilled supervision of a fully qualified Technical Staff.

The complete Course covers a period of five years, during which Works training in all the above sections will be given, and this will be accompanied by a full Theoretical Course of Instruction in the College Lecture Rooms and Laboratories.

Intending Students should be at least sixteen years of age, and have had a good Public School or Secondary Education.

The Fee is £50 per Session, there being three Terms in the Session.

Boarding accommodation is provided in Hostels attached to the College, full particulars of which, together with Illustrated Prospectus, will be forwarded upon application to the Registrar.

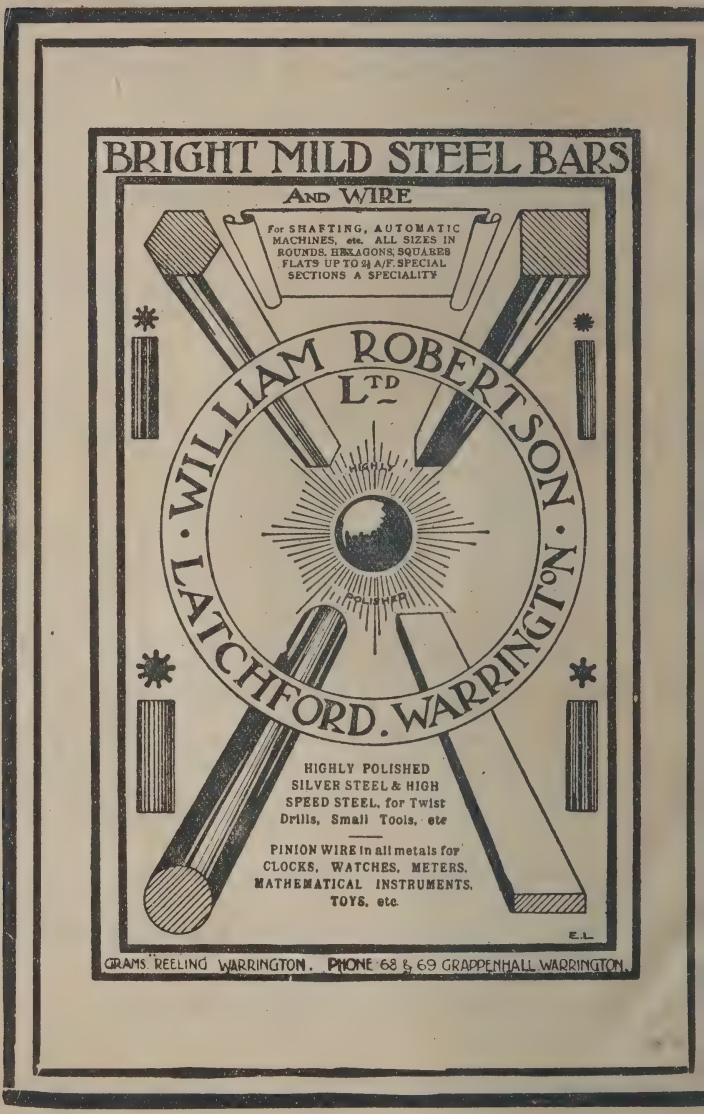
DEGREE COURSES.

The College provides complete courses of study extending over three or four years for the Degrees of London University in Engineering and Mining.

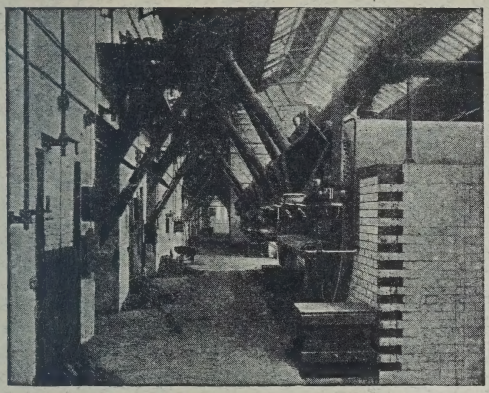
DIPLOMA COURSES.

The Course for the Associateship of the University College of Nottingham in Engineering, Mining, or Mine Surveying extends over three years. Short courses for special purposes can be arranged.

The subjects comprised in the above courses are: Mathematics, Physics, Chemistry, Metallurgy, Machine Drawing and Design, Heat Engines, Hydraulics, Strength of Materials, Theory of Structures, Surveying, Theory of Machines, Electrical Technology and Design, Geology, Petroleum Technology, Mining, Mine Surveying, etc.



The Mechanical and Electrical Engineering and Mining Laboratories are fully equipped with the latest apparatus and testing machinery. Metal-working tools of all types are provided in the workshops.



ENTRANCE EXAMINATION.

For those who have not passed the London University Matriculation or an equivalent examination an Entrance Examination is held in July and September.

Prospectus and all particulars may be obtained from
THE REGISTRAR.

The Station with the Lowest Costs

TO attain this enviable position—to be at the *bottom* for low running costs and at the top for efficiency—is the aim of every ambitious station engineer. The stations with the established reputations are those which have installed 'Bennis' Machine Stokers and coal-handling plant. The truth of our assertion can be easily tested by reference to Garcke's Manual.

OUR catalogue on 'Coal and Ash Plant' is now available. If you are looking for ways and means of economising labour in power houses, you will find it in this book, which is packed with interesting information, figures, and photographs of actual installations. We shall be pleased to send the book on request. Ask for Catalogue YB 724.
